serum half-life of 15 to 20 minutes.[205,206] Because the effects of ASA are irreversible, they last for the life of the platelet (approximately 7–10 days); thus, once-a-day dosing is sufficient to sustain platelet inhibition. Enteric coated preparations are associated with longer absorption time, reaching peak plasma levels 2 to 4 hours after ingestion.[207]

After a single dose of ASA, platelet production begins to recover. Approximately 10% of new platelets are released from the bone marrow each day, with full replacement of ASA-free platelets within 10 days after discontinuing the drug. Such platelets tend to exhibit a "rebound effect" characterized by an exaggerated response to procoagulant

stimuli.[208] This phenomenon has been demonstrated experimentally and may in fact increase thrombotic risk in certain populations. Moreover, it is not necessary to wait for full platelet turnover, because normal hemostasis can be seen with as little as 20% of platelets maintaining normal COX1 activity.[209] Many subjects have 80% normalized platelet function after 72 hours from their last ASA dose.[210]

When compared to other platelet antagonists, ASA is comparatively weak, because it has no effects on other receptor-mediated pathways triggered by adenosine diphosphate (ADP), thrombin, or collagen. Nevertheless, its benefits in risk reduction against myocardial infarction in patients with established coronary artery disease are undeniable.[211] Currently, the strongest indications for chronic ASA include secondary prevention of coronary artery disease and post-PCI patients. The latter is the cornerstone for DAPT and for lifelong monotherapy in most patients, unless contraindicated.

Adenosine Receptor Antagonists

Currently available drugs for clinical use are the thienopyridines clopidogrel and prasugrel and the nucleoside analogue ticagrelor. All three share a common mechanism of action (binding to the P2Y12 platelet receptor), yet there is major pharmacokinetic variability among them[212] (Fig. 44.8). These differences translate into significant clinical differences regarding efficacy and bleeding risk.

Clopidogrel

Clopidogrel is a second-generation thienopyridine (the first-generation thienopyridine ticlopidine is no longer used because of toxicity concerns). Ingested clopidogrel acts as a prodrug whose active thiol metabolite binds permanently to the P2Y12 platelet receptor, thus preventing ADP-mediated activation of the GpIIb/IIIa complex.[213] Platelets blocked by clopidogrel remain so for the remainder of their 7- to 10-day life span.

Following a loading dose of 300 to 600 mg, the time to maximum inhibition of platelet aggregation (IPA) (37% inhibition) is 6 hours.[214] The parent compound is absorbed in the intestine, after which it is carried to the liver where 85% is hydrolyzed to an inactive metabolite by liver esterases. The other 15% must undergo a two-step enzymatic process via the actions of several isoenzymes of cytochrome P450. First it is converted to 2-oxoclopidogrel (predominantly by the action of CYP2C19), and then to the active thiol metabolite (mainly by the actions of CYP3A4 and CYP2C19).[215] Elimination of the parent drug is in 6 hours and of the active metabolite about 30 minutes. Approximately 50% of the drug is eliminated in urine and 45% in feces.

Disadvantages of clopidogrel include the many possible interactions, which can interfere with the drug's antiplatelet ability. Different genetic polymorphisms involved in clopidogrel biotransformation or the platelet receptor's response, and interactions with commonly prescribed drugs, yield a certain degree of unpredictability resulting in either an increased risk for thrombosis or bleeding.[215] Despite its inherent limitations and modest antiplatelet effects, clopidogrel is the P2Y12 receptor antagonist of choice in most patients because of its proven efficacy in many clinical studies.[216–218] It is considered the standard component with ASA as part of DAPT.

On discontinuation of clopidogrel, complete platelet recovery is expected within 7 days, but appreciable platelet aggregation is already noticed by 72 hours.[219] A phenomenon of platelet rebound has been described associated with an increased prothrombotic state. The cause is likely multifactorial and its clinical significance is unclear, but an increased risk for ischemic syndromes has been reported.[220]

Prasugrel

Prasugrel is a third-generation thienopyridine. Like clopidogrel, prasugrel must be biotransformed into an active metabolite to achieve its antiplatelet effect. The inhibition of the P2Y12 receptor is also irreversible and thus lasts for the life span of the platelet.

Prasugrel undergoes hydrolysis in the liver, and CYP elements assist in biotransformation to the active metabolite.[212] However, this drug is less subject to interference with other agents, and important genetic polymorphisms that seriously affect its metabolism are less frequent. The end result is a more predictable and potent antiplatelet effect. The time to maximum IPA (85% inhibition) achieved after a loading dose of 60 mg is approximately 4 hours.[221] The maintenance dose is 10 mg/day. To decrease bleeding risk, certain groups of patients, such as those older than 65 years and those weighing less than 60 kg, require reduced doses of 5 mg/day. Prasugrel is eliminated primarily by the kidneys. On discontinuation of the drug, platelets fully recover within 7 to 10 days, reflecting new platelet production.

The most common side effect is bleeding. This drug is contraindicated in patients with a history of transient ischemic attack or stroke or active bleeding. Although less common than with clopidogrel, poor platelet responsiveness has been described in some patients receiving maintenance doses of prasugrel.[221]

Several studies have shown the superiority of prasugrel over clopidogrel in reducing the incidence of LST and VLST; however, this improvement occurs at the expense of increased bleeding, which may necessitate discontinuation of the drug.[222–224]

Ticagrelor

This drug represents a nonthienopyridine class of ADP receptor antagonist.[225] Ticagrelor does not require conversion to an active metabolite to produce inhibition of platelet aggregation, although an active metabolite is also generated by the action of hepatic CYP3A4.[212] Ticagrelor acts by an allosteric reversible binding to the P2Y12 receptor. Its effects are more potent than those exerted by the thienopyridines. Because of its reversible interaction with the P2Y12 receptor, recovery of platelet function is likely with decreased serum concentrations of the drug or metabolites.

Following a 180-mg loading dose of ticagrelor, the time to maximum IPA (88% inhibition) is 2 hours, which may be maintained up to 8 hours.[226] The maintenance dose is 90 mg twice a day. Less than 10% IPA is seen 5 days following discontinuation of the drug. The main route of elimination is enteric with a lower percentage via the urine.

In clinical trials, ticagrelor has been shown to be superior to clopidogrel or prasugrel in the prevention of stent thrombosis, at the expense of a higher risk for bleeding.[227,228] This drug is contraindicated in patients with a history of active bleeding or intracranial hemorrhage. Patients may also experience dyspnea due to an apparent mild autoimmune response. When given in combination with ASA as part of DAPT, the dose of ASA should not exceed 100 mg; higher doses are associated with decreased effectiveness.[227] The mechanism of this blunted response is currently unknown.

Protease-Activated Receptor 1 Antagonists

The importance of thrombin in platelet aggregation via interaction with PARs has led to efforts to synthesize inhibitors in order to provide additional benefits over standard antiplatelet therapy. Although multiple compounds have been synthesized, only one, vorapaxar, has recently been approved for clinical use.

Vorapaxar is a synthetic 3-fenyl-pyridine structurally derived from himbacine (a natural alkaloid present in the bark of Australian magnolia).[229] Its mechanism of action is by high affinity yet reversible attachment to the PAR-1 platelet receptor. This action prevents granule procoagulant release and further platelet expression of fibrinogen receptors, without interfering with thrombin-induced fibrin formation.[230]

Unlike thienopyridines, vorapaxar does not require biotransformation into an active metabolite. A full inhibitor effect (>80% IPA) is reached following a loading dose of 40 mg.[231] When a maintenance dose of 2.5 mg is administered for several days, platelets are effectively inhibited for 4 weeks.

Vorapaxar is rapidly absorbed through the intestine and undergoes biotransformation by CYP3A4 mainly into an inactive metabolite. However, with prolonged dosing an active metabolite (M20) becomes relevant, representing up to 25% of the parent compound.[229] The drug

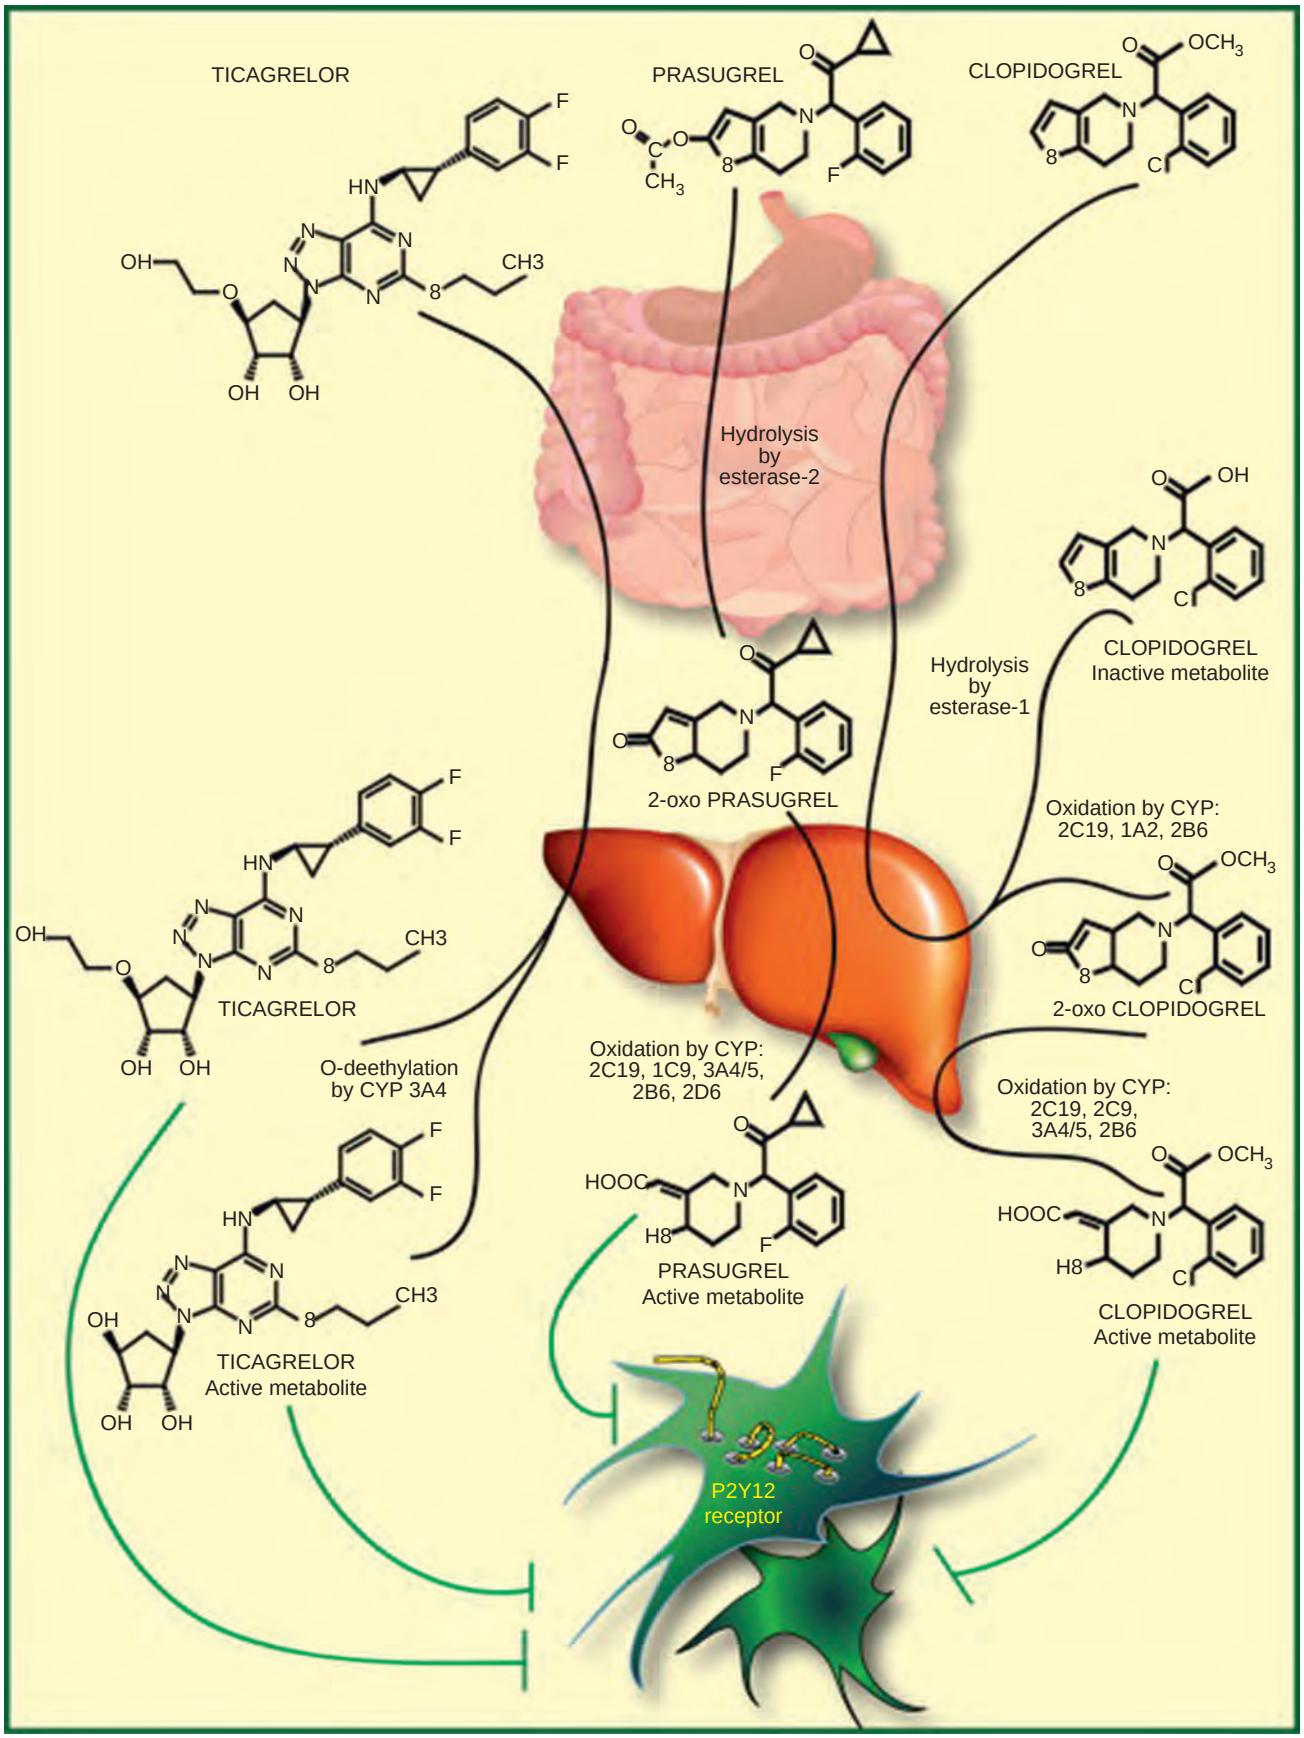

Fig. 44.8 Metabolic pathways of adenosine diphosphate receptor blockers. The actions of clopidogrel and prasugrel depend on hepatic biotransformation to an active metabolite, which binds irreversibly to the platelet P2Y12 receptor. In contrast, both ticagrelor and its active metabolite bind to the P2Y12 receptor in a reversible fashion. *CYP,* Cytochrome P450. *(Reproduced with permission from Siller-Matula JM, Trenk D, Schror K, et al. Response variability to P2Y12 receptor inhibitor: expectations and reality.* JACC Cardiovasc Interv. *2013;6:1111–1128. Copyright Elsevier.)*

is primarily eliminated as the inactive metabolite and has a plasma half-life of 5-13 days with no significant accumulation in the presence of kidney or liver disease. The concomitant administration of CYP3A4 inducers or inhibitors can exert significant influence on the antiplatelet effects of vorapaxar.[229]

When added to a preexisting regimen of aspirin and clopidogrel, vorapaxar reduces the risk of thrombotic events, albeit at the risk of significant bleeding (particularly intracerebral hemorrhage) in certain populations.[232] A recent analysis of patients after PCI and stenting showed that the net clinical outcome analysis favored the use of vorapaxar in patients with no history of stroke.[233]

Its long half-life may represent a challenge in management for patients undergoing NCS, because it may require discontinuing the drug several weeks prior to the procedure. Vorapaxar is currently approved for use during ACS and in patients with peripheral vascular disease but not as standard therapy for patients with coronary stents.

Intravenous Antiplatelet Agents

Glycoprotein IIb/IIIa Inhibitors

The GpIIb/IIIa integrin is the most abundant and only platelet-specific receptor found on the platelet surface. Fibrinogen is the main receptor's ligand, and its attachment constitutes the common pathway toward platelet aggregation. GpIIb/IIIa inhibitors bind to the receptor, thus impairing platelet-dependent thrombogenesis due to cross linkage between neighboring platelets.[234] Currently, three molecularly distinct agents are approved for clinical use as adjunctive therapy during PCI or ACS; these agents are abciximab, eptifibatide, and tirofiban.

Abciximab

Abciximab is a monoclonal Fab molecule that binds with high affinity to the GpIIb/IIIa receptor. When given as a bolus dose of 0.25 mg/kg or as a continuous infusion of 0.125 μg/kg per minute, maximum IPA (80% inhibition) is achieved almost immediately. The serum half-life of the drug is 10-15 minutes, but recovery of platelet function is not seen until 48 hours because of slow dissociation of the drug from platelets.[235] In the presence of ADP antagonists the effects can last up to 15 days after the drug is discontinued.[236] Because very little free drug is present in the blood, platelet inhibition can rapidly be reversed with platelet transfusion.

Eptifibatide

A cyclic peptide, eptifibatide produces selective inhibition. With a loading dose of 180 μg/kg and a continuous infusion of 2 μg/kg per minute, the time to maximum IPA (80% inhibition) is about 15 minutes. The serum half-life is approximately 2.5 hours and it undergoes renal elimination. Eptifibatide dissociates rapidly from platelets; thus free drug is likely to be present for several hours following its discontinuation.[237] Transfusion of platelets is unlikely to be helpful in reversing platelet inhibition, because free circulating drug will rapidly bind to the new platelets. Drug reversal in this case is achieved primarily by stopping the medication and may take several hours.

Tirofiban

Tirofiban is a small, nonpeptide antagonist that causes rapid (5 minutes) selective blockade of GpIIb/IIIa receptors. The usual loading dose is 0.4 μg/kg followed by a continuous infusion of 0.1 to 0.15 μg/kg per minute. The serum half-life is 1.5 to 2 hours, and the primary elimination route is by the kidney. Four hours after discontinuation, less than 20% platelet inhibition remains.[238] Tirofiban also dissociates rapidly from platelets, so the main approach for return of platelet function is stopping the drug.

Adenosine Diphosphate Antagonists

Cangrelor

This drug is an intravenous analogue of ticagrelor and produces selective and reversible inhibition of the P2Y12 receptor.[239] Its major advantage is its rapid onset and short duration of action, both of which are desirable properties during acute interventions. With a loading dose of 30 μg/kg followed by a steady state infusion of 2 to 4 μg/kg per minute, it produces 80% platelet inhibition within less than 5 minutes. On discontinuation, cangrelor is rapidly deactivated by serum ectonucleotidases, resulting in a serum half-life of 2 to 5 minutes. Complete platelet recovery occurs within 60 to 90 minutes.[240]

Cangrelor during PCI has not proven superior to oral interruption of chronic therapy. In cardiac surgical patients, a study showed a positive association between preoperative use of cangrelor and decreased postoperative chest tube drainage.[241] No studies have been performed in patients undergoing NCS, although its use is theoretically appealing for high-risk patients.

Long-Term Antiplatelet Management

Dual Antiplatelet Therapy

The majority of patients undergoing coronary stenting require DAPT to protect the stented vascular segment from stent thrombosis while vascular healing occurs. Evidence shows adverse outcomes, including stent thrombosis, when DAPT is discontinued during the period of time when incomplete endothelialization is likely. This period is longer with DESs than with BMSs.[165,166]

Unlike the incidence of restenosis, which peaks several months post-PCI, the long-term cumulative incidence of stent thrombosis seems to be similar whether BMSs or DESs are employed, as long as patients are treated with DAPT for the recommended duration of therapy[242–244] (Fig. 44.9). In addition, prolonged DAPT might also confer protection from atherothrombotic events occurring outside the stented segment. In general, DAPT for most patients refers to the combination of ASA and clopidogrel. With first-generation DESs, initial recommendations were for 3 months with sirolimus stents and 6 months with paclitaxel stents, respectively. In 2006, reports of stent thrombosis beyond 6 months after discontinuation of clopidogrel prompted the U.S. Food and Drug Administration (FDA) to reexamine the duration of antiplatelet therapy in patients with DESs. New guidelines were issued recommending 12 months of DAPT with reevaluation at the end of 1 year. Current recommendations are for ASA to be taken indefinitely after PCI regardless of stent type. For P2Y12 inhibitors, a minimum of 1 year is recommended for all patients after PCI to treat ACS. For non-ACS indications, patients with a BMS should receive DAPT at least for 1 month (minimum of 2 weeks with high bleeding risk) and ideally for 12 months. Patients with DESs must remain on DAPT for 1 year or even longer if tolerated.[245] If the risk of bleeding outweighs the benefit of the recommended duration of DAPT, it may be reasonable to discontinue the P2Y12 inhibitor before 12 months has passed.[245]

Newer stents with less prothrombotic tendencies prompted trials of short versus long-term DAPT with positive results, but these studies had limited statistical power.[246] A recent large randomized controlled trial added to the controversy by demonstrating that a prolonged period up to 30 months of DAPT with aspirin and clopidogrel was associated with decreased rates of stent thrombosis compared to 12 months of DAPT.[247] This advantage was seen regardless of the type of DES. A subsequent meta-analysis concluded that long DAPT (30 months) is associated with a lower risk of definite and probable stent thrombosis and myocardial infarction, when compared with short DAPT (12 months). This benefit, however, is tempered by a higher risk of bleeding and an apparent increase in noncardiac mortality.[248] In the absence of prolonged DAPT beyond 1 year, the stent thrombosis risk is lower with second-generation DESs.[249]

Certain groups that are more likely to benefit from prolonged DAPT include those with high-risk clinical factors for stent thrombosis and patients undergoing complex PCI. Most experts recommend clopidogrel as the initial drug in stable patients, with prasugrel and ticagrelor reserved for patients with ACS and patients deemed nonresponsive to clopidogrel.

Optimal timing of noncardiac surgery after stents.* Circulation. *2012;126:1322–1324. Copyright Wolters Kluwer Health.)*

Triple Antithrombotic Therapy

Current estimates are that 5% to 10% of patients undergoing coronary stent placement are or will require oral anticoagulant therapy.[250] The three most common indications are stroke prevention in patients with atrial fibrillation, prevention of recurrent deep venous thrombosis or pulmonary embolism, and mechanical heart valves. Management of these patients is extremely challenging and largely based on scarce evidence and expert opinion, with most experts preferring placement of BMSs.

Current recommendations are that for elective procedures in patients with low/intermediate risk of bleeding, triple antithrombotic therapy (DAPT plus oral anticoagulant) is recommended for 1 month if the patient is undergoing BMS implantation, followed by up to 12 months with a single antiplatelet agent plus the oral anticoagulant. For patients undergoing DES implantation, triple antithrombotic therapy is recommended for 3 to 6 months, followed by 12 months of anticoagulant therapy with either clopidogrel or ASA.[251] In general, oral anticoagulants plus one single antiplatelet agent with careful monitoring of international normalized ratio is preferable to DAPT. After 12 months in patients requiring lifetime oral anticoagulant therapy, low-dose ASA is preferred over an ADP antagonist.[249]

Variability in Patient Response to Antiplatelet Therapy

Optimal use of DAPT with ASA and clopidogrel does not ensure that the patient will not experience stent thrombosis. In a large study, 86% of cases of early or subacute stent thrombosis and 57% of patients with late stent thrombosis occurred while on DAPT.[252] Atherothrombotic events also have been described during NCS despite continued use of DAPT throughout the perioperative period.[253] In these patients it is likely that the presence of a high prothrombotic environment made it difficult for DAPT to be fully effective. Some patients, however, may also exhibit what has been termed *high on-treatment platelet reactivity* (HTPR),[254] due to variable efficacy of the antiplatelet drugs, leading to clinical treatment failure (Box 44.6). Evidence from numerous studies has emerged demonstrating a strong association between HTPR and post-PCI ischemic events such as stent thrombosis.[255–258] On the other hand, certain patients exhibit an exaggerated response to ADP antagonists (particularly prasugrel and ticagrelor) and are found to have low platelet reactivity (LPR).[259] These patients frequently exhibit bleeding complications (perhaps excessive surgical bleeding) with standard doses of platelet inhibitors.

BOX 44.6 CAUSES OF HIGH ON-TREATMENT PLATELET REACTIVITY

Noncompliance with antiplatelet agents
Drug interactions (NSAIDs, PPIs)
Pharmacokinetic variants (eg, CYP2C19)
Platelet receptor and enzyme polymorphisms
Clinical conditions:
- Diabetes mellitus
- Obesity
- Congestive heart failure
- Chronic kidney dysfunction
- Old age
- Chronic smoking
- Cocaine use

NSAIDs, Nonsteroidal antiinflammatory drugs; *PPIs,* proton pump inhibitors.

Response to Aspirin

Variability in the response to ASA, in cases in which thrombotic events occur despite the use of the drug, has been known for many years.[260,261]

In the past, the term was labeled *ASA resistance*. When defined by clinical events, the incidence of ASA resistance has been estimated to be approximately 13%,[262] but when based on laboratory tests it ranges between 5.5% and 60%, depending on the assay used.[263] A strict definition of *resistance* consists of the inability of ASA to inhibit platelet COX1, thus preventing TXA2 production measured directly by laboratory methods. *Nonresponsive* or *treatment failures* are more accurate terms used to refer to these patients. Evidence from real-world experience has demonstrated that the most common cause of nonresponsiveness to ASA is poor patient compliance.[264] Consequently, when compliance is ensured, the occurrence of this phenomenon is significantly reduced.

In patients known to be compliant, several reasons can explain why they might be at risk for stent thrombosis. The presence of multiple pathways for platelet aggregation independent of COX1-induced TXA2 production (eg, ADP and PAR activation) can override the effects of ASA despite effective inhibition of COX1, particularly in a prothrombotic environment such as surgery. In addition, many chronic clinical conditions are associated with HTPR independent of ASA therapy (see Box 44.6). Mechanisms include endothelial dysfunction, accelerated platelet turnover, F2 isoprostanoid production, and non-COX1 pathways of TXA2 production.[265–267]

While on ASA, failure to inhibit COX1 function can be due to either pharmacokinetic or pharmacodynamic factors. Pharmacokinetic elements limit drug bioavailability due to poor absorption of the drug as with enteric preparations,[268] increased inactivation by gastrointestinal esterases by proton pump inhibitors (PPIs),[269] increased volume of distribution (eg, obesity), or interaction with other COX1 inhibitors such as ibuprofen and other nonsteroidal antiinflammatory drugs (NSAIDs), which compete with ASA for the COX1 binding site.[270,271] Pharmacodynamic resistance is related to genetic polymorphisms of COX1, which decrease the inhibitory response to ASA.[272]

The first steps in management of a patient with apparent nonresponse to aspirin are to address issues of compliance, avoid PPIs if possible, and delay the intake of NSAIDs. In addition, better control of comorbidities, weight loss, and cessation of smoking decrease platelet activity.[273] Use of nonenteric preparations and a higher dose of ASA may increase effectiveness in some patients (eg, those who are obese or have chronic inflammation), whereas twice-a-day dosing may prove more efficacious in conditions of high platelet turnover such as in patients with diabetes.[274] Lastly, the addition of another antiplatelet agent may be indicated.

Response to Adenosine Antagonists

Between 25% and 50% of individuals taking clopidogrel exhibit HTPR.[273] A reduced response to these drugs has a strong association with ischemic events, thus confirming the importance of ADP-induced platelet aggregation as the best marker for prediction of stent thrombosis in these patients.[212]

When issues of noncompliance are excluded, poor response to these agents is more often due to abnormal absorption, biotransformation, or interaction with other drugs.[274] This issue occurs more commonly with clopidogrel, since multiple variants of polymorphisms associated with the generation of the active metabolite have been identified.[274,275]

As with ASA, clinical factors such as diabetes, obesity, renal failure, age, hyperlipidemia, heart failure, and ACS can trigger platelet reactivity independent of the ADP pathway. Additionally, variable generation of clopidogrel's active metabolite can be due to genetic variants of the intestinal transport mechanism for clopidogrel coded in the *ABCB1* gene, which may result in decreased absorption of the parent compound.[276] Of the different isoenzymes of cytochrome P450 involved in the hepatic metabolism of clopidogrel, CYP2C19 is most important because it is involved in both transformative steps. Several genetic polymorphisms of CYP2C19 have been identified; the two most frequent variants associated with decreased function are CYP2C19*2 and CYP2C19*3.[275,277] Approximately 15% of Caucasians and up to 30% of Asians are carriers of at least one of these alleles.[212] The variant CYP2C19*17 is associated with increased enzyme function and greater response to clopidogrel, which may increase the risk of bleeding.[278,279] Because identification of these polymorphisms can predict clopidogrel responsiveness, two current commercial assays for CYP2C19 genotype are available as point-of-care devices. The Spartan RX system uses a buccal swab and produces results in 1 hour. The Verigene system detects more CYP2C19 variants; it uses blood sampling, and results are obtained in 3 hours.[212]

Interaction with certain drugs also plays an important role in clopidogrel's metabolism, which can either enhance or compete as substrates for CYP activity. Statins and PPIs are two commonly prescribed agents that have been shown to decrease the activity of clopidogrel. With statins, the clinical significance is unclear, with no specific evidence demonstrated against a particular statin.[280] In the case of PPIs, reduced antiplatelet effects and increased ischemic events have been suggested, particularly with omeprazole and esomeprazole[281]; however, the only prospective trial showed no difference in cardiovascular outcomes.[282] Nevertheless, the FDA labeling for clopidogrel includes a black box warning to avoid these two PPIs, opting instead for the use of pantoprazole because it has minimal effects on CYP2C19. Of interest, cigarette smokers exhibit a mildly exaggerated antiplatelet response due to enhanced activity of CYP1A2, which also participates in clopidogrel's metabolism.[283] Similarly, CYP3A4 inducers such as St John's Wort or rifampin may result in LPR as a result of much greater availability of the active compound.

Management of patients exhibiting thrombotic events while on clopidogrel usually consists of switching to a more potent drug such as prasugrel or ticagrelor. Some clinicians test for HTPR and decide on treatment accordingly. Hyporesponsiveness in the absence of ACS may sometimes be reversed by removing adverse drug interactions or increasing the maintenance dose of clopidogrel, although this approach seems to be effective in only some patients. Prasugrel also must undergo metabolic activation; however, polymorphisms of ABCB1 and CYPC19 do not seem to affect the antiplatelet response.[212] In addition, the risk of interactions with statins and PPIs is minimized. Some patients will exhibit HTPR to prasugrel, possibly because of multiple clinical risk factors or platelet receptor polymorphisms rather than abnormal pharmacokinetics. A recent meta-analysis comparing HTPR between the three available P2Y12 inhibitors, demonstrated the lowest platelet reactivity with standard maintenance doses of ticagrelor, followed by prasugrel, with clopidogrel being the least effective at either standard or high maintenance doses.[284]

Platelet Function Tests

Because response to antiplatelet drugs varies from one patient to another, platelet function tests represent an attractive strategy to optimize antiplatelet therapy. A host of platelet function tests of varying specificity and sensitivity are available, each with its own advantages and disadvantages[285–288] (Table 44.6).

Light transmission aggregometry is considered the gold standard to measure platelet aggregation. This technique measures changes in light transmission as a result of GpIIb/IIIa receptor–dependent (final common pathway) platelet aggregation in response to a specific agonist. Based on this test, the degree of change or in baseline platelet function/responsiveness has been categorized into various degrees: nonresponsiveness is defined as less than 10% change in platelet aggregation; hyporesponsiveness reflects a change between 10% and 30%; and responsiveness is when a more than 30% difference is seen. The routine use of light transmission aggregometry in real-world experience is impractical because it is not available as a point-of-care test. Additional disadvantages are that blood needs to be separated from plasma, the test is time consuming, and a high sample volume is required.

Platelet function tests more commonly used to evaluate antiplatelet agents during clinical trials of coronary stents include (1) the VerifyNow system, (2) thromboelastography with platelet mapping, (3) Multiplate analyzer, and (4) vasodilator-stimulated protein phosphorylation.[289]

TABLE 44.6 Tests to Measure Platelet Function in Patients

Test	*Measurement*	*Advantages*	*Disadvantages*
Light transmission aggregometry	Platelet aggregation	Gold standard	Needs plasma, time consuming, high sample volume
Impedance aggregometry	Platelet aggregation	Measures smaller platelet aggregates than with light transmission	Time consuming, high sample volume
VerifyNow	Platelet aggregation	Point of care	Limited hematocrit and platelet count range
Plateletworks	Platelet aggregation	Minimal sample prep	Not enough experience
TEG Platelet Mapping system	Platelet contribution to clot strength	Clot information	Limited studies
Impact cone and plate analyzer	Shear-induced platelet adhesion	Point of care	Not widely used
PFA-100	High shear blood cessation by platelet plug	Point of care	Depends on hematocrit, von Willebrand factor Lack of correlation with thienopyridines
VASP	Platelet P2Y12 receptor activation signaling	Specific for ADP antagonists	Requires flow cytometer and experienced technician
Serum thromboxane B2	Activation-dependent release from platelets	Relates to ASA inhibition of COX1	Indirect measure, not platelet specific
Urinary 11-dehydro-thromboxane B2	Urinary metabolite of thromboxane B2	Relates to ASA inhibition of COX1	Indirect measure, not platelet specific

1. VerifyNow (Accumetrics, San Diego, Calif). This point-of-care device is based on GpIIb/IIIa receptor–dependent platelet aggregation, augmented by the presence of fibrinogen-coated beads. It requires only a small sample of anticoagulated whole blood and it can be performed rapidly. Results are expressed as platelet reactive units (PRUs). ASA response is measured with the use of a cartridge containing AA, whereas an ADP cartridge is used to test the effects of ADP antagonists. Values greater than 550 PRUs with ASA and greater than 208 PRUs with P2Y12 inhibitors are considered diagnostic of HTPR. A response of less than 85 PRUs with ADP suggest LPR.

2. Thromboelastography (TEG) analyzer with platelet mapping system (Haemoscope, Niles, Ill). Updated to a more platelet-specific test in the form of the thromboelastographic platelet mapping system, this test has been used to evaluate the effects of antiplatelet therapy and it requires whole blood. A particular advantage is that it measures platelet function and also the platelet contribution to clot strength. Its disadvantages are that it is not a true point-of-care instrument and experience with it is limited. Within a thromboelastographic trace the maximum amplitude reflects platelet function. HTPR to ADP antagonists is said to occur if the MA ADP is greater than 47 mm and LPR is less than 30 mm.

3. Multiplate analyzer (Roche Diagnostics, Manheim, Germany). This is a point-of-care method that measures GpIIb/IIIa integrin–dependent platelet aggregation by changes in electrical impedance, as platelets attach to electrodes in plates containing different agonists (collagen, AA, ADP). The increase in impedance is measured by arbitrary aggregation units (AUs) plotted against time; a value of more than 46 AUs is associated with HTPR and less than 19 AUs with LPR.

4. Phosphorylation of vasodilator-stimulated phosphoprotein (VASP-P; BioCytex, Marseille, France). This test uses prostaglandin E, which binds to its platelet membrane receptor, thus triggering the production of cyclic AMP (cAMP) by activation of adenylyl cyclase, which, through protein kinase A, converts VASP to phosphorylated VASP (VASP-P). Binding of ADP to the P2Y12 receptor inhibits adenylyl cyclase, decreasing intracellular cAMP, thus preventing the formation of VASP-P. In the presence of a P2Y12 receptor inhibitor, the level of VASP-P will increase as measured by whole blood flow cytometry. Results are expressed in terms of platelet reactivity index (PRI). The platelet reactivity cutoff of more than 50% implies HTPR and lower than 16% suggests LPR. The principal advantage of this test is that it is the most sensitive assay for P2Y12 receptor signaling. The disadvantages include the number of steps involved and requirements for flow cytometry equipment and experienced technicians.

BOX 44.7 CUTOFF VALUES OF HIGH AND LOW PLATELET REACTIVITY WITH COMMONLY USED PLATELET FUNCTION TESTS

VerifyNow: ASA > 550 PRUs; P2Y12 inhibitors > 208 PRUs or < 85 PRUs
TEG: MA > 47 mm or < 30 mm
Multiplate analyzer: >46 AUs or <19 AUs
VASP-P: >50% PRI or <16% PRI

Use of Platelet Function Tests

Current recommendations are against the routine use of platelet function tests in post-PCI patients, as a result of prospective randomized trials showing the lack of benefit of personalized therapy based on results of platelet function.[290–292] Similarly, the routine use of genetic testing for CYP2C19 variants discovered up to now is not recommended, because it explains only a small part of the pharmacodynamic effect of clopidogrel.[292] However, a large number of observational studies have demonstrated that HTPR during clopidogrel treatment represents a strong and independent risk factor for stent thrombosis.[293–297] Platelet function tests may be considered in selective patients thought to exhibit HTPR (such as patients with insulin-dependent diabetes mellitus or prior stent thrombosis), thus allowing a switch to more potent agents like prasugrel or ticagrelor.

Another potential advantage of platelet function tests is the capability to tailor antiplatelet management in the perioperative period, thereby reducing preoperative waiting time, compared to recommended guidelines.[298] Although currently no studies evaluating such an approach in NCS are available, a few small studies have shown that testing for platelet reactivity before coronary artery surgery led to improved times to surgery and less postoperative transfusion.[299,300] Platelet function tests are currently endorsed for selected patients by the Society of Thoracic and Cardiovascular Surgeons.[301]

Studies using receiver operating characteristic (ROC) analysis to define a threshold or cutoff value largely depend on the patients studied (Box 44.7). Reported indicators of HTPR have a very negative

Copyright Elsevier.)*

predictive value for thrombotic events, yet their positive predicted value is low.[289] This observation is consistent with the fact that HTPR, although an important determinant, is not the sole factor responsible for thrombotic events. Moreover, current evidence suggests that there may be a ceiling effect in decreasing the incidence of stent thrombosis, whereas the risk of bleeding may be heightened.[302,303] Thus, the focus has shifted to finding strategies that can avoid excessive bleeding while maintaining the benefit of reduced ischemic thrombotic events. Accordingly, a model of a therapeutic window of platelet reactivity has been suggested in which an optimal balance between the risk of bleeding and stent thrombosis is achieved. This approach, in theory, should help to design better antiplatelet therapy[289] (Fig. 44.10).

Noncardiac Surgery and Coronary Stents

Surgery as a Prothrombotic State

One of the major challenges in the care of patients with coronary stents is caring for those undergoing NCS. It is well recognized that surgery constitutes a risk factor for myocardial ischemic events, including stent thrombosis, which may be triggered by the physiologic response to surgical stress.[304–307] Enhanced sympathetic response increases catecholamines, cortisol, and renin, leading to increased myocardial stress and heightened platelet activation.[308] These increases are accompanied by concomitant increases in procoagulant factors (fibrinogen and plasminogen activator inhibitor), with simultaneous inhibition of fibrinolysis.[309–311] Thus, the cumulative result is a prothrombotic, proinflammatory, and catabolic state, the magnitude of which correlates with the severity of surgical trauma and preexisting inflammatory state.

BOX 44.8 MAJOR ADVERSE CARDIAC EVENTS

Perioperative myocardial ischemia or infarction
Ischemia-related acute heart failure
Target vessel revascularization
Stent thrombosis (uncommon)
Death

The risk for thrombosis in the presence of a foreign body such as a stent is enhanced, particularly in the setting of incomplete endothelial strut coverage. However, it is important to recognize that perioperative myocardial ischemic syndromes other than stent thrombosis can also occur as a result of stent restenosis or progression of native disease elsewhere in the coronary circulation.[312] In fact, the frequency of documented perioperative stent thrombosis in published series is low, with most researchers reporting major adverse cardiac events (MACEs) as a composite outcome[313–315] (Box 44.8). Consequences of perioperative stent thrombosis, however, can be devastating because it is associated with a 50% to 70% incidence of STEMI and up to 40% mortality.[316,317] Additionally, performing a PCI in the perioperative period is particularly challenging because of the added risk of major bleeding from the use of antithrombotic agents.

Limitations of Current Guidelines and Physician Knowledge

There is general agreement that elective PCI and stent placement should not be performed as a preoperative revascularization strategy aiming at risk reduction prior to NCS.[12,13] This concept is largely reinforced by the results of two trials in which preoperative revascularization was ineffective when performed for the sole purpose of reducing perioperative cardiac events.[318,319]

Nevertheless, a recent report from a large administrative database showed that approximately 4% of elective PCIs were performed with the explicit purpose of reducing perioperative NCS risk, despite evidence to the contrary and against published guidelines.[320] Not surprisingly, the incidence of MACE was higher in those undergoing NCS when compared to those who had PCI for other reasons. Thus, despite being performed infrequently, preoperative elective PCI is still viewed by some providers as a beneficial strategy in selected patients, when in fact it does not improve perioperative risk, and at a minimum it may delay the operative procedure.

In selected high-risk surgical patients, preoperative revascularization may be indicated based on preoperative risk assessment (eg, left main or proximal LAD lesion). In this circumstance, the decision to perform PCI versus myocardial revascularization must be reached after considering the risk/benefit ratio of the cardiac procedure and the risk associated with the planned surgery.

For patients with preexisting coronary stents, several societies[12–14] have guidelines available to assist providers with decision making, but the guidelines focus primarily on timing of elective surgery and management of antiplatelet agents according to stent type. Because all of the guidelines are based on poor quality evidence and expert opinion, the recommendations vary. This situation is highlighted by a recent review of 11 clinical practice guidelines in which different recommendations were issued.[5] Moreover, such recommendations address primarily the first 12 months after PCI. Very little guidance is provided beyond 12 months, although the risk of VLST and MACE is well described up to several years after PCI.[153,321]

The recently updated guidelines from the American Heart Association (AHA) and European Society of Cardiology/ European Society of Anaesthesiology (ESC/ESA),[12,13] although an improvement over their predecessors, are limited by the lack of incorporation of specific clinical risk factors for stent thrombosis (eg, diabetes, chronic renal failure, PCI during ACS) and a standard classification of surgical hemorrhagic risk. Instead, they provide a broad statement encouraging practitioners to gauge the risk of thrombosis versus bleeding. In addition, they offer very little assistance on the management of antiplatelet therapy when surgery cannot be deferred, or on reinstitution of DAPT in patients who discontinued it preoperatively.

Despite their limitations, there is evidence of a reduction of perioperative MACEs when NCS is delayed according to guideline recommendations, mainly in DES patients.[322] Yet, variable success has been encountered when translated to local practice among individuals, in particular with the management of antiplatelet agents. The reasons are likely multifactorial, such as lack of guideline awareness, disagreement with the recommendations, emphasis on long-standing practice, and personal bias.[323,324] Among specialists, surveys have demonstrated a high degree of agreement in following guideline recommendations among most cardiologists[325] and between cardiologists and anesthesiologists when compared to surgeons.[326] This observation can be explained largely by the fact that cardiologists and anesthesiologists are mainly concerned with ischemic and thrombotic phenomena, whereas surgeons are concerned primarily with hemorrhagic risk, having little to no experience with coronary thrombosis. Within the surgical specialties, vascular surgeons are more likely to follow current guidelines than are nonvascular surgeons.[327]

Minimizing perioperative risk requires the incorporation of several patient and surgical-related factors in decision making, besides the well-described importance of timing of PCI and a particular antiplatelet regimen. Although specific angiographic and procedural data may not be available, the presence of recognized clinical risk factors (eg, diabetes, chronic heart failure, obesity, chronic kidney disease, ACS, prior stent thrombosis) can be identified. Additional data such as stent type, number and coronary location of the stents, and clinical indication for stent placement can be obtained for many patients. Although the individual risk associated with each factor is unknown, it is reasonable to believe that perioperative risk of stent thrombosis and MACE will be related to the number of risk factors in each individual patient, with some (eg, previous stent thrombosis) having perhaps greater predictive value than others (Box 44.9). Similarly, although evidence for surgery-specific thrombotic risk is not widely available, it is reasonable to expect more complex surgeries to carry a higher risk of stent thrombosis and perioperative MACE than more superficial procedures.[328]

Once an estimation of perioperative risk is made, the main decisions for elective NCS are timing of the surgery and perioperative management of antiplatelet therapy. Additional considerations include the anesthetic technique, perioperative surveillance for myocardial ischemia, and whether to perform the procedure in a facility without on-site PCI capability[329] (Box 44.10). For urgent or emergent procedures which cannot be delayed, attention should be focused primarily on the management of antihemostatic agents, minimizing the severity of bleeding, and close perioperative surveillance for ischemic/thrombotic events.

Surgical venue with access to PCI capabilities

PCI, Percutaneous coronary intervention.

Timing of Surgery

This refers to the period between coronary stent placement and occurrence of the surgical procedure. For elective cases the correct timing of surgery is strongly dependent on the clinical indication for antiplatelet therapy.[330] The main concern is primarily the risk for stent thrombosis due to the presence of HTPR after PCI and the time course for endothelial stent coverage.

Cardiologists encountering candidates for elective PCI who are also scheduled for subsequent surgery have several alternatives. They first must consider whether to delay coronary stent placement and to manage the patient medically until after the surgical procedure takes place. In certain patients this option might not be possible (patients with severe ischemia, ACS, high-risk lesions, or high-risk NCS). They traditionally will follow a particular path if a future surgery date is known. For example, if surgery is required within 2 to 4 weeks, more often a balloon angioplasty will be recommended, because it is relatively safe.[331] If surgery is contemplated beyond 6 weeks, placement of a BMS will be entertained, reserving a DES for those patients who will require surgery after 12 months. This approach, however, has been called into question because many patients, particularly those with several risk factors for restenosis, will benefit from placement of a DES. Furthermore, second- and third-generation DESs have a greater safety profile against LST than do first-generation DESs, challenging the current paradigm of automatically placing a BMS in patients known to require surgery less than 12 months after PCI.[332–334]

More commonly, patients present for previously unplanned surgery following PCI and stent placement. Evidence from multiple observational studies demonstrates that NCS during the first 6 weeks after coronary stenting constitutes the highest risk period for stent thrombosis and MACE, regardless of stent type and whether antiplatelet therapy is continued.[335–340] Thus, unanimous agreement exists to withhold elective surgery during this period. Nonelective surgery must be performed at an institution with on-site PCI capability, while maintaining DAPT or bridging therapy with intravenous platelet inhibitors and aggressively monitoring for thrombotic events.

It is important to emphasize that NCS after this waiting period is predominantly based on patients undergoing elective noncomplex PCI and does not necessarily extend to patients with PCI for ACS. Indeed, retrospective data show the risk for perioperative MACEs for this population to be highest within 3 months following PCI.[341] For high-risk ACS patients, as well as for those undergoing complex PCI, it is reasonable to withhold elective surgery for 12 months, if possible. Other patients who may require increased waiting times include individuals with poorly controlled clinical risk factors or those shown to exhibit HTPR.

BMSs have traditionally been touted as safer than DESs for patients requiring surgery within 1 year after PCI. Because endothelial stent coverage in most patients appears to be complete within weeks and the incidence of restenosis peaks between 4 to 12 months, some experts have advocated a safe window in which surgery should ideally be performed between 6 weeks post–elective PCI and before restenosis becomes likely.[244] Current guidelines recommend that NCS can be performed 4 to 6 weeks or more after BMS implantation. Recent studies, however, have shown that the risk of perioperative MACE with BMS is similar to or even greater than DES,[332,342] with clinical factors such as a cardiac risk index score higher than 2, emergency surgery, and myocardial infarction 6 months preceding NCS having a greater predictive value than stent type.[343] These observations can be partially explained by selection bias—with sicker patients or those identified as having future NCS undergoing BMS placement in accordance with current practice—and widespread use of safer newer generation DES. Thus, the higher rates of MACEs with BMS are more likely explained by the individual patient's underlying disease rather than the influence of stent type on the surgical procedure.

In patients with DESs, the risk for perioperative MACEs, although lower after the first 6 to 8 weeks after PCI, remains elevated between 6 weeks and 6 months, particularly in high-risk patients undergoing complex procedures.[344] Thereafter, the risk of stent thrombosis seems to stabilize beyond 12 months, with very little difference between BMSs or any DES.[345,346] Current recommendations are to wait 12 months before elective NCS, with a minimum of 6 months if the risk of delaying surgery is higher than the potential risk of ischemic or thrombotic events. Although recent evidence suggests minimal incremental risk of NCS after 6 months,[6] further studies are needed, particularly with newer generation stents, in patients with complex PCI and other risk factors for stent thrombosis [347] (Box 44.11).

BOX 44.11 MINIMAL WAITING TIME AND DURATION OF DUAL ANTIPLATELET THERAPY BEFORE ELECTIVE NONCARDIAC SURGERY

BMS (elective PCI): >6 weeks
BMS (PCI for ACS): >12 weeks
DES: >6 months

ACS, Acute coronary syndrome; *BMS*, bare metal stent; *DES*, drug-eluting stent; *PCI*, percutaneous coronary intervention.

For time-sensitive NCS an attempt should be made to defer the procedure for at least 6 months whenever possible. If such delay is impossible, every effort should be made to maintain DAPT, fully recognizing that the increase of bleeding may also lead to increased cardiac complications. Additionally, most studies address primarily major- or intermediate-risk surgery with very little information for patients undergoing low-risk procedures.[348] Current available data suggest that performing ambulatory low-risk procedures 4 to 6 weeks or more after patients have been implanted with a BMS and more than 3 to 6 months after patients have undergone DES implantation may be relatively safe.[348,349]

Management of Antiplatelet Therapy

Perioperative management of antiplatelet therapy during NCS is one of the most important and controversial issues in patients who have coronary stent. For patients taking DAPT, a surgical or interventional procedure is considered the most common reason for temporary cessation of DAPT, thereby increasing the risk for perioperative MACEs.[350,351] Alternatively, continuation of DAPT increases the perioperative risk and severity of bleeding, thus leading to additional complications including increased risk for cardiac events.[253]

Most controversies and guideline recommendations on perioperative DAPT have been centered primarily on the first 12 months following PCI, while being conspicuously absent beyond this time frame. As a result, many surgeons and interventional physicians indiscriminately withhold DAPT after 12 months even for low bleeding risk procedures. New evidence, however, shows additional benefits of 30 months of DAPT against ischemic or thrombotic syndromes in DES patients.[247,352] This protection seems to extend to native coronaries, as well, and may require a reexamination of DAPT management in selected subjects undergoing NCS beyond 1 year.

Current guidelines provide a broad framework to guide clinicians in relation to the time of surgery. Thus, a minimum of 4 to 6 weeks of DAPT is required for BMS patients and 6 months (ideally 12 months) for patients with DESs, with continuation of ASA monotherapy in most cases, unless contraindicated by the hemorrhagic risk.[12] It is important to emphasize that most published studies are based on patients taking ASA and clopidogrel; very little evidence is available on NCS patients taking newer and more potent antiplatelet agents.

In the absence of well-designed randomized trials assessing the risk/benefit ratio of perioperative DAPT, most decisions should be based on the balance between thrombotic and hemorrhagic risks associated with each patient and surgical procedure[353] (Fig. 44.11). Thrombotic risk is related to several procedural and clinical factors as well as the time from PCI to surgery, stent type, and degree of surgical trauma[146–148,345] (Table 44.7). Hemorrhagic risk is based on the type of surgical intervention (Table 44.8), plus the patient's inherent bleeding tendencies from additional comorbidities. It is important to recognize the lack of standard definition of surgery-specific degree of hemorrhage, with most classifications based largely on expert consensus.[353] More recently, the Academic Research Consortium has proposed a

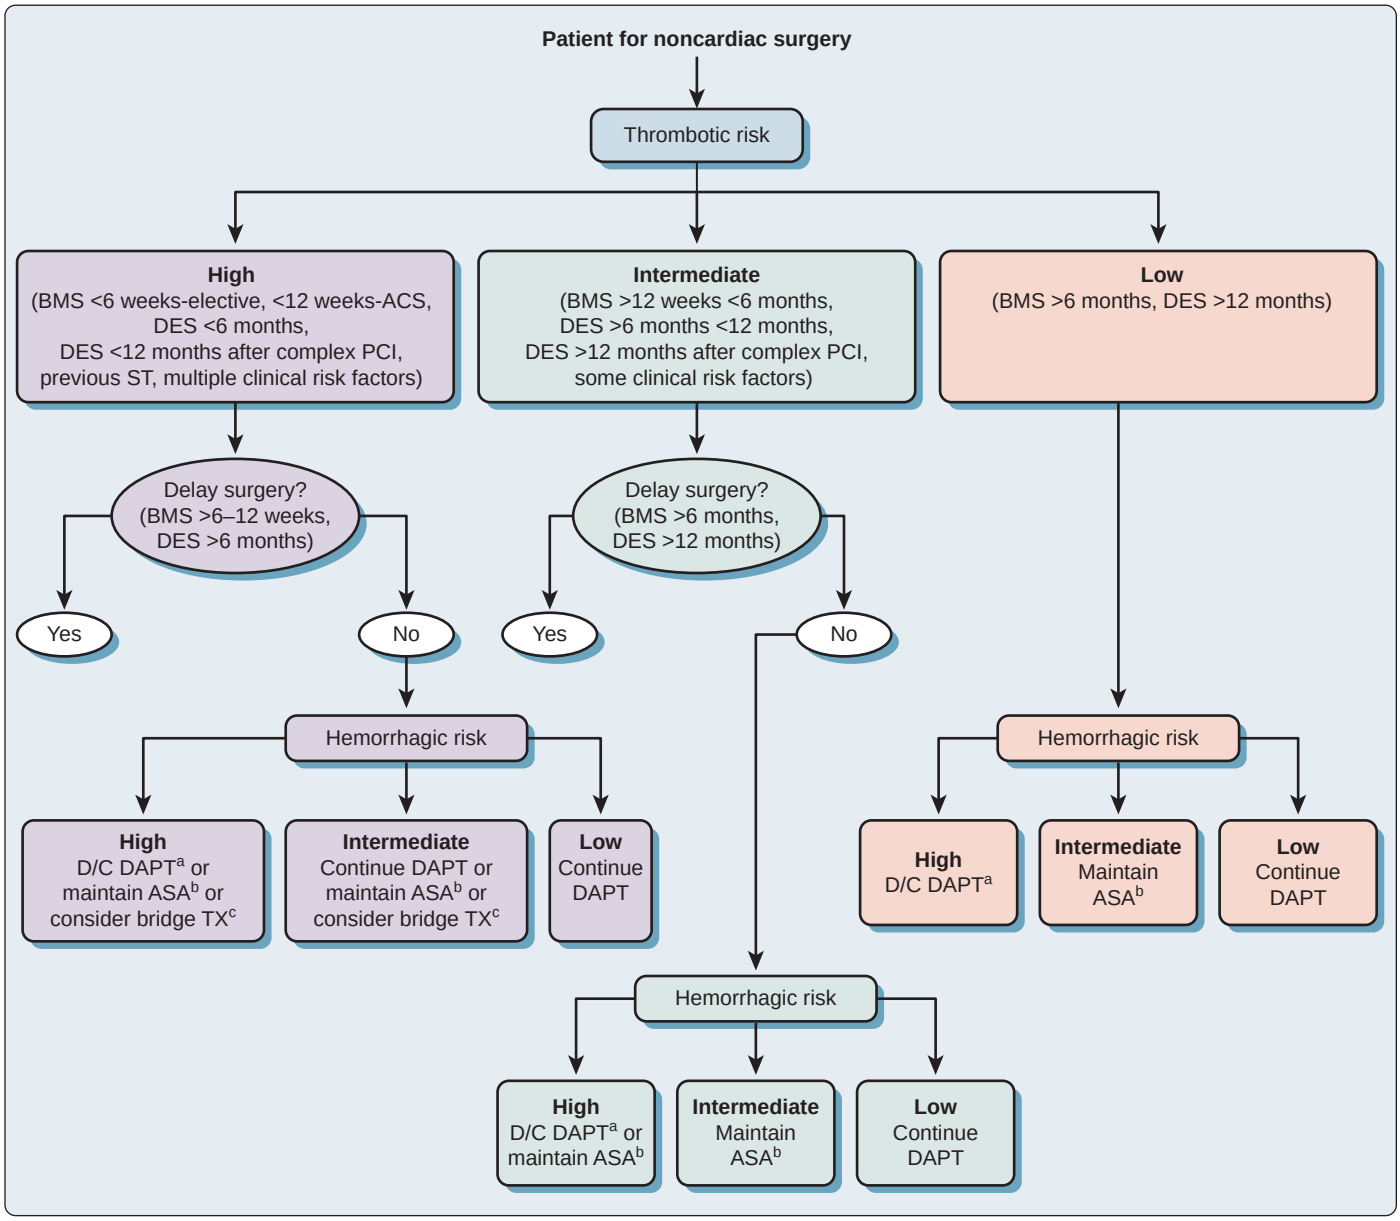

Fig. 44.11 Algorithm for management of patients with coronary stents and noncardiac surgery. Clinical and angiographic risk factors (complex percutaneous coronary intervention [PCI]) are shown in Table 44.4 Surgery-specific hemorrhagic risk is shown in Table 44.8.[a] Discontinue both antiplatelet agents preoperatively: clopidogrel and ticagrelor 5 days before surgery, ASA and prasugrel 7 days before surgery.[b]Discontinue only adenosine antagonist.[c]Discontinue DAPT followed by continuous infusion of tirofiban, eptifibatide, or cangrelor.*ASA,* Acetylsalicylic acid; *BMS,* bare metal stent; *DAPT,* dual antiplatelet therapy; *D/C,* discontinue; *DES,* drug-eluting stent; TX, therapy. *(Based on references 12, 37, 353, 381–383.)*

standardized grading system for patients on DAPT and those with post-PCI bleeding[354] (Table 44.9). Although not originally designed for NCS patients, this scoring method may prove useful in evaluating perioperative bleeding with platelet inhibitors.

Interruption of Antiplatelet Therapy

Interruption of DAPT (particularly both drugs) is associated with an increased risk of perioperative stent thrombosis and other myocardial ischemic syndromes for several reasons. First, in many patients, stent struts might not be completely covered with endothelium. This property has been demonstrated to be much more frequent with first-generation DESs and those that incorporate a durable polymer that can cause a localized chronic inflammatory vessel response. Second, abrupt interruption of either ASA or a thienopyridine may be associated with a rebound phenomenon in which newer platelets generated by the bone marrow exhibit increased activation and aggregation to thrombotic stimuli. Multiple clinical studies have demonstrated unequivocally a peak in ischemic and/or thrombotic phenomena on abrupt discontinuation of either ASA or clopidogrel.[355–360] Whether this is due to platelet rebound or simply loss of the protective effect from antiplatelet therapy is unclear.[361,362] Third, some patients exhibit variable degrees of chronic HTPR that may become fully expressed when DAPT is discontinued and may suffer from thrombotic events in stented areas or native atherosclerotic vessels.

Whereas there is unanimous agreement against interrupting oral DAPT in the first 6 weeks after PCI, studies evaluating the impact

TABLE 44.7 Perioperative Thrombotic Risk

Cangrelor	60–90 min	4–6 h	0.75 μg/kg per min

[a]Absent clinically significant bleeding. Intravenous agents can be discontinued on reinstitution of oral dual antiplatelet therapy. Oral agents can be administered by nasogastric tube if patients have not resumed oral intake.

of preoperative discontinuation of DAPT between 6 weeks and 12 months show inconsistent results. Some show a high incidence of MACE, whereas others suggest that temporary suspension of DAPT under medical supervision is safe.[172,363,364] At this time, the optimal period to perform NCS if surgical bleeding risk requires discontinuing DAPT is unknown. This is not surprising, because every patient's thrombotic and hemorrhagic risk is different. Because wide variability to antiplatelet therapy exists, future use of platelet function tests may prove advantageous by providing a tailored approach to DAPT before surgery, potentially minimizing bleeding and thrombotic risk.[365]

For most patients, discontinuing DPAT means interruption of the adenosine antagonist while maintaining perioperative ASA, because most elective and interventional procedures can safely be performed in patients receiving ASA.[366] Certain operations (eg, certain types of neurosurgery, urologic procedures, complex gastrointestinal endoscopy, or surgeries within an enclosed space) may require withholding both agents because even minimal bleeding might cause significant complications. Discontinuation of DAPT (ADP antagonist) a week before surgery is necessary if a regional anesthetic or neuraxial technique is planned per current guidelines,[367] but maintenance of ASA alone is generally considered safe. Selected patients probably can undergo peripheral nerve blocks while on clopidogrel, but published experience is limited.[368,369]

If one or both antiplatelet agents are discontinued, it is recommended that clopidogrel and ticagrelor be stopped 5 days before surgery, whereas prasugrel and ASA should be stopped seven days before surgery.[370] Limited evidence shows that when an ischemic or thrombotic event occurs after DAPT is interrupted, it most commonly occurs 1 to 30 days after surgery as a result of persistence of a prothrombotic state.[371] Thus, it is imperative that DAPT be resumed as soon as possible, preferably within the first 24 hours. Reinstitution of the P2Y12 inhibitor requires a loading dose, whereas ASA can be restarted with a normal maintenance dose (Table 44.10).

Continuation of Antiplatelet Therapy and Risk of Hemorrhage

In NCS, perioperative DAPT increases the likelihood of surgical blood loss requiring transfusion or reintervention by as much as 50%.[372] Published reports give conflicting results, suggesting that the risk for major bleeding may be rather surgery specific.[373] For example, a large registry of patients undergoing vascular surgery showed no difference in bleeding complications based on the antiplatelet regimen,[373] whereas in patients undergoing elective joint replacement or Mohs procedures, major bleeding complications were significantly higher.[374,375] In general, there is agreement that DAPT should be continued in patients undergoing procedures that have a low risk of bleeding. Nevertheless, it is

important to recognize that most of the published evidence addresses patients on DAPT with clopidogrel, with very little information available regarding prasugrel or ticagrelor.

The use of ASA monotherapy is also associated with increased surgical blood loss, although less than with DAPT.[376,377] Previous studies, including a meta-analysis of 50,000 patients, showed more bleeding with ASA and no differences in outcome except in transurethral prostatectomy and intracranial surgery.[378] A recent large randomized trial in NCS demonstrated a greater number of major bleeding events without reduction in thrombotic or ischemic events.[379] In this study, only a minority (<5%) of patients had coronary stents, so the results may not be representative of this patient population. Current recommendations support continuing ASA, with decisions primarily centered on management of the P2Y12 inhibitor, unless the hemorrhagic risk far exceeds the thrombotic risk.

Several management algorithms have been published.[380–383] with the most comprehensive document put forth by combined Italian medical societies.[354] These algorithms are based primarily on expert consensus. Ultimately, treatment recommendations should center on the careful individual evaluation of each patient's ischemic and thrombotic risk.

Bridging Therapy

This approach is reserved for selected patients who have a high thrombotic profile undergoing a procedure associated with high hemorrhagic risk, in whom DAPT must be suspended and surgery cannot be delayed. Antiplatelet agents are preferred, because therapy is aimed at prevention of a platelet-rich thrombus.[384] Although heparin has been advocated as a bridging agent, it is less than optimal because its beneficial effects on platelets are minimal or may even induce a prothrombotic effect.[385]

Current agents available for bridging therapy are the short acting GpIIb/IIIa inhibitors tirofiban and eptifibatide and the P2Y12 antagonist cangrelor. This therapy calls for discontinuation of the P2Y12 inhibitor 5 to 7 days before the surgical procedure. Patients are then admitted to the hospital and started on a continuous intravenous infusion (without a bolus) of either tirofiban or eptifibatide until 4 to 6 hours (tirofiban) or 4 to 8 hours (eptifibatide) before the planned procedure.[386] The infusion is restarted postoperatively until oral DAPT can be reinstituted. The drug cangrelor represents an attractive alternative. Because of its very short half-life, an infusion of 0.75 μg/kg per minute can be continued until shortly before surgery. However, the use of cangrelor as a potential bridging agent has only been tested on patients undergoing cardiac surgery, with no published experience in NCS. Although bridging therapy is relatively safe, stent thrombosis can still occur and there is an increased risk of bleeding.[387] Furthermore, it is associated with increased hospitalization and costs.

Patients Undergoing Ambulatory Surgery

Patients with coronary stents undergoing ambulatory surgery raise the issue of safety in locations without an on-site cardiac catheterization laboratory. Although few data exist, current literature suggests that the incidence of MACEs is very low, although the risk of stent thrombosis is still present. Some cardiologists have advocated that all surgical procedures be performed in facilities with immediate access to PCI capabilities.[388] Such recommendations are impractical and economically burdensome because of the large number of patients undergoing ambulatory procedures. Currently, no official position has been promulgated by the various professional societies, with most decisions driven by local and individual practice. A satellite center without PCI capabilities may be appropriate for patients who have undergone elective PCI, lack significant risk factors for stent thrombosis, and have exceeded the minimal duration of DAPT, who undergo procedures that do not require interruption of any antiplatelet therapy (eg, low bleeding risk endoscopic intervention).[389] More importantly, it is essential that practitioners establish protocols for treatment of STEMI and expeditious referral (less than 90 minutes) to a PCI center for immediate revascularization in the event of an ACS.

An Integrated Approach

When treating NCS patients with coronary stents, clinicians face a potentially complex clinical conundrum that offers many challenges in efforts to find the optimal balance between thrombotic/ischemic and bleeding risk. This problem is compounded because interventional cardiology is undergoing rapid advances in stent technology and availability of newer antiplatelet drugs. This explosion of innovations frequently finds its way into clinical use, and many patients receive new devices and drugs with which most perioperative physicians are relatively unfamiliar.

Inevitably a significant percentage of individuals will require a surgical or interventional procedure, thus placing practitioners at a disadvantage, because published evidence frequently lags behind clinical use. Current recommendations contained in expert reviews and society guidelines rely in large part on studies that frequently involve outdated or obsolete devices (eg, Cypher stents), forcing clinicians to extrapolate from the nonsurgical population. Moreover, techniques with significant potential for use in NCS (eg, platelet function tests) remain unexplored. The complexities of this issue highlight the importance of a multidisciplinary and regimented approach that is incorporated into an evidence-based comprehensive framework addressing surgery specific risks, PCI and clinical risk factors, the pharmacologic profile of various antiplatelet agents, and the surgical venue. Only in this manner can the care of these patients be truly optimized.

Ventricular Assist Devices, Cardiac Transplants, and Implanted Electrical Devices in Noncardiac Surgery

SWAPNIL KHOCHE, MBBS | BRETT CRONIN, MD

KEY POINTS

1. Modern left ventricular assist devices (LVADs) are increasingly used for long-term support. They feature a small footprint, durability, and pulsatile flow.
2. Right ventricular failure, infection, and bleeding (especially from the gastrointestinal tract) are complications in patients with LVADs that can be life-threatening.
3. Anticoagulation modulation, monitoring strategy, and hemodynamic management are key features of anesthesia care for patients with LVADs.
4. Advances in surgical techniques and immunosuppression have increased the longevity of cardiac transplant recipients.
5. The transplanted heart undergoes various degrees of reinnervation after a period of denervation. Responses to pressors and inotropes can be unpredictable, and the transplanted heart requires a higher preload for optimal function.
6. Rejection (primarily within the first year) and coronary allograft vasculopathy (ie, form of coronary occlusion in the graft) are complications that must be excluded because the presentation can be nonspecific and the consequences can be lethal.
7. Immunosuppression can have widespread side effects on various organ systems that can affect safe delivery of anesthesia.
8. Active rate modulation in cardiac implantable electrical devices (CIEDs) may result in heart rate alterations intraoperatively related to changes such as hyperventilation.
9. ST-segment elevation of 5 mm or more in leads without QRS concordance may be a sign of myocardial ischemia in patients who are ventricularly paced.
10. The potential for electromagnetic interference with CIEDs is markedly reduced with reduction in the burst of cautery to less than 5 seconds and when the distance from the electrocautery current to the CIED generator or leads is greater than 6 inches.
11. External defibrillator pads should be placed perpendicular to the major axis of the CIED (eg, anterior to posterior) to minimize current through the device or leads.
12. The use of a magnet or programming to an asynchronous mode in a pacemaker with a ventricular lead can result in an R-on-T phenomenon and significant ventricular arrhythmias.

With an almost 1% incidence among patients older than 65 years of age, heart failure (HF) continues to plague the population. The rising incidence is posing a growing burden on health care systems as life expectancy increases and the elderly form a larger portion of society. The total cost of caring for these patients was approximately $40 billion in 2010, and it has continued to increase.

Despite significant improvements in management, the 5-year mortality rate remains a staggering 40% to 50% for people with HF between 65 and 74 years of age.[1] Although surgical cure in the form of transplantation is effective, with a 1-year survival rate greater than 90%, it is not without limitations. Shortage of transplant organs, age restrictions (usually <65 years), and restrictive comorbidities mandate the need for other therapies.[2]

Although left ventricular assist devices (LVADs) were originally developed for temporary cardiovascular support, they are now used for increasingly longer periods. The REMATCH trial ushered in a new era for long-term mechanical circulatory support with improved 1-year survival rates with ventricular assist devices (VADs) compared with medical therapy alone for patients with advanced HF.[3] Almost 9000 VADs have been implanted since 2006, and the number continues to increase (see Chapter 28). With good survival rates reported after Heartmate II LVAD implantation, it is reasonable to assume that anesthesiologists will increasingly encounter patients with these devices who are undergoing noncardiac surgery.[4] General surgical problems occur in almost one-third of patients with VADs, and these patients often undergo elective surgery.[5]

The expanding indications for LVADs also extend to organ donation.[6] LVADs are used to support patients with severe HF as a bridge to transplantation or as destination therapy. The first-generation VADs were designed to replicate pulsatile flow and consequently were large. Their design made them susceptible to wear and tear, and the need for a large pumping chamber precluded implantation within the body. Second-generation devices abandoned pulsatile flow for continuous flow in favor of a smaller footprint and the ability to be implanted in the thoracic or preperitoneal space. The second-generation devices improved survival, reduced complications, and improved quality of life.[7] The latest VADs, including some in development, use novel technologies such as magnetic levitation and are designed for long-term use (Box 45.1).[2]

Ventricular Assist Devices

A few devices are available for long-term therapy, and the most commonly used is the HeartMate II (Thoratec Corporation, Pleasanton, CA) (Fig. 45.1). Thoratec reports that more than 20,000 of these units have been implanted, and many have been in for many years. It is a second-generation device with an axial flow pump that draws blood in through an inlet cannula placed into the left ventricle and ejects blood into the aorta through an outlet cannula. A power driveline connects the unit with the external power source and exits the body in the right upper quadrant of the abdomen.

BOX 45.1 LEFT VENTRICULAR ASSIST DEVICES

- Transplantable hearts are in short supply.
- Heart failure continues to increase.
- Left ventricular assist device (LVAD) technology continues to expand and is used as a bridge to transplantation or as destination therapy.
- Patients with LVADs have more noncardiac surgery than other groups.
- A coordinated team approach is recommended for patient care.

Fig. 45.1 The Thoratec HeartMate II. The device is intrathoracic, with a driveline that attaches to an external module. *(Courtesy Thoratec, Inc., Pleasanton, CA.)*

The speed of the pump in rotations per minute (rpm) is adjustable, with a range of 6000 to 15,000 rpm. The display panel on the control unit shows speed (in rpm), power (in watts), calculated flow (in L/min), and pulsatility or pulse index (PI). The PI (average range, 4–6) is a reflection of the left ventricular (LV) contribution to flow, resulting in changes to flow coinciding with the cardiac cycle. It varies inversely with the contribution of the LVAD to the cardiac output (CO); the higher the PI, the more the left ventricle is working. Parameters influencing the PI are shown in Table 45.1. Pump power (average range, 5.6–8 W) indicates the power needed to drive the VAD. Pump flow (average range, 4.7–6.5 L/min) is a calculated output derived from the other parameters such as power and speed, and it is prone to inaccuracies, necessitating other measures of CO.[8,9] The patients are anticoagulated only mildly (aspirin, 81 mg/day, and warfarin to an international normalized ratio [INR] of 1.5–2.5) because of the relatively low risk of thrombosis and embolism with the newer devices (Box 45.2).[10,11]

Complications of Ventricular Assist Devices

The postimplantation period can be subdivided into early (<30 days after placement) and late (>30 days) periods, and the types of complications can be correspondingly divided. The major complications of

BOX 45.2 LEFT VENTRICULAR ASSIST DEVICE PATIENTS

- Pulsatility of the arterial pressure is proportional to the native heart work and inversely proportional to the flow from the left ventricular assist device (LVAD).
- Flow becomes less pulsatile as the LVAD takes over.
- Some pulsatility is desired because it is physiologic.

TABLE 45.1 Cardiovascular Parameters and Pump Output Effects on Arterial Pulsatility

Cardiovascular Parameter	*Pulsatility Index*[a]
Preload	Increases with increasing preload
Contractility	Increases with increasing contractility
Pump Output	Decreases with increasing pump output

[a]The pulsatility index is equal to the difference between the peak systolic velocity and the minimum diastolic velocity divided by the mean velocity during the cardiac cycle. The value decreases with distance from the heart.

TABLE 45.2 Postdischarge Complications of Left Ventricular Assist Devices

Left Ventricular Assist Device Complication	*Incidence (%)*
Infection	22–50
Arrhythmias	20–30
Gastrointestinal bleeding	14–31
Other bleeding	11
Thromboembolism	6
Pump thrombosis	2–9
Neurologic events	10–20
Right ventricular failure	2–3
Renal failure	2–7
Device failure	Rare
Hemolysis	0–2

LVAD placement are coagulation disorders (both bleeding and thrombosis), right ventricular failure, and infection (Table 45.2).

Infection

Infection is a complication of hardware implanted anywhere, and VADs are no exception. The REMATCH trial reported an infection rate of 53.7% per patient-year in 2001. The continuous-flow devices have a lower rate of infectious complications (11–36%).[12] In a prospective study of 150 patients, 22% had an infection, with a median time to infection after implantation of 68 days. The driveline was most commonly affected, and depressed and elevated creatinine levels emerged as risk factors.[13] Driveline infections negatively affect outcome,[14] and bloodstream infections increase stroke risk.[15] The infections are notoriously difficult to eradicate and can be a cause of sepsis in the perioperative period.

Bleeding

Bleeding is a concern for all implanted LVADs, and many mechanisms have been postulated and tested to define this process.[16] Reduction in the effects from the VAD–blood component interaction (ie, hemocompatibility augmentation) has been a goal of VAD design from the start. Acquired von Willebrand factor deficiency, platelet activation and damage from shear stress and trauma, heparin-induced thrombocytopenia (HIT), and microparticle shedding from cell surfaces contribute to abnormalities in coagulation.[17] The continuous-flow LVADs require

anticoagulation, mostly with aspirin and warfarin, further increasing the risk of bleeding.

In one trial, more than one-half of the patients studied required a transfusion, and many needed reoperation for bleeding.[18] Between 17% and 40% of patients with VADs have gastrointestinal bleeding that is thought to be related to angiodysplasias, and some patients require endoscopic treatment.[19,20] Increased incidence of sensitization, emergence of antibodies, right ventricular (RV) dysfunction from pulmonary hypertension (PH) over time, and infections are complications possibly related to bleeding that affect noncardiac surgery in this patient population.[17]

Thrombosis

Despite lower thromboembolic risks with the newer continuous-flow devices, there still exists the possibility of catastrophic device thrombosis and embolism. Pump thrombosis manifests as poor output with high pump power, hemolysis, and HF. The rate of pump thrombosis is between 1% and 4%.[20–22] Aortic root thrombosis, embolic cerebrovascular accidents, and thrombotic events related to HIT occur and must be carefully monitored for in the perioperative period because surgery can result in a prothrombotic state, precipitating any or all of these events.[17]

Right Ventricular Failure

Development of right ventricular failure (RVF) after LVAD implantation can negate all of the benefit derived from the device because it puts the patient back in HF. Although some degree of RVF accompanies all cases of left-sided failure, a small subset of patients manifests RVF after LVAD implantation that requires inotropic support or a right-sided VAD (RVAD). The reported incidence of RVF is between 10% and 50%.[22–24]

Development of RVF correlates with increased intensive care unit (ICU) stay, mortality rates, and end-organ failure resulting in significant burdens for the patient and the health care delivery system.[25,26] Low RV output, female gender, high central venous pressure and pulmonary vascular disease can predict development of postimplantation RVF. After LVAD implantation, alteration of LV-RV relationships resulting from changes in LV geometry in conjunction with increased RV preload are largely responsible for RVF.[27–29]

Prevention of RVF after LVAD implantation is possible and useful. It involves maintenance of sinus rhythm, optimization of volume and nutritional status, normocarbia, and judicious reduction in RV afterload.[27] Clinicians must be vigilant to promptly diagnose and treat RVF in the perioperative period because of its high incidence, the multiorgan effects, and the limited therapeutic options available.

Noncardiac Surgery in Patients With Left Ventricular Assist Devices

During the early postimplantation period, noncardiac surgical procedures related to bleeding or infection and airway operations such as tracheostomy may be performed. As the duration after the implantation increases, the pathology becomes more varied. The median times to noncardiac surgery after LVAD implantation range between 285 and 500 days, underscoring the longevity of the devices.[30–32]

An LVAD team model consisting of surgeons, anesthesiologists, perfusionists, nurses, and engineers has been suggested to care for these complex patients.[33] It forms a resource for information and support for management in centers caring for patients with VADs. Because patients may be admitted to centers not involved in prior care or without such a team, anesthesiologists must be prepared to care for them with little background information.

Physiologic Changes After Left Ventricular Assist Device Placement

The restoration of systemic CO with an LVAD has profound effects on end-organ perfusion, especially the kidneys and the liver, as assessed by normalizing serum levels of creatinine, bilirubin, liver enzymes, and other markers. Improvements in organ function are sustained for months to years.[7,34] VAD use seems not to significantly affect cerebral autoregulation, although this is based only on a small, preliminary trial.[35]

LVAD implantation results in pressure and volume unloading of the left ventricle. This reduces LV size, with some improvement in function at a global level as measured by improved ejection fraction (EF) and at a microscopic level as evidenced by a reduction in myocyte size, collagen content, and myocyte tumor necrosis factor-α level.[36] There are reductions in circulating levels of catecholamines and neuroendocrine hormones that reflect improved hemodynamics.[37] QRS shortening seen on the electrocardiogram (ECG) can contribute to improvement in function, likely related to better synchronization of depolarization.[38]

The optimal duration and intensity of LV unloading is unknown. Previous work suggests that prolonged unloading can restore the EF to pre-LVAD values,[36] although with loss of contractile function[39] and expression of fetal genes in the heart.[40] This suggests that an optimal amount of load and strain is essential for normal cardiac function; Unloading the heart completely provides optimal functional restoration for only a short period, after which cardiac function does not improve further and may deteriorate.

HF results in downregulation of β-adrenergic receptors in response to an adrenergic overload. This results in reduced responsiveness to exogenously administered β- and α-adrenergic agonists to patients with advanced HF. LVAD implantation can restore β-adrenergic receptor density and reverse the downregulation.[41–43]

Calcium and its release from the sarcoplasmic reticulum is an integral part of myocyte contraction. After LVAD implantation, cardiac myocytes tend to have more sarcoplasmic calcium, faster calcium release into the cell, and shorter action potential duration, with biochemical and electrical profiles similar to those of nonfailing hearts.[44–47] Regression of stress-induced proteins, reduction in apoptosis, DNA degradation, and autophagy is seen after LVAD implantation.[48–50] Why some patients recover better cardiac function than others is being studied.[51]

Whereas most patients getting an LVAD are in biventricular failure, with up to one-third manifesting some degree of RV failure after LVAD implantation, only about 10% require RV support.[52–54] Unloading of the left ventricle results in an RV afterload reduction, and improvements in diastolic ventricular interdependence favoring the right ventricle.[55–57] However, the degree of macroscopic and microscopic improvement in the left ventricle cannot be replicated to the same degree in the right ventricle.[58] This means that the right ventricle remains susceptible to ischemia, injury, and failure after LVAD implantation and needs careful handling during anesthesia to maintain flow to the LVAD (Box 45.3).

Preoperative Evaluation

In addition to the evaluation of end-organ dysfunction, medications, and functional status of the patient, certain aspects of preoperative preparation of patients with LVADs deserve attention. This starts with clear and effective communication among the team members regarding timing, urgency, and procedural aspects of surgery. Clear discussion about the procedure can help to avoid damage to the driveline or the device in thoracic and abdominal procedures.

Another aspect of the preoperative discussion is assessment of electromagnetic interference (EMI) during the procedure, particularly

BOX 45.3 RIGHT VENTRICULAR FAILURE WITH A LEFT VENTRICULAR ASSIST DEVICE

- Right ventricular (RV) failure is always a risk with left ventricular assist device (LVAD) support.
- LVAD output increases the preload to the right heart.
- Susceptibility to RV failure and ischemia must always be considered.

with regard to defibrillation and electrocautery.[59] Most of the newer continuous-flow VADs have extensive electrical shielding and are minimally affected by electrocautery.[33] Older devices, however, may produce erratic output. Care should be taken with the placement of the return pad to avoid the path of electricity crossing the device. Defibrillation can similarly disrupt VAD electronics, leading to malfunction, and manufacturer's recommendations should be followed. This information should be available before the start of surgery so an appropriate plan can be instituted if there is interference related to the cautery or emergency defibrillation is required.

Anticoagulation management of patients can be challenging and needs to start early. The LVAD team needs to decide on an individual basis whether it requires hospital admission and inpatient care. For elective surgery, lowering of INR (ie, goal of 1.5) using warfarin adjustment and aspirin discontinuation may be all that is required for patients with a low risk of bleeding and low risk of thrombosis. However, higher surgical bleeding risk may require warfarin discontinuation in conjunction with heparin, depending on the risk of thrombosis. The risk of thrombosis with a VAD increases significantly with risk factors such as mechanical valves, deep venous thromboses, or other hypercoagulable states, including surgical stress.[30]

Reversal of anticoagulation may be considered for emergent cases. This requires a fine balance between the goals of reducing perioperative bleeding and avoidance of thromboembolic events. Fresh frozen plasma, vitamin K, and blood products must be used judiciously and often in consultation with a hematologist and guided by point-of-care testing such as a thromboelastogram.[31] It is often wise to avoid complete reversal or overcorrection of the coagulopathy.

Many investigators have analyzed the need for blood and product transfusion for patients with LVADs undergoing noncardiac surgery and found wide variation in the reported percentage of patients receiving transfusion (0–100%).[31,59–61] Most of these patients are likely to have required blood product transfusions because of prior cardiac surgery and ongoing anticoagulation. The possibility of allosensitization and presence of antibodies should be considered when arranging for the availability of blood products.

The infectious risk is substantial and carries significant outcome implications. These patients are considered at high risk for infectious endocarditis due to prosthetic cardiac material implantation.[62] In the absence of clear guidelines for this unique subpopulation, the investigators recommend using broad-spectrum antibiotics alone or in combination and consideration of the usual flora that cause infections such as staphylococci and gram-negative bacteria.[13] The addition of antifungals should be individualized and depends on risk. Strict aseptic technique during procedures is imperative.

During surgery, the VAD must be plugged into a power source, even for brief cases.[9,63,64] The battery life on the portable power packs is in the range of a few hours, but using the base power console is recommended. The console usually has a display screen with the VAD parameters on it, and it should be easily visible to all practitioners in the operating room. An alternative power source in the form a fully charged battery pack should be readily available. Defibrillator and tachycardia detection therapies should be turned off, and external pads should be used. In case there is pacemaker dependence, conversion to asynchronous pacing should be carried out as indicated, along with device interrogation (Box 45.4).

Monitoring

The application of usual American Society of Anesthesiologists (ASA) monitoring poses unique challenges in treating patients with continuous-flow LVADs. The sphygmomanometer or the noninvasive blood pressure (NIBP) cuff relies on pulsatile flow for blood pressure measurement. Although most patients with LVADs have some degree of pulsatility related to the contraction of the native heart, NIBP cuff measurements are not possible in about one-half of patients. For them, Doppler-guided estimation of the mean arterial pressure (MAP) is reliable and correlates well with invasive arterial measurements.[65,66]

BOX 45.4 ELECTRICAL ISSUES WITH LEFT VENTRICULAR ASSIST DEVICES

- Left ventricular assist devices (LVADs) must always be plugged in and have a backup battery available.
- Electromagnetic interference may compromise LVAD function.
- Defibrillation using external pads may be needed.

Arterial catheter insertion should be based on the condition of the patient, complexity of the procedure, and the comfort level of the anesthesiologist. Most practitioners lean toward invasive arterial monitoring for all but the shortest procedures because it is reliable and provides access for blood gas sampling.[61] Arterial access may require the use of Doppler or ultrasound to aid in locating the vessel.

The pulse oximeter can give accurate readings without the need for as much pulsatility as the for the NIBP cuff, although its function also needs pulsatile flow. In the absence of an accurate pulse oximeter plethysmograph and pulsatile flow, serial measurement of arterial blood gases and cerebral oximetry can be used to monitor oxygenation and tissue perfusion.[67] End-tidal carbon dioxide (CO_2) measurement can provide surrogate information about ventilation, CO, and pulmonary blood flow.[9]

Most minor procedures in stable patients can be carried out without central venous catheters.[31] In complicated cases with anticipated hemodynamic instability, blood loss, massive fluid shifts, or need for pressor support, their use can be invaluable. The debate about utility of pulmonary artery catheters (PACs) extends to patients with LVADs, with the risks and the benefits weighed for each patient. The PAC has some advantages in patients with RV dysfunction, ischemia, and PH because it can differentiate between increased RV afterload and RV contractility issues.[68]

The CO calculated by the VAD console is based on the power used by the pump, and the resistance against which it works. It is prone to error because the algorithm makes certain assumptions in the calculations that may not always be appropriate. To add to the inaccuracy, the total output is a sum of the VAD flow and the native heart output, and the latter in certain cases may be significant.[69] Continuous CO by thermodilution measurements and pulse contour analysis is likely to be unreliable; the Fick CO measurement provides a more accurate assessment of total CO.[63,69]

Intraoperative Management

The question of who should administer anesthesia for procedures in patients with LVADs often arises. Nonsubspecialist anesthesiologists have treated patients with LVADs for noncardiac procedures successfully with minimal or no support from cardiac anesthesiologists.[31,70] A survey of members of the Society of Cardiovascular Anesthesiologists, however, found that most of these anesthesias are still being performed by cardiac anesthesiologists.[61] Another trend was that care is resource intensive, requiring high staffing ratios and postoperative care in the ICU. In the same report, a higher institutional volume was associated with lower use of invasive monitoring. This probably reflects the familiarity of the clinicians with the devices, the associated conditions and complications, and the relative comfort in managing them.

The availability of an LVAD team promotes caring for LVAD recipients by general anesthesiologists because it provides a layer of safety with significant specialist resources available in case of queries or to help when unexpected clinical situations arise.[31] Our preference at our institution focuses on education and encouragement of general practitioners to undertake anesthesia responsibility for noncardiac surgery in patients with LVADs. Cardiac anesthesiologists usually provide care in thoracic or vascular operations if large fluid shifts or hemodynamic instability is expected or if transesophageal echocardiography (TEE) is required.

Regional anesthesia is seldom a choice for patients with LVADs. Perioperative anticoagulation is the main reason for this, although difficulty in patient positioning, infectious risk, and presence of the device and driveline in the needle trajectory are also factors. Local anesthetic toxicity and arrhythmias can be catastrophic in these patients. The use of regional anesthesia is usually restricted to infiltration and ultrasound-guided peripheral nerve blocks that use low amounts of local anesthetics.

Patients with LVADs have poor cardiopulmonary reserve with abnormal physiology. Irrespective of the drug combinations used, induction of anesthesia and the resultant decrease in preload and contractility may result in unpredictable decreases in CO that are not easily reversible.[2,71] Preload to the left heart in these patients is essential and is influenced negatively by hypovolemia, patient position (eg, reverse Trendelenburg), RVF, anesthetic-induced venodilation, and laparoscopic insufflation of the abdomen. Responses to laryngoscopy and intubation, with the resultant increase in afterload, need to be blunted.[63] Continuous-flow devices respond to increased afterload with sustained rotation speed but decreased CO. This can be difficult to detect because the calculated pump flow may not reflect the true systemic output.

It has been suggested that these patients be treated as "full stomachs" and aspiration precautions undertaken because the device pocket in the preperitoneal space can alter abdominal mechanics and pressure-volume relationships.[31,70,71] Almost any combination of drugs can be use to maintain anesthesia if the factors affecting their pharmacokinetics and pharmacodynamics are kept in mind. Circulation times may be prolonged, and volume of distribution may be altered depending on volume status. Liver or kidney abnormalities from hypoperfusion can result in prolonged activity of the drugs administered.

The goals for intraoperative hemodynamic management focus on maintenance of volume status and RV forward flow, avoidance of sudden changes in afterload, and maintenance of stable cardiac rhythm and rate.[63] Fluid management needs to achieve a difficult balance between ensuring adequate filling of the right ventricle and overloading it, and the margin for error is small. Ventilatory strategy should ensure that there is adequate exhalation time and reduction of intrathoracic pressures to promote venous return.[71,72] Effective and adequate ventilation is essential because hypoxia, hypercarbia, and acidosis can increase pulmonary arterial resistance, increasing RV work against a higher afterload.[9] Positioning should be done carefully and gradually to minimize fluid shifts and changes in preload (see Chapter 28).

There is no clear consensus regarding the choice of inotropes and vasopressors in these clinical situations.[32] The choice of agent should be dictated by hemodynamic need, although with an understanding of the implications on the right ventricle. Milrinone, vasopressin, and norepinephrine may be useful drugs with favorable profiles.[9] Slininger and colleagues proposed a useful clinical algorithm based on the PI in the HeartMate II and central venous pressure (Table 45.3).[63]

Hypothermia increases afterload and myocardial oxygen demand from vasoconstriction and shivering, respectively. Hypothermia may cause decompensation in patients with LVADs. It also causes disorders in coagulation and platelet function, leading to increased perioperative blood loss.[73] Resultant bleeding can be substantial because hypothermic effects on coagulation are superimposed on the pharmacologic anticoagulation necessary with the device.

Despite its potential neuroprotetective and cardioprotective effects, efforts must be made to avoid hypothermia perioperatively. Extubation of these patients is a high-risk event because of the possibility of sympathetic stimulation with decreased VAD output. The risk of aspiration persists, and tracheal extubation should be undertaken only when the patient's airway reflexes and muscular strength have been confirmed to be adequate.

Laparoscopic Surgery

Laparoscopic surgery is significantly more difficult in patients with LVADs. Trocar and port placement must avoid the VAD and driveline in the upper abdomen.[60] CO_2 insufflation for visualization can decrease preload due to compression of the inferior vena cava, especially in a reverse Trendelenburg position. When combined with increases in afterload, which accompany laparoscopy, CO_2 insufflation can be deleterious to forward flow. Absorption of CO_2, acidosis, and higher ventilatory pressures can increase pulmonary vascular resistance (PVR) and the risk of RVF.

Laparoscopic surgery has been carried out successfully with careful compensation for these factors.[9,74] Intravascular volume repletion and gentle inotropy can be used to augment forward flow. Intraabdominal insufflation should be carried out gradually, and insufflation pressures should be held below 12 mm Hg.[75] This allows control of hemodynamic perturbations and gradual equilibration, providing a time window to institute interventions.

TABLE 45.3 Guide for Using the Pulse Index of the HeartMate II and Central Venous Pressure

Parameter	*Pulse Index*	*Central Venous Pressure (mm Hg)*	*Management*
Normal, goal	4–5	10–12	—
Hypovolemia	<3	<12	Fluids Ensure venous return
Right ventricular dysfunction	<3	>12	Inotropes Rule out hypoxia, hypercarbia, acidosis Inhaled nitric oxide
High afterload	>5.5	<8	Vasodilators Ensure adequate flow in the ventricular assist device

From Slininger KA, Haddadin AS, Mangi AA. Perioperative management of patients with left ventricular assist devices undergoing noncardiac surgery. *J Cardiothorac Vasc Anesth*. 2013;27:752–759.

Cardiopulmonary Resuscitation

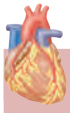
Cardiac arrest is cessation of perfusion to end organs due to a loss of forward flow from the device and the native heart. In continuous-flow devices, this can be difficult to diagnose rapidly because the fall in MAP may be gradual and pulse oximetry usually is unreliable. Sudden decreases in or loss of the capnometric waveform can provide important clues to this catastrophe. The onset of nonperfusing rhythms in patients can be compatible with life and a stable mental status for significant periods.[76] More commonly, loss of RV function leads to nonfilling of the LVAD and loss of systemic flow.

Implanted defibrillators are electronic instruments, and like any other machine, they are not immune to failure.[76] Attention must be paid to alternative means of restoring flow. In most non-LVAD patients, this is provided by external cardiac compressions. Unfortunately, in patients with LVADs, cardiac compression carries the risk of device dislodgment, air embolism, bleeding and trauma, and it usually is not advisable.[32,70] The European Association for Cardiothoracic Surgery (EACTS) recommends against use of cardiac compressions, acknowledging the complexity of this clinical scenario. There is no clear comment on this issue in the guidelines from the American Heart Association released in 2010.[77,78] There has been reported use of abdominal-only CPR in an isolated case,[79] but strong recommendations cannot be made for or against it.

TEE can provide valuable information, and it should be used as soon as possible when severe hemodynamic instability occurs. Empiric epinephrine and other aspects of the guidelines for cardiopulmonary resuscitation (eg, intubation, ventilation) should be followed (Box 45.5).[80]

Anesthesia for Noncardiac Surgery After Heart Transplantation

Cardiac transplantation is no longer a rare entity. With more than 100,000 transplantations reported and more than 4000 procedures



BOX 45.5 CARDIOPULMONARY RESUSCITATION WITH A LEFT VENTRICULAR ASSIST DEVICE

- Standard cardiopulmonary resuscitation (CPR) may be detrimental for patients with a left ventricular assist device.
- CPR may cause bleeding, device damage, air emboli, or trauma.
- Pharmacologic treatment is preferable to CPR.
- Transesophageal echocardiography may help in diagnosing the hemodynamic problem.

being performed yearly, thousands of people have hearts that were once in other persons.[81] The 5-year survival rate of more than 70% and the median survival time of more than 10 years are a testament to the strides forward in care.[82] With an increasing number of patients surviving and remaining functional long after heart transplantation (HT), it is no longer economically feasible to have specialized teams and centers perform noncardiac procedures in transplant recipients (see Chapter 25).

Anesthesiologists must have a comprehensive knowledge of the physiology of the transplanted heart, the pharmacologic implications of immunosuppressive therapy, and optimal means of anesthesia delivery for the HT population. Consultation with specialists for advice and titration of immunosuppressive therapy in the perioperative period is an essential part of the management plan.[83]

Physiology of the Transplanted Heart

Donor heart connection to the native circulation is carried out in one of two ways. Biatrial anastomosis with suturing of the native atria to the donor atria was practiced originally, but it has given way to the bicaval technique. The anastomosis occurs at the cavae, the great vessels, and along a line of atrial tissue surrounding the pulmonary veins. The bicaval technique has been associated with less sinus node dysfunction, less tricuspid regurgitation, and lower atrial size after HT.[84] The sinus node is preserved, but it is probably nonfunctional due to denervation and disruption of the blood supply. The risk of atrial fibrillation is thought to be less with this approach.[85] With the biatrial technique, dual P waves may be seen on the ECG due to activation of native atrial tissue, and it can sometimes mimic atrial flutter.[86]

There is debate about the extent, duration, and impact of reinnervation after cardiac surgery. Without question, in the early postoperative period, the transplanted heart is without any innervation, responding only to humoral catecholamines. Sympathetic stimulation and chronotropic responses to exercise, stress, and hypovolemia are not seen. This includes blunting of baroreceptor responses and those to laryngoscopy and intubation.[87] Parasympathetic denervation dominates, and most recipients have a high resting heart rate (HR) with low variability. Afferent denervation impedes vasoregulatory response by means of renin-angiotensin axis activation; and the perception of pain on ischemia (angina) is lost.[88] Eventually, nerve sprouting occurs, with both parasympathetic and sympathetic reinnervation. However, this is unpredictable. Innervation occurs more in patients with previous ischemic heart disease than in patients who received transplants for dilated cardiomyopathy.[89]

The transplanted heart significantly depends on preload for augmentation of output in response to demand. This results in a mild rightward shift on the Frank-Starling curve during rest.[88] Circulating brain natriuretic peptide (BNP) levels are elevated even with normal hemodynamic parameters, suggesting atrial stretch and the need for elevated filling pressures.[90] Myocardial metabolism appears to remain normal. The filling pressures, which are significantly elevated immediately after HT, never fully return to normal, suggesting restrictive physiology. Donor-recipient size mismatch, increased afterload in the form of hypertension, and rejection can be contributory.[91]

The result often is an abrupt rise in LV filling pressure in response to fluid challenge, making these patients prone to pulmonary and systemic venous congestion.[92] During exercise, the initial increase in CO results from increased preload and stroke volume, whereas later during exercise, contractility and HR augmentation from circulating catecholamines take over. Peak exercise capacity remains lower than that of comparable controls.[91,93] Mild rejection does not affect function significantly, although systolic and diastolic parameters are adversely affected by significant rejection.[94]

Resting coronary blood flow increases due to an absence of sympathetic tone. Serotonin hypersensitivity, likely related to endothelial damage, causes decreased flow reserve in the transplanted heart.[95] Abnormalities of response to endothelium-derived vasodilators such as substance P and acetylcholine have been described, although the response to non–endothelium-derived vasodilators such as adenosine and dipyridamole is preserved.[96] Because coronary demand-supply mismatch does not result in ischemic pain or angina in HT patients, surveillance is required to identify coronary vasculopathy in the absence of symptoms.[88]

Complications After Transplantation

Rejection, infection, and cancer are common complications. Other conditions such as diabetes, hypertension, and cardiac vasculopathy occur and are related to immunosuppression. Preeclampsia is a risk in transplant recipients who become pregnant.[83]

Rejection

With the advent of improved techniques of immunosuppression, rejection rates have been dropping. Development of a cytotoxic crossmatch (using recipient antibodies) to stratify and reduce the risk of rejection has been helpful. The risk of allograft rejection remains highest within the first 3 to 6 months of transplantation and drops significantly after the first year.[97]

These episodes, which can be difficult to detect, are often related to poor medication compliance. Acute rejection is seen on histologic examination as an inflammatory response mounted by the host against the grafted organ. On a functional level, it results in gradual failure and dysfunction of the transplanted heart. Cell-mediated immunity has been recognized as the primary offender in rejection; although antibody-mediated rejection is increasingly recognized as playing an equally important role.

The onset of symptoms can be nonspecific, such as fatigue, unexplained weight gain, edema, and atrial fibrillation. Diagnosis of rejection requires an alert treating physician. Endomyocardial biopsy carried out by the internal jugular or femoral route remains the standard for the diagnosis of rejection. It is performed with decreasing frequency after transplantation (ie, weekly for the first month, two times in the next month, and monthly for the next 4 months) according to guidelines from the International Society of Heart and Lung Transplantation. The results can help differentiate between cellular and antibody-mediated rejection, although it has the disadvantage of being invasive and sometimes requiring general anesthesia. Patch inflammatory infiltrate may be missed on random biopsy sampling, and a histologic diagnosis often means that significant myocardial damage has already occurred.[97]

Echocardiography can detect rejection using tissue Doppler imaging and by the finding of diastolic dysfunction.[98] However, it is not specific and has limited utility in the early detection of rejection. Cardiac magnetic resonance imaging (MRI) using myocardial contrast enhancement has shown some promise as a noninvasive method for detecting rejection early.[99]

Serum markers such as troponin and BNP are not specific in the low to positive range and are not elevated until later in the disease. The only US Food and Drug Administration–approved, noninvasive test used in routine clinical practice uses identification of genetic markers

TABLE 45.4 Treatment of Cardiac Transplant Rejection

to create a genetic profile that suggests susceptibility to rejection. In one trial, it was shown to be comparable with endomyocardial biopsy in monitoring for rejection.[100]

Treatment of rejection depends on whether the patient is symptomatic and the nature of the rejection response (ie, whether it is primarily cellular or antibody mediated). A detailed description of the therapy is beyond the scope of this chapter, but the principles are summarized in Table 45.4.

Cardiac Allograft Vasculopathy

Cardiac allograft vasculopathy (CAV) is a unique form of atherosclerosis in patients who undergo HT with delayed graft failure. It is characterized by early intimal proliferation, followed by luminal stenosis in the epicardial branches in the later stages. More than one-half of the arteries in transplanted hearts demonstrate intimal thickening within 1 year of transplantation.[101] CAV and malignancy are the most important causes of death after this period.[102]

The lesions in CAV are diffuse and hyperplastic, affecting the entire coronary tree, and the proliferation tends to be concentric. This contrasts with native coronary atherosclerosis, in which the lesions are eccentric and distributed in a patchy manner. Calcification, which is common with native disease, is uncommon with CAV. Because angina is uncommon due to denervation at transplantation, CAV manifests in much more sinister forms as HF, arrhythmias, or sudden death. The usual cardiac risk factors such as obesity, hypertension, smoking, and diabetes influence the risk of CAV. CAV development is also closely related to the degree of human leukocyte antigen (HLA) incompatibility and the amount of rejection.[101] There is growing recognition that viral infections, particularly cytomegalovirus (CMV) infections, may have a causal role in the development of CAV.[103]

Because treatment of CAV is difficult, it must be recognized early. Intravascular ultrasound is the most sensitive tool to detect CAV, quantify intimal thickness, and provide prognostic information.[104] An increase of 0.5 mm or more in intimal thickness within the first year after transplantation is a powerful predictor of all-cause mortality, myocardial infarction, and angiographic abnormalities.[105] Management of CAV involves aggressive risk modification, optimization of blood pressure control and lipids, and the use of inhibitors of proliferation signaling such as sirolimus. The use of statins has also been associated with a reduction in the CAV burden.[106] Due to the diffuse and hyperplastic nature of the disease, percutaneous coronary intervention for stenosis is neither easy nor very successful.[101,107] Retransplantation remains the definitive treatment for this difficult condition, although it carries with it significant technical and ethical challenges.

Infection

Immunosuppression brings with it the risks of malignancy and infection. The risk of infection decreases with time since transplantation, likely reflecting alterations in immune suppression. In the immediate postoperative period, nosocomial or iatrogenic infections predominate. Between 1 and 6 months, opportunistic infections and activation of latent infection occur, and after 6 months, community-acquired infections are more common.[108]

Improved bacterial and viral prophylaxis has decreased infections with *Pneumocystis*, CMV, *Listeria*, *Nocardia*, and *Toxoplasma*. Prophylactic therapy usually includes sulfamethoxazole and trimethoprim for *Pneumocystis jirovecii*, ganciclovir for CMV, acyclovir for herpes simplex virus, pyrimethamine for toxoplasmosis, and nystatin for *Candida*.[108] These drugs should continue perioperatively, and clinicians should be aware of drug interaction issues that may occur with their use. Antifungal prophylaxis and treatments have improved, resulting in improved survival despite the emergence of resistant *Candida* and *Aspergillus* strains.[109]

Strict asepsis is essential in the perioperative care of HT patients, particularly for catheter placement, urinary catheterization, and other invasive procedures. Antibiotic prophylaxis should be individualized, with attention to the patient, the procedure, and the bacterial spectrum. Because fever and leukocytosis do not usually accompany infection in transplant recipients, vigilance is required to avoid progression to catastrophic sepsis (Box 45.6).[110]

BOX 45.6 LONG-TERM TRANSPLANTATION COMPLICATIONS

- Chronic diastolic dysfunction
- Mild to moderate heart failure
- Infection
- Immunosuppression effects

Immunosuppression

Since its inception in the 1960s, the long-term success of HT has largely resulted from development of efficacious immunosuppressive regimens.[111] Immunosuppression involves induction (ie, initiation of high-intensity therapy), maintenance, and reversal of rejection (if needed). Native and memory T lymphocytes are involved in the process of alloimmunity, especially lymphocytes sensitized to HLA antigens. sensitivity is thought to reflect previous infection with viral agents that show some cross-reactivity with the HLA antigen domains.

After activation and transformation in the lymphoid tissue around the graft, effector T cells emerge and orchestrate an inflammatory response.[82,112] This is carried out in conjunction with B lymphocytes, which mediate the humoral antibody response. It has a characteristic histopathologic appearance, with deposition of complement C4a. Antibody-mediated rejection is associated with more severe hemodynamic compromise and worse outcome; the primary site for damage is the capillary endothelium.[113] The process of rejection can take a few days to reach its peak, even after the patient has been discharged after the initial procedure.

The function of immunosuppressive drugs is to prevent or ameliorate rejection while minimally affecting normal physiology. Immunosuppressant medication has three main effects: therapy (ie, suppression of rejection), unwanted results of immunosuppression (ie, infection and cancer), and nonimmune cytotoxicity. Most drugs act by depleting lymphocytes, diverting the traffic of the ones that exist, or blocking response pathways for activated lymphocytes.[112]

The efficacy of induction therapy (ie, intensive beginning of immunosuppression) has been argued and debated; and it is currently recommended only for selected patients.[111] It is carried out using two types of drugs:

1. Drugs that deplete protein (eg, OKT3, antithymocyte globulin): They act by destroying T cells or B cells, or both. They cause cytokine release, producing severe systemic symptoms. Use is also

associated with an increased incidence of lymphoproliferative disorders.[114] Suppression of humoral immunity is better tolerated than suppression of cell-mediated immunity due to the absence of cytokine release.

2. Drugs that do not deplete protein (eg, monoclonal antibodies such as basiliximab, fusion proteins): They introduce immunosuppression without destruction of lymphocytes. These drugs have limited efficacy but much better side effect profiles.

Maintenance therapy targets graft-host adaptation while trying to minimize complications. The usual combination consists of a corticosteroid, a calcineurin inhibitor (ie, cyclosporine or tacrolimus), and an antiproliferative agent (eg, mycophenolate). Steroids are used for a limited period, with an effort to keep the duration between 1 and 5 years.[82] Tacrolimus is the preferred calcineurin inhibitor,[81] and it is used in cases with higher chances of rejection, hypertension, and hyperlipidemia; whereas cyclosporine is used more commonly for patients with diabetes mellitus. Sirolimus, an inhibitor of the mammalian rapamycin receptor, has shown promise reducing nephrotoxicity, CAV, and cardiac morbidity.[115,116]

Acute rejection, when it is cellular and associated with significant hemodynamic compromise, is treated with high-dose steroids or antithymocyte globulin. Severe humoral rejection that causes hemodynamic compromise is usually managed with high-dose corticosteroids and plasmapheresis followed by intravenous immunoglobulin or rituximab, a B-cell–depleting monoclonal anti-CD20 antibody.[82]

Interaction of Immunosuppressants With Anesthetics

It is not surprising that immunosuppressants affect the pharmacokinetics and pharmacodynamics of anesthetic drugs, and vice versa. It is surprising that there is very little information about these effects in humans; most data come from animal studies.[88]

At the simplest level, massive perioperative fluid resuscitation or cardiopulmonary bypass can result in drug level decreases from dilution.[117] Monitoring drug levels is essential because dose adjustment may be needed to maintain therapeutic levels. Many drugs, including commonly used immunosuppressants, antifungal agents, and lipid-lowering medications, are metabolized by the cytochrome P450 (CYP450) enzyme system and extruded from cells by the multidrug-resistance transporter protein 1, P-glycoprotein. Both systems show genetic polymorphism, which significantly influence drug metabolism.[118] Hypothermia during or after surgery can result in reduced clearance of and higher levels of drugs metabolized by the P450 system.[119] Tables 45.5 and 45.6 and Box 45.7 outline the drugs that affect immunosuppressant levels, immunosuppressants with an impact on perioperative management, and drugs that can cause renal dysfunction when administered with immunosuppressants, respectively.

Because tacrolimus and cyclosporine may reduce the seizure threshold, hyperventilation under anesthesia should be avoided.[120] Due to reduced gastric emptying, levels of cyclosporine and other oral medications may be subtherapeutic if oral administration occurred just before induction.[121] Cyclosporine also can prolong the effect of muscle relaxants.[88] Extrahepatic glucuronidation pathways appear to be similar for propofol and mycophenolate and may result in decreased elimination in cases of coadministration.[122] Drugs such as midazolam, verapamil, and erythromycin are inhibitors of the P-glycoprotein system and can enhance the effects and toxicity of the immunosuppressants that are substrates for it. Anaizi described the drug interactions that can occur with immunosuppressants.[123]

Perioperative Management

When patients with transplants undergo another operation, the transplantation team should be contacted about details of the procedure

BOX 45.7 DRUGS THAT IMPAIR RENAL DYSFUNCTION WHEN GIVEN WITH CYCLOSPORINE OR TACROLIMUS

- Amphotericin
- Cimetidine
- Ranitidine
- Melphalan
- Nonsteroidal antiinflammatory drugs
- Cotrimoxazole
- Vancomycin
- Tobramycin
- Gentamycin

and patient status. They can provide the latest diagnostic information and study results relevant to the anesthesia. The preoperative assessment evaluates graft function (eg, echocardiography), rejection status (eg, endomyocardial biopsy), CAV (eg, intravascular ultrasound, angiography), functional status, and end-organ involvement.[124]

Complications should be carefully sought and ruled out. It is important to communicate the patient's CMV status with the blood bank because CMV-seronegative recipients require products from CMV-negative donors. Perioperative consultation with a transplantation microbiologist can help to screen for infection and devise an individual antimicrobial prophylaxis plan according to the patient's infection profile, the proposed procedure, and the duration since transplantation. Health care providers must be sensitive to the fact that these patients can suffer from subtle mental and psychiatric ailments such as depression despite improved physical status and indices.[125]

The preoperative ECG may show dual P waves or pacing spikes from an implanted device. To obtain information about the patient's dependence on the device and recent arrhythmia episodes, all cardiovascular implantable electrical devices (CIEDs) should be interrogated before surgery. Depending on the type of electrical interference anticipated, pacing might be converted to an asynchronous mode and antitachycardia therapies disabled. If this is the case, continuous monitoring with easy access to external pacing or defibrillation is required, as is the need to reprogram the device at the end of the procedure.[126]

Preoperative echocardiography can provide valuable information about systolic and diastolic function and valvular competence. Diastolic dysfunction may signal rejection, whereas systolic dysfunction may be a sign of CAV.[127] Pertinent laboratory tests include hematology, chemistry, coagulation, and liver enzyme studies, which can assist in the detection of end-organ dysfunction due to hypoperfusion or immunosuppressant toxicity.

The transplantation service should be consulted about immunosuppressants; they usually should be continued perioperatively. However, steroid administration for patients previously receiving them is a controversial issue. It has been suggested that patients receiving immunosuppressive doses of steroids do not need additional doses of steroids for surgery, and hypotension under anesthesia is often related to hypovolemia rather than adrenal insufficiency.[128,129] Excessive steroid administration is associated with gastric erosions, hyperglycemia, and psychological disturbances. We do not routinely administer steroids to patients who are on steroid therapy if they have received their daily dose of steroids on the day of surgery. If hypotension refractory to fluids and pressor administration occurs, 25 mg of hydrocortisone may be administered. A lower threshold for steroid administration should be used when steroid therapy was recently discontinued, there is coexisting infection, or the operation is major and invasive.

Patients are aware of the increased risk they face as transplant recipients, and judicious premedication can help alleviate anxiety and improve their experience. Electrocardiographic monitoring is essential for these patients. Myocardial ischemia detection is critical, as is detection of changes in HR and atrioventricular nodal conduction caused by anesthetics and other drugs used perioperatively. Specialized monitoring should be based on the patient's condition, the procedure and its timing, blood loss, and anticipated fluid shifts.[88,120] The PAC can be useful if large fluid shifts are expected, especially if there is preexisting cardiac dysfunction. TEE is a useful, minimally invasive method to guide fluid therapy, monitor global cardiac function, and titrate vasoactive and cardioactive medications.[83] Strict aseptic precautions and infection prevention during placement of invasive monitors cannot be overemphasized for this particularly vulnerable population.[120] Catheters, drains, and airways should be removed as early in the postoperative period as is safe and feasible.

The choice of anesthesia technique requires individualization. There is no clear contraindication to any type; sedation, regional, and general techniques have all been successfully used.[130] The anesthesia goals include maintenance of preload, preservation of sinus rhythm, avoidance of sudden changes in afterload, and careful monitoring for intraoperative complications.

The use of a laryngeal mask airway is acceptable.[124] Oral intubation of the trachea is preferable to the nasal route to reduce infection risk. Gingival hyperplasia related to cyclosporine and alteration of airway anatomy due to lymphoproliferative disorders can occur in transplant recipients.[83] Laparoscopic procedures can be carried out safely if sudden fluctuation in preload and afterload (as can occur with insufflation and desufflation) are detected and managed expeditiously.[131] Regional anesthesia administration may be contraindicated by coagulopathy because thrombocytopenia can accompany immunosuppression. The more gradual, controlled establishment of a regional block with an epidural may be better than spinal anesthesia in patients with a compromised ability to compensate with a sympathetic chronotropic response.

Hemodynamic management principles should take into account the altered physiology of a transplanted heart. Drugs using the sympathetic nervous system are ineffective, and drugs with direct and indirect effects (eg, ephedrine) manifest only the direct effects. Table 45.7 summarizes the effects of some medications.

Normal responses should be expected from epinephrine, norepinephrine, glucagon, isoproterenol, and metaraminol. Levosimendan, a calcium sensitizer, improves cardiac function in the graft and can reduce inotrope requirements.[132] Neostigmine causes bradycardia and can cause cardiac arrest when used for reversing neuromuscular blockade, although the exact mechanism is unclear. Preadministration of glycopyrrolate and availability of direct chronotropic agents are essential when administering neostigmine to these patients.[133] Sugammadex is a good alternative to neostigmine because it appears to be devoid of significant cardiac effects.

Patients on immunosuppressants are at increased risk for renal injury, and the use of nephrotoxic drugs such as nonsteroidal antiinflammatory agents should be avoided. Caution also should be exercised when using β-blockers or vasodilators. In the absence of organ dysfunction, the choice of opiates or muscle relaxants is based on the operation and anticipated recovery. Patient positioning should take into account the easy bruisability and osteoporosis that accompany steroid therapy.

Postoperative care is similar to that for other patients. Adequate analgesia, normothermia, and hydration are essential. Thromboprophylaxis should be started when safe because the deep vein thrombosis risk is increased.[120]

With appreciation of their unique physiologic aspects, HT recipients can be safely managed during noncardiac surgery. Organ transplantation is often described as the exchange of one disease state for another, although with modern medicine, that exchange is fast becoming a more propitious one.

TABLE 45.7 Cardiovascular Effects of Drugs on Normal and Transplanted Hearts

		Heart Rate		Blood Pressure	
Drugs	*Type of Action*	*Normal*	*Transplanted*	*Normal*	*Transplanted*

Cardiovascular Implantable Electronic Device Management in Noncardiac Surgery

Unfortunately, avoidance and complete reliance on a magnet are no longer effective strategies for the management of CIEDs in patents undergoing noncardiac surgery. The increasing number of indications for implantation and an aging population have made it impossible to avoid these patients. Their care is made challenging by the many types of devices, programming modes, and magnet responses in use. CIED variation makes a thorough knowledge of every device impractical for the average anesthesiologist and precludes the development of a universally applicable perioperative management algorithm.

Expecting every anesthesiologist to become a CIED programmer or memorize the specifications of all CIEDs on the market is unrealistic, but anesthesiologists should have a basic understanding of CIEDs and the general perioperative management strategies available. The goal of this section is not to create a universally applicable perioperative management algorithm or present all CIED models in detail, but rather to supplement Chapter 5 by reviewing some basic concepts, potential adverse outcomes, and current recommendations for noncardiac surgery.

Pacemakers

Pacemaker configurations include devices with leads in a single chamber, two chambers, or multiple chambers (eg, biventricular pacing), which is denoted by the North American Society of Pacing and Electrophysiology/British Pacing and Electrophysiology (NASPE/BPEG) Group generic (NBG) code (Table 45.8). Pacing and sensing can occur in the atrium, the ventricle, or both chambers (Fig. 45.2), depending on the configuration and pacemaker programming. More complicated multichamber pacing and sensing schemes (eg, dual-chamber pacing) may pose clinical challenges for the anesthesiologist, but they also provide atrial-ventricular synchronicity and increase CO for the patient.[134] The indication for and patient reliance on the pacemaker should be ascertained before making perioperative management decisions.

Because the first position of the NBG code denotes the pacing chambers, the fifth position may seem redundant, but it is used to denote multiple leads in a single chamber. Examples of multisite pacing are multiple atrial leads to suppress atrial fibrillation and biventricular pacing for cardiac resynchronization therapy (CRT). Rate modulation is also denoted by the NBG code, but additional information such as magnet response, battery life, pacemaker dependence, and mode switching can be determined only by communicating with the device company or by device interrogation.

Rate Modulation

Rate modulation and *rate adaptation*, denoted by an R in the fourth column of the NBG code (see Table 45.8), are terms used to describe a pacemaker's ability to automatically change the rate in response to certain monitored parameters. Because an estimated 85% of pacemakers implanted in the United States are rate responsive and 99% have this capability, anesthesiologists should be familiar with rate modulation in case an experienced programmer is not available preoperatively.[135,136]

The parameters that can induce rate modulation include acceleration due to motion; patient movement; QT interval; central venous temperature, oxygen saturation, and pH; RV pressure, minute ventilation determined by thoracic impedance; and a combination of acceleration and minute ventilation.[137,138] When required, the pacemaker with rate modulation can alter HR and CO to meet metabolic demands through atrial, ventricular, or atrial and ventricular leads.[139]

In their 2011 ASA practice advisory, the ASA and Heart Rhythm Society (HRS) provided an equivocal recommendation that rate-adaptive therapy should be disabled preoperatively if advantageous.[140] Intraoperative rate changes, which result from elective continuation of rate modulation or a lack of CIED programming resources, are usually benign. However, an increase in HR may be hemodynamically significant, unfavorable for certain comorbidities (eg, coronary disease), or misinterpreted as patient discomfort.[141] Changes in rate due to active rate modulation can result from succinylcholine-induced muscle fasciculations, an oscillating saw, myoclonic jerks, postoperative shivering, electroconvulsive therapy, and QT alterations (eg, medications, pH, electrolytes). The most commonly encountered stimuli for rate changes in the operating room are electrocautery and mechanical hyperventilation.

If active rate modulation results in an intolerable or undesirable increase in HR, there are several treatment options. The eliciting stimulus (eg, hyperventilation, electrocautery) can be withdrawn, a magnet can place the pacemaker into an asynchronous mode, or a CIED programmer can disable rate modulation.[138]

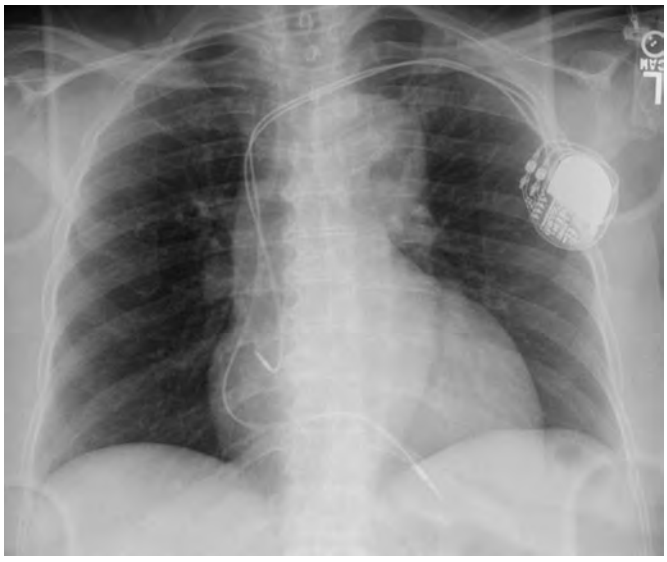

Fig. 45.2 Supine frontal chest radiograph shows an example of a dual-chamber pacemaker with leads in the right atrium and right ventricle. Notice the difference between the pacing leads shown in this example and the shock coils of an implantable cardioverter-defibrillator located in the right atrium and right ventricle in Fig. 45.4.

TABLE 45.8 2002 Revised NASPE/BPEG Generic Pacemaker Code

Pacing Chamber	*Sensing Chamber*	*Response*	*Rate Modulation*	*Multisite Pacing*

Automatic Mode Switching

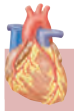
Automatic mode switching (AMS) enables identification of atrial tachyarrhythmias and automatic conversion of pacemaker settings to prevent pacemaker-mediated tachycardia (PMT). The new mode typically does not track the atrial activity, but rather paces the ventricle at a fixed, slower rate. *PMT* is a term used to describe any undesirable pacemaker generated tachycardia.[142] For example, atrial fibrillation can result in ventricular tachycardia in patients with a dual-chamber pacemaker. Without AMS, the ventricle can track the high atrial rate in atrial fibrillation and inappropriately pace to an undesirable rate. Although mode switching does not usually present significant challenges in the perioperative period, it can be used to a clinician's advantage by determining the past atrial arrhythmia burden.[143]

Electrocardiographic Diagnosis of Myocardial Ischemia in Ventricular Paced Rhythms

Ventricular pacing, specifically that originating from the RV apex, often elicits an ECG with a negative QRS followed by an elevated ST segment and positive T wave. This electrocardiographic pattern can be confused for myocardial ischemia, a diagnosis that may not be incorrect given the prevalence of coronary artery disease (CAD) in the patient population into which CIEDs are increasingly implanted. However, the classic criteria for electrocardiographic detection of myocardial ischemia may not apply to the ventricularly paced patient.

Although a pacemaker can be inhibited to analyze the underlying rhythm, this may not be feasible or even diagnostic. Comparison with a previous 12-lead ECG is an alternative approach, but an ECG is not always readily available. Sgarbossa and colleagues[144] proposed criteria for electrocardiographic detection of acute myocardial infarction in the setting of ventricular pacing (Box 45.8). Of the criteria studied, ST-segment elevation of 5 mm or more in leads without QRS concordance was the only criterion with high specificity and statistical significance.[144] An example of ST segment and QRS discordance is shown in Fig. 45.3. Although the suggested criteria are less applicable when depolarization is generated from locations other than the RV apex (eg, RV outflow tract, left ventricle), are based on a relatively small study, and their specificity questioned, they are nonetheless used to identify myocardial ischemia in the setting of a ventricularly paced rhythm. Normalization of the ST-segment elevation for the corresponding QRS amplitude and QRS prolongation have been proposed as additional electrocardiographic markers of myocardial ischemia.[145,146]

Electrocardiographic detection of myocardial ischemia in this patient population can be extremely challenging, but the ASA/HRS guidelines in addition to the clinical context can aid in identifying individuals who require further testing (eg, cardiac enzymes, echocardiography, angiography).[147] When clinical suspicion is high, additional means of diagnosing myocardial ischemia or damage such as echocardiography or serum troponin levels should be pursued.



BOX 45.8 SGARBOSSA CRITERIA FOR MYOCARDIAL ISCHEMIA IN PATIENTS WITH VENTRICULAR PACING

- ST-segment elevation ≥1 mm in a lead with QRS concordance
- ST-segment depression ≥1 mm in leads V_1 through V_3
- ST-segment elevation ≥5 mm in a lead with negative QRS concordance

Data from Sgarbossa EB, Pinski SL, Gates KB, et al. Early electrocardiographic diagnosis of acute myocardial infarction in the presence of ventricular paced rhythm. *Am J Cardiol*. 1996;77:423–424.

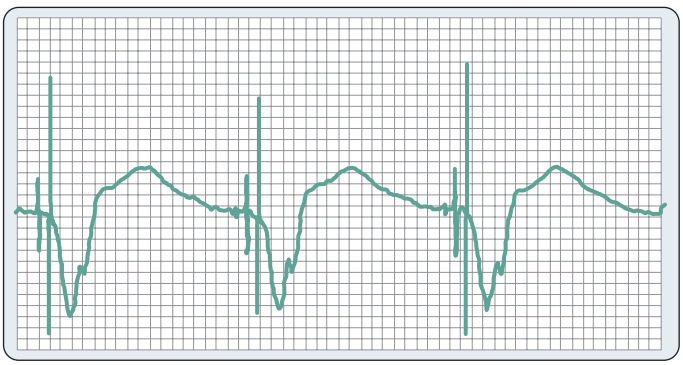


Fig. 45.3 Tracing from lead V– of the electrocardiogram shows a QRS *(negative deflection)* and ST segment *(positive deflection)* discordance in a dual-chamber pacemaker–dependent patient.

Automatic Implantable Cardioverter-Defibrillators

An automatic implantable cardioverter-defibrillator (AICD) is a CIED that can detect and treat arrhythmias with a defibrillatory shock through leads in the right ventricle and occasionally in the right atrium. The addition of a right atrial lead, which is denoted by the NASPE/BPEG Group generic defibrillator (NBD) code (Table 45.9), can be advantageous in differentiating supraventricular tachycardia from ventricular tachyarrhythmias (Fig. 45.4).[159] Treatment of identified ventricular tachyarrhythmias entails overdrive pacing or defibrillation, depending on the diagnosis of ventricular tachycardia or fibrillation. In addition

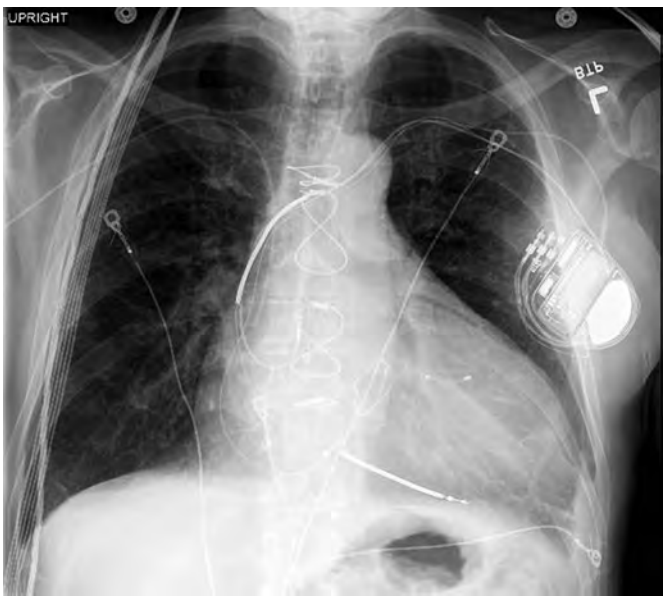

Fig. 45.4 Upright frontal chest radiograph shows a cardiac implantable electrical device with atrial and ventricular implantable cardioverter-defibrillator leads and multisite pacing for biventricular pacing (ie, cardiosynchronous therapy).

to tachyarrhythmia therapies, all AICDs are equipped with pacing capabilities. Although this feature is advantageous when defibrillation results in bradycardia or asystole, it also mandates perioperative programming in pacemaker-dependent patients.

The application of a magnet to an AICD is expected to disable tachyarrhythmia therapies. However, the typical magnet response may be disabled or ineffective.[148] Application of a magnet may not be a benign, immediately reversible process because there are reports of magnet application permanently deactivating tachyarrhythmia therapy.[149] Additional intraoperative concerns include the unrecognized displacement of the magnet and its lack of effect on the pacing function of the device. Although appropriate magnet application typically disables tachyarrhythmia therapies, it cannot change the pacing function to an asynchronous mode in an AICD. Pacemaker-dependent patients with an AICD and an increased risk of perioperative EMI require reprogramming.

Electromagnetic Interference

Although the myriad CIED options present a challenge for anesthesiologists, technologic advancements have also made the devices more resistant to EMI. Newer CIEDs use noise-protection algorithms, filters (ie, bandpass), and circuit shields to help minimize EMI. An additional explanation for the reduction in EMI is the trend to implant pacemakers with bipolar rather than unipolar leads. Bipolar leads are more resistant to EMI because the anode and cathode are contained within the lead itself. In contrast, unipolar leads are more susceptible to EMI because the distance between the anode (ie, pulse generator) and cathode (ie, tip of the lead) is much greater.[139]

Despite these improvements, EMI can still occur, and the crux of any perioperative management plan is determining the likelihood of encountering interference (Fig. 45.5). EMI can result from any device that emits radiofrequency (RF) waves between 0 and 10^9 Hertz. The

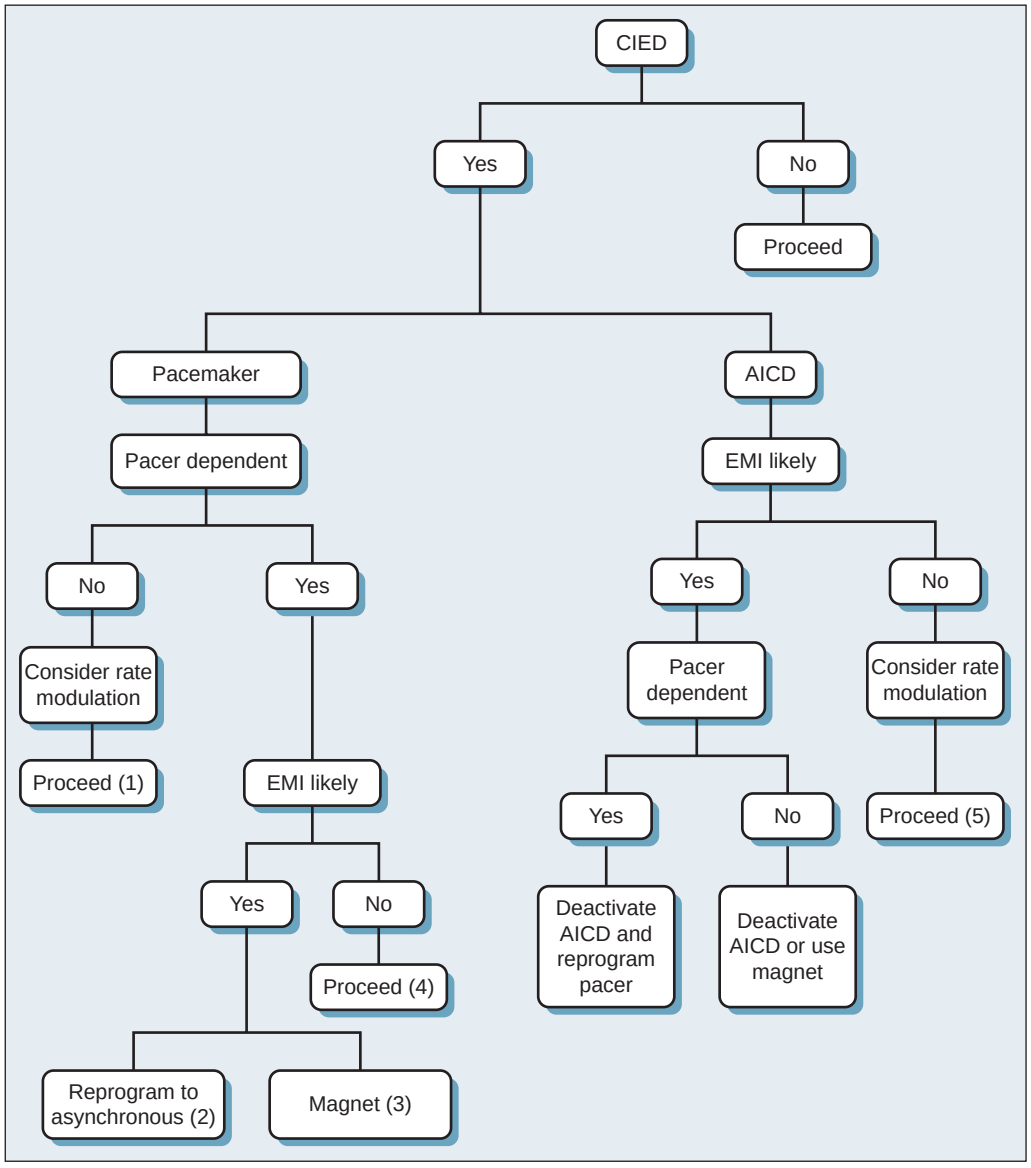

Fig. 45.5 Perioperative implantable cardiovascular electronic device *(CIED)* management. Additional considerations: *(1)* have a magnet available; *(2)* be aware of potential R-on-T phenomenon if applicable; *(3)* consider the magnet mode settings, patient comorbidities, and potential R-on-T phenomenon; *(4)* complete preoperative CIED assessment and have a magnet available; and *(5)* consider rate modulation and have a magnet available. *AICD*, Automatic implantable cardioverter-defibrillator; *EMI*, electromagnetic interference.

extensive list of potential EMI sources includes electrocautery, external defibrillation, electroconvulsive therapy, and RF waves used in ablation procedures.[137]

Although a potential source of EMI may exist, EMI may still be unlikely. For example, the potential for interaction is considered to be markedly reduced if the distance from the electrocautery current to the CIED generator and leads is greater than 6 inches.[150] One protocol further defines a *critical zone* of increased risk of EMI to include the area from the mandible to the xiphoid.[151] For operative procedures below the umbilicus, electrocautery is not thought to interfere with a generator and leads that are located in upper chest.[152]

Techniques other than absolute distance can reduce the possibility or effect of EMI, such as the use of bipolar rather than monopolar electrocautery, short bursts of electrocautery (<5 seconds), lower electrocautery power settings, and proper positioning of the electrocautery return pad to minimize return current interaction with the CIED.[140]

Potential Adverse Outcomes

Aside from preoperative preparation (eg, knowledge regarding the model type, dependency, magnet mode, EMI potential) and a careful perioperative management plan, a thorough understanding of the potential complications or adverse outcomes is paramount to the successful perioperative management of a patient with a CIED. Early recognition and action by the anesthesiologist can be facilitated by reviewing the published experience of others and known EMI interactions.

The list of potential complications with CIEDs is extensive. EMI from monopolar electrocautery or RF ablation can result in oversensing and inhibition of pacemakers, inappropriate tachyarrhythmia therapy from AICDs, device reset, pulse generator damage, lead damage, lead displacement, inappropriate rate-adaptive HR changes, inappropriate mode switching, impedance changes, and tissue damage by conduction through device leads.[152–154] One study identified a trend toward alterations in threshold and sensing in devices that required reprogramming postoperatively. One proposed explanation is changes in lead tissue interaction from intraoperative EMI.[151] However, other studies offer contrary evidence and suggest that these interactions are uncommon.[152,155]

External cardioversion or defibrillation can also result in tissue damage by conduction through leads and device reset.[154] Tachyarrhythmia therapies should be reenabled by removing a magnet or reprogramming to allow device-delivered therapy. If this is not feasible or effective, emergency guidelines must be followed. In an effort to minimize current through the device or leads, the pads should be placed as far away from the generator as possible and perpendicular to the axis of the CIED (eg, anterior to posterior).[140]

Although therapeutic irradiation in patients with CIEDs is not contraindicated, ionizing radiation can result in damage to the pulse generator or lead insulation. Evidence suggests that modern AICDs may be more susceptible to radiation damage than pacemakers. The damage incurred can result in electrical resets or AICDs unable to deliver a high voltage shock.[156,157] It is recommended that the device be shielded or relocated and interrogation be completed during and at the completion of radiation treatment.[140]

Current Recommendations

It is challenging to develop a perioperative CIED management algorithm that is universally applicable. Current recommendations from the ASA and HRS focus on an individualized, multidisciplinary approach with less reliance on direction from industry-employed allied health professionals and increased involvement of the primary CIED management team.[137,140,154] Although these recommendations excel at optimizing patient safety, strict adherence to them may not always be feasible because of the clinical situation or limited resources.

Alternative protocols for device management such as the pacing and cardioverting electronic device perioperative (PACED-OP) protocol (Table 45.10) advocate for more selective criteria for CIED reprogramming in an effort to operate within the confines of restricted resources and avoid reprogramming errors.[151] In response to high rates of reprogramming and interrogation, which require resources and personnel and create the potential for programming errors before and after surgery, the PACED-OP protocol provides a simplified perioperative management algorithm. The PACEP-OP protocol requires device reprogramming only when EMI was expected within a *critical zone* (ie, area between the mandible and the xiphoid) and the patient is pacemaker dependent or has an AICD. *Pacemaker dependency* was also simplified to encompass individuals who have a preoperative ECG displaying a paced rhythm.

TABLE 45.10 PACED-OP Protocol Summary for Perioperative Management of Automatic Implantable Cardioverter-Defibrillators

Clinical Situation	*Management*
Pacemaker-dependent patient or AICD + EMI in critical zone	Reprogram preoperatively and interrogate postoperatively
AICD + EMI outside the critical zone	Apply magnet (exception: devices with a reed switch)
Pacemaker-dependent patient + EMI outside the critical zone + bradycardia postoperatively	Interrogate postoperatively

AICD, Automatic implantable cardioverter-defibrillator; *EMI*, electromagnetic interference; *PACED-OP protocol*, pacing and cardioverting electronic device perioperative protocol.

AICDs are managed with a magnet if EMI is anticipated outside of the critical zone. Exceptions are AICDs that contain a reed switch, which are reprogrammed. Postoperatively, additional CIED interrogation is recommended only if an ECG-identified bradycardia occurred in a pacemaker-dependent patient who had electrocautery outside the critical zone. Implementation of the PACED-OP protocol resulted in a further decline in the rates of interrogation and reprogramming of CIEDs and produced no statistical difference in the rate of complications in the investigators' institution.[151]

Despite the fact that many organizations have released recommendations that call for increased involvement of the primary CIED management team and perioperative interrogation and reprogramming, anecdotes suggest these devices are frequently managed by magnet application or EMI avoidance. A few considerations regarding magnet application merit attention. Placing a pacemaker in an asynchronous mode may not be benign. The use of a magnet or programming to an asynchronous mode in a pacemaker with a ventricular lead can result in an R-on-T phenomenon and significant arrhythmia. The use of a magnet may result in atrial-ventricular dyssynchrony or a set rate that is disadvantageous in the setting of certain comorbidities (eg, CAD). There are also reports of magnet application permanently deactivating AICD tachyarrhythmia therapy. The perioperative use of a magnet should not be taken lightly or without careful consideration.

It is assumed that an overextension of the available programming resources and personnel and perioperative time constraints are reasons for the difference between the recommendations and clinical practice. In a movement similar to the evolution of intraoperative TEE, groups of specially trained anesthesiologists have taken on the responsibility of perioperative CIED management. In an effort to decrease perioperative programming delays, anesthesiologists at institutions such as the University of Washington interrogate devices preoperatively, reprogram if necessary, and restore the settings postoperatively.[158] Although the anesthesiologists' role in perioperative CIED interrogation is evolving, it is not unreasonable to expect anesthesiologists to play an increasing role in the future.[159]

Although not applicable to every situation, a general approach to perioperative CIED management is shown in Fig. 45.5. Perioperative management largely relies on determining the patient's CIED dependence and EMI potential. Based on the risk assessment, CIED management may require a magnet to be available, the use of a magnet, or interrogation and reprogramming.

46 Echocardiography in Noncardiac Surgery

BYRON FERGERSON, MD | JOSHUA ZIMMERMAN, MD, FASE

KEY POINTS

1. The portability, ease of use, and rapid diagnostic capability of transesophageal echocardiography (TEE) makes it the diagnostic modality of choice during acute hemodynamic instability.
2. Qualitative analysis of a condensed TEE examination aids in efficiency during the rapid diagnostic demands required in the emergency setting.
3. Rescue echocardiography is a process, not an event, and thus requires continuous reevaluation when treating hemodynamic instability.
4. Acute valvular insufficiency is evaluated in the same manner as chronic insufficiency with a focus on new-onset regurgitation or a large change in chronic regurgitation.
5. An intimal flap visualized on TEE is the best method of determining the presence of aortic dissection.
6. TEE findings in cardiac tamponade include hypoechoic fluid around the heart, systolic collapse of the right atrium, and exaggerated respiratory variation in right and left ventricular (LV) inflow and outflow.
7. The complex geometry of the right ventricle makes quantitative assessment of function difficult. Qualitative evaluation of right ventricular free wall thickening, tricuspid annular excursion, and interventricular septal shape aid in diagnosis of dysfunction.
8. Although echocardiography is not the tool of choice for diagnosing pulmonary embolism, it can help to guide management. The primary echocardiographic manifestations of pulmonary embolism are secondary to right heart failure.
9. LV dysfunction has multiple possible causes beyond ischemia. Qualitative assessment of function primarily through the LV short-axis view is a well-validated method of diagnosing dysfunction.
10. A hypercontractile left ventricle can lead to a dynamic outflow obstruction that is diagnosed by a "dagger"-shaped LV outflow pattern on Doppler imaging.
11. Alterations in the end-diastolic and end-systolic areas of the LV short-axis help determine whether hemodynamic instability is caused by hypovolemia or low afterload.
12. Pulsed-wave Doppler interrogation of the LV outflow tract can yield a stroke distance from which the stroke volume can be calculated.
13. The ability to assess multiple cardiac parameters, including contractility, valvular function, and loading conditions, makes TEE a valuable tool in general hemodynamic monitoring and goal-directed therapy.
14. In conjunction with echocardiographic assessments of stroke volume and contractility, Doppler-derived estimates of left atrial pressure can be used to evaluate the effectiveness of an intervention.
15. Transthoracic echocardiography can be very useful in the perioperative management of patients undergoing noncardiac surgical procedures. It can be substituted for TEE in many situations.

This chapter focuses on the applications of echocardiography to noncardiac surgical procedures. Echocardiography performed in the emergency setting, also known as rescue echocardiography, is discussed in detail. In addition, the utility of echocardiography as a hemodynamic monitor in general and the use of echocardiography in goal-directed fluid therapy are reviewed. Finally, the perioperative applications of transthoracic echocardiography (TTE) and instructions for performing a basic TTE examination are discussed.

Rescue Echocardiography

Echocardiography in general and transesophageal echocardiography (TEE) in particular are well suited for the rapid diagnostic demands of acute hemodynamic instability. The American Society of Echocardiography (ASE) recommends the use of TEE for acute, persistent, unexplained hypotension.[1] Unexplained hypotension has multiple possible causes that potentially require a wide range of diagnostic modalities. Echocardiography encapsulates these modalities through its ability to reveal disturbances in contractility, valvular function, volume, and intracardiac and extracardiac pressures (see Chapters 14–16). Echocardiography not only provides a detailed, quantitative analysis but also allows for qualitative monitoring through rapid visual assessment. The ease and speed with which echocardiography can reveal diagnoses make it an ideal diagnostic modality in the emergency setting and one that is easily teachable.[2]

Prospective data on the use of echocardiography in the emergency perioperative setting are sparse. Shillcutt and colleagues[3] looked retrospectively at 31 patients undergoing various types of noncardiac procedures who were evaluated by echocardiography (using both TEE and TTE modalities) during hemodynamic instability in the perioperative period. A diagnosis by echocardiography explained the hemodynamic instability in all patients. Of the 60% of patients who had a

preoperative TTE examination, two-thirds had a new cardiovascular (CV) abnormality to help explain the hemodynamic instability, thus highlighting the importance of reevaluation as hemodynamic values change. In addition, more than one-half of the patients had a change in their CV support regimen, and 13% underwent additional surgical procedures based on the echocardiographic findings. Markin and associates[4] retrospectively looked at 364 perioperative rescue echocardiograms also using both TEE and TTE modalities. In this study, evaluation of hemodynamic instability was performed throughout the perioperative period. A change in management occurred in 59% of the patients studied, including a change in surgical management in 7% (see Chapter 15).

Inherent in the assessment of hemodynamic instability is urgency. The cause of the instability must be rapidly diagnosed and managed. To aid in efficiency, rescue echocardiography is best performed through a qualitative analysis of a condensed examination. The value of focusing on visual estimation of hemodynamic parameters instead of a detailed quantitative analysis is recognized by the ASE and the Society of Cardiovascular Anesthesiologists (SCA), which created training pathways for basic TEE certification.[5] The echocardiography literature is replete with examples of practitioners with limited training who accurately perform and evaluate echocardiographic examinations by using primarily qualitative analyses.[6–9,9] The comprehensive TEE examination is effective but time consuming (see Chapter 14). A condensed examination focusing only on the essential views significantly improves efficiency. The limited examination (Box 46.1) is a modification of the 11 cross-sectional views recommended by the ASE and SCA for the basic TEE examination and covers most clinically relevant disorders. Cardiac disturbances found on the limited examination can be further analyzed by using appropriate additional views. In agreement with the ASE and SCA,[5] we suggest performing and storing the examination in its entirety before focusing on segments specific to the area of interest. Similar protocols have been studied and used effectively.[4,10,11]

Rescue echocardiography is a process, not an event. The CV system is complex and dynamic, changing frequently based on loading conditions. What may be considered an appropriate intervention one minute may not be the next. In the report by Markin and colleagues,[4] 14% of the patients reviewed had no findings to explain their hemodynamic instability. It is often difficult to discern the precise cause of the CV abnormality, particularly with regard to low afterload, hypovolemia, and right ventricular (RV) and left ventricular (LV) dysfunction. In addition, multiple abnormalities are often present. Markin and associates[4] suggested a "best guess" of the abnormality, followed by reevaluation after the proposed intervention. If parameters improve, the intervention should be continued. If they do not improve or worsen, an alternate diagnosis should be sought.

The most common causes of hemodynamic instability are acute valvular and aortic disease, cardiac tamponade, RV dysfunction, pulmonary embolism (PE), and LV hypocontractility and hypercontractility.

TABLE 46.1 Causes of Acute Valvular Dysfunction

AV Insufficiency	*MV Insufficiency*
Endocarditis	Endocarditis
Aortic dissection	Chordal rupture
Chest trauma	Papillary muscle rupture
Iatrogenic causes	Ischemic cardiomyopathy Iatrogenic causes

AV, Aortic valve; *MV,* mitral valve.

Acute Valvular Dysfunction

Although it must be considered in the differential diagnosis, acute valvular insufficiency is an unlikely cause of hemodynamic instability. If it occurs, it is more likely to occur on left-sided valvular structures.[11] Potential causes of acute aortic valve (AV) and mitral valve (MV) insufficiencies are listed in Table 46.1. The echocardiographic evaluation of valvular dysfunction is similar regardless of the acuity of the dysfunction. Assessment of valvular regurgitation with rescue echocardiography should be limited to a rapid, qualitative assessment. Quantitative measures such as effective regurgitant orifice area and regurgitant volume may be inaccurate in acute regurgitation.[12] Visual assessment of the regurgitant jet with color-flow Doppler (CFD) focusing primarily on the vena contracta is the preferred approach. It is unlikely that any regurgitation that is less than moderate to severe would cause significant hemodynamic instability. Because chronic regurgitation leads to myocardial remodeling, moderate-to-severe regurgitation in the setting of a normal ventricular size should alert the clinician to the high probability of new-onset dysfunction. Noting new-onset regurgitation or a large change in chronic regurgitation is more important than grading the severity of the regurgitation. Acute or subacute regurgitation in the setting of hemodynamic instability may be either the cause or a manifestation of changes in ventricular function and loading induced by another cardiac abnormality. Treatment of the underlying abnormality may improve the regurgitation.

Acute Aortic Disease

The echocardiographic assessment of aortic dissection and traumatic aortic rupture is discussed in Chapter 23 and is mentioned only briefly here. The mortality rate is high in acute dissection of the thoracic aortic and increases with a delay in diagnosis.[13] Helical computed tomography, magnetic resonance imaging, and TEE are equally reliable for diagnosing or ruling out a dissection,[14] but TEE has the advantage of portability. The diagnosis of dissection is based on the detection of an intimal flap that divides the aorta into true and false lumina[15] (Video 46.1). Color-flow interrogation of the aorta helps to discern the true lumen from the false lumen. TEE is also valuable in assessing for intimal tears, intramural hematomas,[16] and penetrating ulcers.[17] Equally important as identifying dissection is identification of associated complications such as acute aortic regurgitation and pericardial effusions with or without tamponade.

Cardiac Tamponade

Proper identification of pericardial tamponade is vital because the hemodynamic consequences can be devastating and the treatment is specific: maintain contractility and preload, and drain the pericardial fluid. The pericardium consists of two layers: visceral and parietal. The visceral layer adheres to the epicardium, and the parietal layer is the

fibrous sac surrounding it. Five to 10 mL of fluid is normally found between the layers. Potential causes of pathologic fluid accumulation are listed in Box 46.2. The pericardium is of limited size and distensibility, thereby restraining the four chambers and dampening the effects of changes in intrathoracic pressure. Acute effusions are most likely secondary to trauma (including surgical) or myocardial infarction. Pericardial tissue affected by chronic effusion tends to be more distensible and thus causes less hemodynamic instability. The effusion can envelop the space in a free-flowing fashion or may be loculated, affecting only a portion of the heart. Free-flowing effusions tend to accumulate in the dependent portion of the space. Pericardial fat is a relatively common finding in the anterior space and should not be confused with fluid accumulation (see Chapter 24).

Pressures within the pericardium and cardiac chambers during fluid accumulation follow a recognized pattern.[18] Initially, fluid accumulation in the pericardial space compresses the right ventricle and causes the filling pressures to rise with little effect on the stroke volume (SV) of either ventricle. As the pericardial pressures rise, the right ventricle begins to collapse, but the thicker-walled left ventricle is unaffected. In the final stage, both the RV and LV SVs are significantly affected as the pericardial pressure determines passive flow. The external pressure on the cardiac chambers also exaggerates the normal respiratory variation in RV and LV SVs.. In mechanically ventilated patients, elevated intrathoracic pressure compresses the superior vena cava (SVC) and inferior vena cava and thus reduces RV preload and SV. At the same time, LV preload and SV are enhanced by increasing return from the inflated lungs. Intrathoracic and pericardial pressures decrease on expiration, augment flow into the right ventricle, and push the interventricular septum into the left ventricle. Diastolic filling and LV SV are thus reduced. In the physiologically normal patient, these hemodynamic swings are minimal. Box 46.3 lists the values for normal respiratory variation in the right and left ventricles, and Table 46.2 summarizes the changes in SV associated with cardiac tamponade.

The limited TEE examination should be performed in its entirety because some hemodynamically significant effusions may be difficult to visualize. Pericardial effusions are viewed as darkened areas between the heart and the parietal pericardium. No universally accepted rule exists for quantification, but effusions measuring less than 1 cm are considered small, effusions of 1 to 2 cm are considered moderate, and those larger than 2 cm are considered large. Echogenic "standing" in the pericardial space alerts the examiner to the possibility that the effusion is inflammatory or hemorrhagic. In the case of extreme hemodynamic instability, a large pericardial effusion should be considered to cause cardiac tamponade regardless of the results of the continuing study.

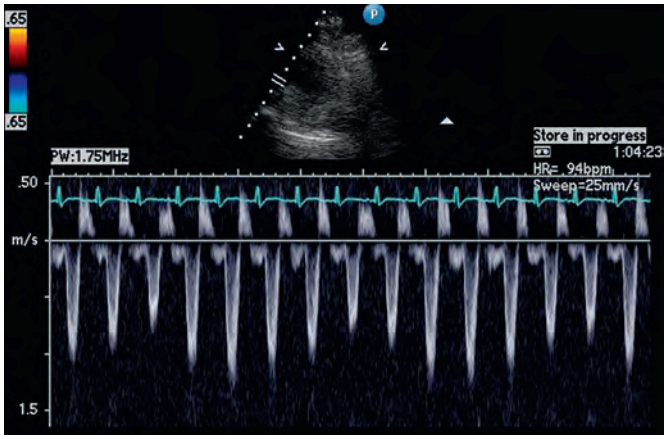

Fig. 46.1 Pulsed-wave echocardiographic interrogation of the left ventricular outflow tract by using the deep transgastric view in a patient with tamponade physiology showing respiratory variability. *HR,* Heart rate.

Pulsed-wave Doppler (PWD) interrogation of RV inflow or outflow may reveal exaggerated respiratory variations. These changes are the earliest signs of tamponade physiology and are followed by exaggerated variations in LV inflow and outflow. Because of the position and variable anatomy of the right ventricle, Doppler assessment of RV inflow and outflow can prove difficult, particularly within the time constraints of rescue echocardiography. LV inflow is best assessed in the midesophageal (ME) four-chamber view with the PWD cursor placed at the MV leaflet tips (Table 46.3). LV outflow is best assessed by placing the PWD cursor in the LV outflow tract (LVOT) seen in the deep transgastric (TG) view (Fig. 46.1). The sweep speed should be 25 to 50 mm/second to view the variability most clearly. With increasing fluid accumulation the pericardial pressure starts to exceed the right atrial (RA) pressure, thereby causing exaggerated atrial systolic (ie, ventricular diastolic) contraction that extends into atrial diastole (ie, ventricular systole). Assessment of this collapse is best performed in the ME RV inflow-outflow view or the ME four-chamber view (Videos 46.2 and 46.3). As the pericardial pressure increases further, the right ventricle begins to collapse in diastole. The RV outflow tract is most likely to collapse, and thus the preferred view is the RV inflow-outflow view (Box 46.4). A similar collapse of the thicker left-sided structures would indicate very high pericardial pressures. Once the diagnosis is

established, echocardiography can be a useful adjunct to guide needle placement during pericardiocentesis.[19]

Right Ventricular Dysfunction

RV failure, defined as the inability of the right ventricle to provide adequate blood flow to the left ventricle in the setting of normal central venous pressure, is associated with a high mortality rate in both cardiac and noncardiac surgical procedures.[20] Potential causes of RV failure are numerous and include the following: RV contractile dysfunction as seen in ischemia, volume overload, sepsis, and nonischemic cardiomyopathy; and the acute elevations in pulmonary artery pressures seen in hypoxia, acute respiratory distress syndrome,, LV dysfunction, and PE.[21] Abrupt, catastrophic RV dysfunction can result once the contractile reserve is reduced secondary to a feedback loop involving RV dysfunction, reduced cardiac output (CO), and decreased coronary perfusion causing worsening RV dysfunction (see Chapter 26).

Because the anatomy and function of the right ventricle are complex, geometric modeling and quantitative analysis are very difficult.[22] For this reason, the echocardiographic assessment of RV function in the emergency setting should be qualitative, and this approach is as good as magnetic resonance imaging at detecting dysfunction.[23] Box 46.5 summarizes the echocardiographic manifestations of RV dysfunction.[24] Visual assessment begins with inspection of right-sided chamber sizes to look for dilation of the right ventricle and right atrium. Encroachment into the left side with right-to-left bowing of the intraatrial septum (seen best in the four-chamber and bicaval views) and a "D-shaped" intraventricular septum (seen best in the LV short-axis [SAX] view) indicates elevated right-sided pressures (Videos 46.4 and 46.5). RV contractility can then be assessed by the fractional

area change (FAC) and/or the tricuspid annular-plane systolic excursion (TAPSE). The RV FAC is calculated by measuring the RV end-systolic and end-diastolic areas (RVESA and RVEDA, respectively) in the four-chamber view and using the following equation: [RVEDA—RVESA] / RVEDA. A reduced FAC has significant prognostic value in myocardial ischemia and PE.[24] TAPSE is best measured by placing the M-mode cursor on the tricuspid annulus in the modified bicaval or TG RV inflow-outflow views and measuring the distance the annulus moves from systole to diastole (Video 46.6 and Fig. 46.2). A distance of less than 1.5 cm is considered abnormal.[25] For purposes of rescue echocardiography, a qualitative assessment of the TAPSE and the RV free wall in the ME RV inflow-outflow and four-chamber views is preferred.

Pulmonary Embolism

The immobility and hypercoagulability associated with surgical procedures increase the risk of PE fivefold. This risk is only partially mitigated by prophylactic measures.[26] Early diagnosis and treatment can reduce the overall mortality 10-fold.[27] The examiner should have a high suspicion for PE in hemodynamically unstable patients with malignant disease, prolonged immobilization, obesity, and/or tobacco use, as well as in patients who use oral contraceptives, hormone replacement therapy, or antipsychotic drugs. The surgical procedures with the highest risks of PE are those associated with hip fractures, acute spinal cord injuries, and general trauma. The pathophysiology of PE begins with an abrupt increase in pulmonary artery pressures. Hypoxia and vasoconstriction worsen pulmonary vascular resistance. RV wall tension and oxygen demand increase, leading to subendocardial ischemia, RV dilation, and regional wall motion abnormalities (RWMAs). The intraventricular septum shifts left, and this shift reduces LV diastolic filling and SV. Overall, the cardiac pathophysiology of PE is complex, involving the interplay of wall tension, ischemia, structural damage, and inflammation[28] (see Chapters 26 and 51).

Although TEE can help guide both diagnosis and management, it is not the gold standard. Echocardiography has high specificity and low sensitivity (90% and 56%, respectively).[29] In fact, end-tidal carbon dioxide is a significantly better diagnostic tool.[30] Although visualization of a clot, which can be found anywhere on the right side from the venae cavae to the pulmonary artery, is pathognomonic of PE and can be seen in more than 80% of cases, the presence of a thrombus does not predict death[30] (Video 46.7). The ideal views to assess for thrombus include the ME bicaval, RV inflow-outflow, and ascending

aorta SAX views. The main and right pulmonary arteries can be seen by withdrawal of the probe to the high esophagus until a cross-section of the ascending aorta is obtained. The left pulmonary artery is often obscured by the trachea. The most clinically useful echocardiographic findings in the setting of PE are those associated with acute RA and RV failure. Bowing of the intraatrial septum to the left indicates high RA pressures, which can be particularly problematic in the setting of a patent foramen ovale. A patent foramen ovale in a patient with PE doubles the mortality rate and quintuples the rate of ischemic stroke, and aggressive thrombolytic treatment is therefore warranted.[31] RV wall motion abnormalities are the most common echocardiographic findings in patients with PE.[30] The extent of RV dysfunction correlates with the overall clot burden, with perfusion defects larger than 20% to 25% more likely to cause dysfunction and dilation.[32,33] A reduced TAPSE correlates with mortality rates,[34] and it can predict the extent of the clot burden as well as residual perfusion defects when the RV dilation has resolved.[35]

RV dysfunction in the setting of PE predicts mortality rates,[36] even in normotensive patients.[37] McConnell and colleagues[38] suggested that RV dysfunction in the setting of PE had a distinct pattern of RWMAs consisting of a hypokinetic free wall and a normal to hyperdynamic apex (Video 46.8), with a sensitivity of 77% and a specificity of 94% in predicting PE. Subsequent studies, however, found reduced sensitivity and specificity,[39] and they even suggested a "reverse" McConnell sign as an indication of PE.[40] RV pressure overload also "flattens" the interventricular septum, thus reducing left-sided filling and CO. The subsequent reduction of coronary perfusion as well as the structural and inflammatory changes in the myocardium can lead to LV dysfunction. A low ejection fraction (EF) is an independent predictor of death.[34] In addition to the diagnosis of PE, echocardiography can aid in assessing the effectiveness of treatment. If a thrombus is visualized at presentation, continuous assessment of the thrombus during thrombolytic administration can show resolution of the clot and return of normal RV function.[41] Echocardiography can also be useful in following the return of RV function over longer periods of time.[35]

Left Ventricular Hypocontractility

Although LV dysfunction has many potential causes, the echocardiographic manifestations are similar. The SCA recommended a qualitative estimation of the LVEF when assessing candidates who may benefit from inotropic therapy.[5] Visual estimation, or "eyeballing," has been validated with Simpson's biplane method,[42] three-dimensional echocardiography,[43] and radionuclide angiography[4–46] In addition, visual estimation of LV function can be accurately performed by noncardiologists[47,48] and clinicians with only limited training.[9,49] The primary method of visual estimation of LV contractility is through the FAC as seen in the LV SAX view. The LV FAC is calculated by measuring the LV end-systolic and end-diastolic areas (LVESA and LVEDA, respectively) in the LV SAX view and using the following equation: [LVEDA – LVESA] / LVEDA (Videos 46.9 and 46.10). The normal values are similar to the normal values for EF.[50] Initially, the calculation should be performed to assess contractile function. However, with more experience (≈≥20 studies[51]), a visual estimate is reliable. However, in patients with regional dysfunction the LV SAX view may miss some pathologic features.[52] A brief, qualitative assessment of the left ventricle in the four-chamber, two-chamber, and long-axis (LAX) views to look for hypokinetic walls aids in the diagnosis. Particular attention should be paid to the apex because it contributes a significant portion of the overall EF (Video 46.11).

When LV dysfunction is encountered, it is important to identify myocardial ischemia as the mechanism quickly because early revascularization improves outcomes.[53] The echocardiographic manifestations of myocardial ischemia occur earlier and are more sensitive than the electrocardiogram,[54,55] even in anesthetized patients.[56] Segmental wall thickening of less than 30% suggests ischemia and can manifest within seconds.[54] Distinguishing between new-onset RWMAs and hypokinesis from chronic ischemia can be difficult. Intraoperative pharmacologic stress testing is ideal,[57] but it is often not practical in the urgent setting. Acute ischemia therefore must be diagnosed by a change in RWMA from baseline by two grades (ie, from normal to severe hypokinesis) in two or more segments.[58] Infarcted myocardium often appears thinner and brighter than surrounding tissue and is therefore easily distinguished from myocardium with acute ischemia. Complications of ischemia such as acute diastolic dysfunction, mitral regurgitation, and papillary muscle rupture can also aid in the diagnosis.

In addition to LV ischemia, the stress, inflammation, and catecholamine excess associated with acute illness can reduce LV contractility. Potentially reversible secondary cardiomyopathies can develop in patients with numerous noncardiac critical illnesses.[59] Sepsis-induced cardiomyopathy, for example, may occur in more than one-half of patients with sepsis as a result of inflammatory mediators, bacterial endotoxins, catecholamines, and microcirculatory dysfunction.[60,61] LV and RV dysfunction ensues, with global and RWMAs, as well as worsening measures of diastolic function[59] (Video 46.12). The myocardial toxicity from excess catecholamines, whether through septic shock, drug administration,[62] or stress,[63] can also induce LV dysfunction. Stress-induced cardiomyopathy, also known as takotsubo cardiomyopathy, is a form of catecholamine-mediated ventricular dysfunction induced by physical or emotional stress.[61] Takotsubo cardiomyopathy most often manifests with normal to hyperkinetic basal function and hypokinesis of the apex,[64] likely secondary to an increased density of β-adrenergic receptors in the apex. The LV apex often appears to "balloon" out,[65] and this is the most prominent feature found on echocardiography.

Left Ventricular Hypercontractility and Left Ventricular Outflow Tract Obstruction

An often overlooked consequence of a hyperdynamic left ventricle, whether secondary to low afterload, hypovolemia, or inotropic support, is dynamic LVOT obstruction (LVOTO). Although often associated with hypertrophic cardiomyopathy, LVOTO has been reported in the setting of hypertension,[66] type 1 diabetes,[67] myocardial ischemia,[68,69] pheochromocytomas,[70] takotsubo cardiomyopathy,[71,72] valvular replacements and repairs[73,74] and catecholamine administration.[75,76] The mechanism of LVOTO remains unclear and varies by cause.[66] The primary mechanism likely results from localized increases in flow velocity during ejection that results from a narrow LVOT from LV thickening and/or hypovolemia. This change causes the anterior mitral leaflet and chordae to be drawn toward the septum through both a Venturi effect and a hydrodynamic "drag."[77,78] This process distorts the mitral leaflet coaptation and results in middle- to late-systolic mitral regurgitation. Precipitating factors that further narrow the LVOT include hypovolemia, sepsis, inotropic agents, and diuretic agents. LVOTO should be considered in any hemodynamically unstable patient with risk factors for LVOT narrowing whose hemodynamic status worsens with inotropic support.

On echocardiographic examination, the left ventricle likely appears underfilled and hypercontractile. LV hypertrophy of varying degrees and morphologic features may be present. It is often possible to see movement of the anterior leaflet of the MV toward the upper septum in the ME LAX view (Video 46.13). CFD may show mitral regurgitation with an anteriorly directed jet that begins in middle- to late-systole. CFD may also show turbulent flow in the LVOT (Video 46.14). This finding is often the initial indicator of altered ejection dynamics in LVOTO. The hallmarks of LVOTO are a "dagger"-shaped spectral Doppler pattern in the LVOT and midsystolic closure of the AV. Early systolic ejection is usually normal because it takes time for the flow velocity to build. Obstruction occurs late in ventricular contraction, thus causing flow to diminish transiently and resulting in partial closure of the AV. M-mode interrogation of the AV in the ME LAX view shows a "notch" indicating midsystolic partial closure of the AV with a secondary opening. In addition, this dynamic property of the obstruction yields a late-peaking continuous-wave Doppler pattern as the gradient tends to develop in middle- to end-systole producing

Fig. 46.3 Continuous-wave Doppler echocardiography in the left ventricular outflow tract of a patient with dynamic left ventricular outflow tract obstruction reveals a "dagger"-shaped waveform. *CW,* Continuous-wave; *FR,* frequency.

TABLE 46.4 Example of the Effects of Hypovolemia and Low Afterload on End-Diastolic and End-Systolic Volumes[a]

	EDV (mL)	*SVR*	*EF (%)*	*ESV (mL)*
Patient A	100	Normal	50	50
Patient B (hypovolemia)	50	Normal	50	25
Patient C (low afterload)	100	Low	75	25

[a]End-diastolic and end-systolic areas in the left ventricular short-axis view should reflect the changes in volumes.

a "dagger" shape (Fig. 46.3). The peak velocity of the wave is high, consistent with an elevated pressure gradient. The gradient can be measured by tracing the waveform.

Hypovolemia and Low Afterload

Cardiac tamponade, PE, and severe LV and RV dysfunction are relatively infrequent causes of hemodynamic instability. More commonly, reduced afterload or preload is encountered. A qualitative assessment of volume and afterload begins with LV end-diastolic and end-systolic areas (LVEDA and LVESA, respectively) in the TG SAX view, as well as Doppler quantification of SV. The LVEDA reflects the amount of fluid in the left ventricle. A euvolemic patient usually has a normal LVEDA. If the same patient also has reduced systemic vascular resistance, the LVEDA usually remains normal because the preload is unchanged. Conversely, the LVEDA of a hypovolemic patient is often reduced. The LVESA, in contrast, should reflect the end point of the LVEF. A hypovolemic patient who starts off with a reduced LV diastolic volume (reduced LVEDA), ends with a reduced systolic volume (reduced LVESA). Alternatively, a patient with a normal LV diastolic volume (normal LVEDA) but an elevated EF secondary to reduced afterload also ends with a reduced end-systolic volume (reduced LVESA). As examples, consider the patients with varying LV end-diastolic volumes, EF, and systemic vascular resistance in Table 46.4. Video 46.15 shows an example of a patient with hypovolemia compared with a patient with low afterload.

Normal values for LVEDA are 8 to 14 cm^2.[79] These values may vary depending on multiple factors,[80] including age, sex, FAC,[81] and even the anesthetized state.[49] LV SAX assessment by TEE has been shown to

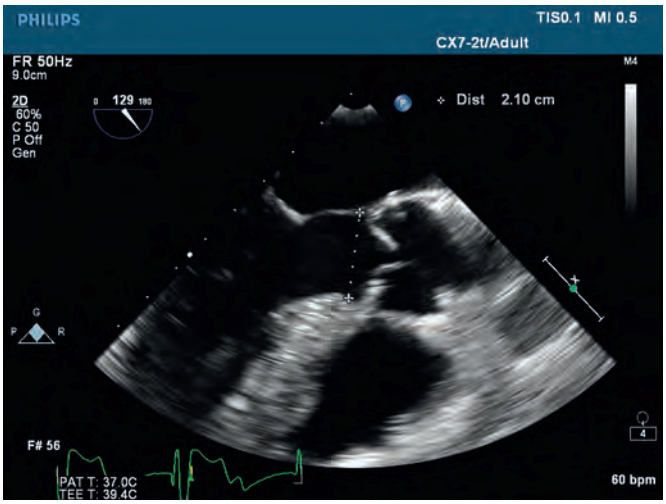

Fig. 46.4 Measurement of the left ventricular outflow diameter in the echocardiographic left ventricular long-axis view. *FR,* Frequency.

be a reasonable method of assessing ventricular volumes,[82–84] and it is more accurate than pulmonary artery occlusion pressures.[85] In addition, evidence indicates a correlation between LV volume and LVEDA in animals,[86,87] pediatric patients after congenital heart defect repair,[88] and anesthetized cardiac patients.[89] Cheung and associates[89] found the LVEDA to decrease linearly at 0.3 cm^2 per reduction in 1% of the estimated blood volume in cardiac patients. Several other studies confirmed the correlation between LV volume and LVEDA,[90–92] although at varying strengths of correlation. A correlation between a reduced LVESA and hypovolemia has also been established.[93] A direct relationship between a low LVESA and low afterload, however, has not been well established in the literature.[93,94] A qualitative assessment of the LVEDA and LVESA can therefore suggest hypovolemia, low afterload, or both, but it may require further evaluation through an estimation of SV to confirm the diagnosis.

Stroke Volume Assessment

A reduced LVESA likely represents either hypovolemia or low afterload. Hypovolemia results in a reduction in SV, whereas low afterload results in a high-CO state. SV can be calculated using the LVOT area and stroke distance.[95] The LVOT diameter is usually measured in the LV ME LAX view (Fig. 46.4), but it can be measured in any image that allows for an unobstructed view of the LVOT. The measurement should be obtained at the same level as the PWD cursor, usually approximately 5 mm proximal to the AV, measured from endocardium to endocardium.[95] Because the radius is squared, small inaccuracies in this measurement can introduce significant errors in the overall calculations. For this reason, it is important to use the baseline annular measurement for all calculations when performing serial SV measurements. The stroke distance, which is the average distance a red blood cell travels during systolic ejection, can be calculated by measuring the red blood cell velocities in the LVOT with PWD. This parameter is best measured in the deep TG or TG LAX views because of the parallel alignment between the flow and the transducer. The PWD cursor should be placed just proximal to the insertion of the AV leaflets. The image obtained is of the velocities (ie, speed and direction) of the red blood cells in the LVOT over time (Fig. 46.5). The machine can then calculate the velocity-time integral (VTI) after tracing the outer border of one of the waveforms. The VTI is the calculated stroke distance. To understand this concept better, consider a car traveling 70 miles an hour for 2 hours. Fig. 46.6 shows this plotted on a graph with velocity on the y-axis and time on the x-axis. The area of the rectangle created by these measurements would yield a distance (ie, 70 mph × 2 h = 140 miles). The VTI is similar to this calculation in that it is the area under the curve of red blood cell velocities over time. In this case,

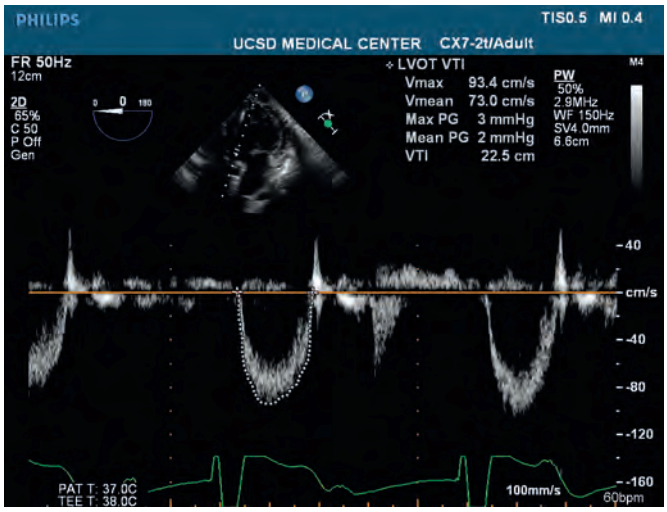

Fig. 46.5 Left ventricular outflow tract *(LVOT)* velocity waveforms obtained in the echocardiographic deep transgastric view. *FR,* Frequency, *PG,* pressure gradient; *PW,* pulsed-wave; *Vmax,* maximum velocity; *Vmean,* mean velocity; *VTI,* velocity-time integral. *(Courtesy University of California San Diego, La Jolla, Calif.)*

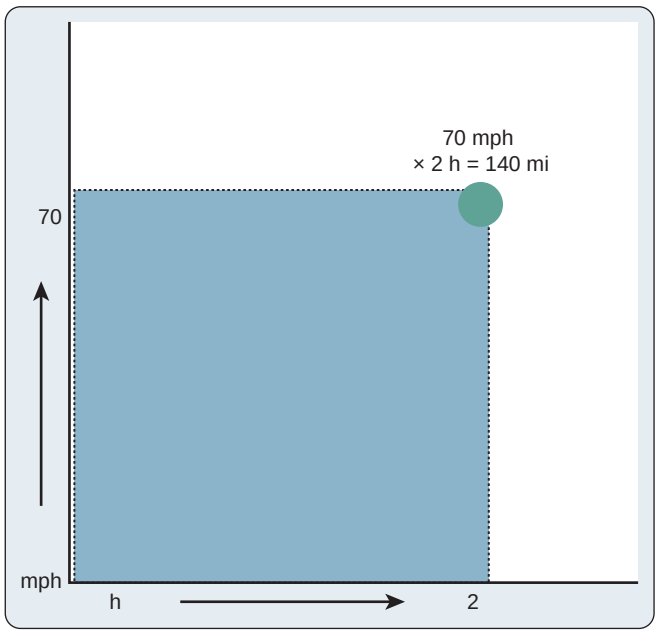

Fig. 46.6 Area under the curve for a velocity-time graph. If a car is going 70 miles per hour for 2 hours, one can calculate the distance traveled (ie, 140 miles) by calculating the shaded area. The same principle applies to the velocity-time graph obtained through spectral Doppler echocardiography. The area under a curve obtained in the left ventricular outflow tract using pulsed-wave Doppler yields a distance (centimeters). This is called the velocity-time integral.

the velocities are represented by centimeters per second, the time by seconds, and the VTI by centimeters (see Chapters 14 and 15).

The calculation of SV assumes a cylindrical LVOT with the volume being the product of the area and the length. The area of a circle is π × radius^2 or diameter^2 (D^2) × 0.785. The length is represented by the VTI. SV is expressed in milliliters and can be calculated using the following equation:

$$SV = D^2 \times 0.785 \times VTI$$

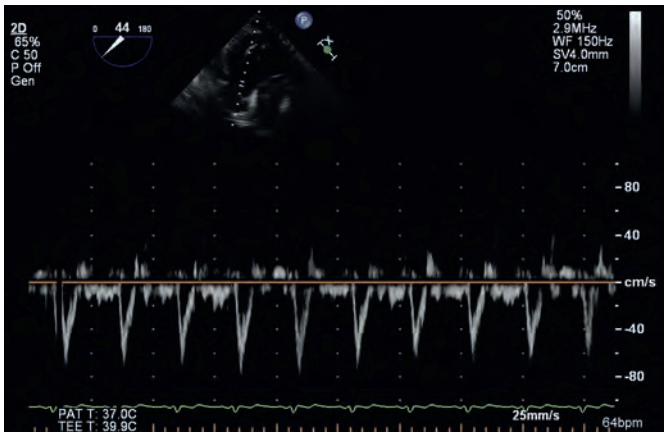

Fig. 46.7 Deep transgastric echocardiographic view with the pulsed-wave Doppler probe placed in the left ventricular outflow tract. The respiratory changes seen in the peak velocities indicate fluid responsiveness.

CO can then be calculated by multiplying SV by the HR. This method of SV calculation has been validated when compared with thermodilution,[96,97] and it is the ASE-recommended method for determining CO.[95]

Dynamic Indicators of Hypovolemia

Although changes in LVEDA and LVESA show that the cardiac chambers fill with volume administration, they do not predict whether volume administration improves SV[98] (ie, volume responsive). Dynamic indices, conversely, assess the effects of a change in preload on SV or its surrogate.[99] Positive-pressure ventilation increases pleural and transpulmonary pressures, which reduce RV preload and increase RV afterload, respectively. This process reduces overall RV SV. At the same time, insufflation pushes blood out of the lungs into the left ventricle, thus augmenting LV SV. After several beats, the reduced RV SV results in reduced LV preload and hence reduced SV, which can be seen at end-expiration. These changes are exaggerated when the ventricles are on the steep part of the Frank-Starling curve. The magnitude of the variation has been shown to predict fluid responsiveness (see Chapter 47). Euvolemia puts the ventricles on the flatter portion of the curve and limits respiratory variability. PWD interrogation of the LVOT has been shown to assess these changes in SV accurately and thus predict fluid responsiveness[100–102] (Fig. 46.7). Feissel and colleagues[11] derived the following equation in which V_{min} represents the minimum velocity in the LVOT, and V_{max} the maximum velocity, and Δ represents change:

$$\Delta V_{peak}(\%) = 100 \times (V_{max} - V_{min})/[(V_{max} - V_{min})/2]$$

A ΔV_{peak} of 12% or greater indicates volume responsiveness with a sensitivity of 100% and a specificity of 89% (as indicated by an increase in cardiac index by ≥15%). ΔV_{peak} was found to decrease after fluid administration. In addition, with a negative predictive value of 100%, these data suggest that no patient with a ΔV_{peak} of less than 12% responds to fluid administration. Volume responsiveness can also be measured by M-mode interrogation of the SVC in the LAX view (ie, in the ME bicaval view) or the SAX view (ie, in the ascending aorta SAX view) to look for collapsibility during respiration (Fig. 46.8). Vieillard-Baron and associates[103] derived the following equation in which D_{min} represents the minimum diameter and D_{max} the maximum diameter:

$$\text{SVC collapsibility index} = (D_{max} - D_{min})/D_{max}$$

An SVC collapsibility index greater than 36% discriminated between responders (an increase of 11% in cardiac index with a 10 mL/kg fluid bolus) and nonresponders with a sensitivity of 90% and a specificity

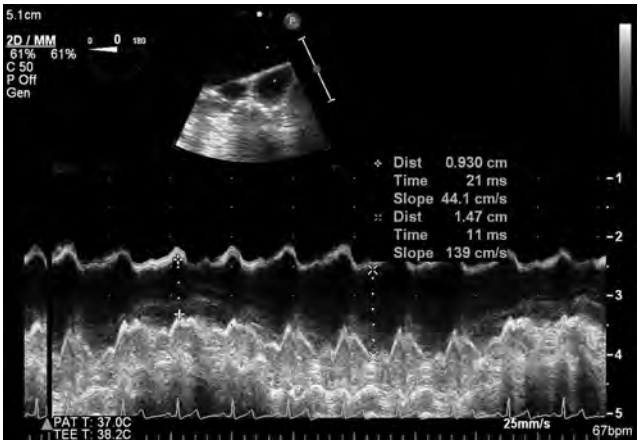

Fig. 46.8 Ascending aorta short-axis echocardiographic view. The right pulmonary artery is at the top of the screen. The superior vena cava is in the short axis beneath it. Note the collapsibility with positive-pressure ventilation.

of 100%. Spontaneous ventilation, cardiac arrhythmias, and low tidal volumes limit the accuracy of both these measurements.

Transesophageal Echocardiography as a Monitor in Noncardiac Surgical Procedures

An Argument for Use as a Monitor in Noncardiac Cases

The hemodynamic status of the intraoperative patient need not be acutely unstable for TEE monitoring to be effective. Although distinct entities such as PE and tamponade have been discussed, it is the effect of these processes on preload, afterload, contractility, and thus SV that is most important to diagnosis and treatment. It is well known that general anesthesia affects all these parameters.[104] TEE is well suited to assess the more moderate changes in hemodynamic values that occur with surgical procedures and general anesthesia. Although evidence of the outcome benefits of intraoperative TEE as a monitor is currently lacking, evidence does indicate that echocardiography can change perioperative morbidity.[105] In addition, a significant number of data indicate that the information gained from echocardiography can change perioperative management[106–111] and management in the intensive care unit.[47,112–15] As an example, Denault and associates[116] showed that intraoperative TEE in noncardiac surgical procedures not only changed management in those patients with category I indications (67% change in management) but also changed management 20% to 30% of the time in patients with category II and III indications. The benefits are clear, and the complication rate is low, with an overall morbidity rate of 0.2% and a 0% mortality rate.[117,118] The ASE and SCA currently recommend a noncomprehensive examination for intraoperative monitoring and cite that it can "dramatically influence a patient's intraoperative management."[5]

The data supporting the use of TEE as a monitor in noncardiac surgical procedures also apply to specific clinical situations. In addition to its use as a monitor for ischemia and volume in the high-risk vascular surgical patient,[119,120] TEE is valuable in assessing ventricular changes during aortic cross-clamping,[121,122] as well as to guide endovascular stent placement and monitor for complications.[123–125] In fact, TEE is more sensitive and specific than angiography in detecting leaks and thrombi,[123,126] and it can change the surgical procedure a significant amount of the time.[127] Echocardiography is also useful in identifying traumatic cardiac and vascular injuries, including cardiac contusion,[128–130] valvular disruption,[128] and traumatic aortic injuries.[131,132] Plummer and colleagues[133] showed that information derived from echocardiography reduced mortality rates in patients with penetrating cardiac injuries by more than 40%. The literature on hepatic resection and transplantation shows that TEE can have a major impact on intraoperative management,[108] particularly when it is used to assess for PE and RV dysfunction,[134] as well as changes in LV function.[135,137] Regarding orthopedic procedures, Loxdale and associates[137] showed that more than one-third of patients presenting with a hip fracture had aortic stenosis. Not only can echocardiography aid in the diagnosis and management of this and similar coexisting cardiac diseases in orthopedic patients, but it can also aid in identifying and treating emboli associated with total hip arthroplasty with cement[138,139] and without cement,[140] as well as guide resuscitation in prone spine surgical procedures.[141] TEE is also valuable as a guide in patient positioning for neurosurgical procedures,[142] identifying gas emboli and acute valvular dysfunction in laparoscopic procedures,[143,144] monitoring diastolic dysfunction in pneumonectomies,[145] and identifying and monitoring renal cell carcinoma extension into the right atrium.[146,147]

Given that one of the primary arguments against using echocardiography as a routine monitor is that outcome data are lacking, it is important to assess whether the monitors traditionally used have the same issues. Positive outcome data with the use of pulmonary artery catheters and central venous pressure monitoring are lacking. Pulmonary artery catheters do not affect outcome in several different patient groups, including high-risk surgical patients,[148] patients with sepsis,[149] cardiothoracic surgical patients,[150–152] and vascular surgical patients.[153] These data were confirmed in several systematic reviews.[154–156] Moreover, neither central venous pressure nor pulmonary artery occlusion pressure correlates with ventricular preload.[157] Evidence to support improved outcomes with the use of arterial catheters[158] and pulse oximetry[159,160] is similarly lacking (see Chapter 13). This observation is not meant as an indictment of traditional intraoperative monitors, nor does it suggest that seeking further outcome data on intraoperative echocardiography as a monitor is superfluous. This is simply to suggest that intraoperative echocardiography in noncardiac surgical procedures should not be discounted because of a lack of outcome data.

Transesophageal Echocardiography Goal-Directed Therapy

TEE is clearly a safe and valuable monitor in a multitude of intraoperative situations. The wide-ranging utility of TEE as a monitor is not solely the result of its accuracy in detecting singular cardiac events, but it also reflects the ability of TEE to provide a global view of cardiac function and the overall physiologic context within which the event occurs. This makes echocardiography the ideal monitor for goal-directed therapy (GDT). GDT is the optimization of a hemodynamic goal through fluid administration and/or inotropic or vasoactive support with the expectation that this will treatment optimize end-organ perfusion and oxygen delivery[161] (see Chapter 47). Optimization involves assessment of the hemodynamic parameter before and after the intervention and then basing further intervention on the results. Such a concept is not foreign to anesthesiologists, who tend to use normal blood pressure and heart rate as standard hemodynamic goals. Unfortunately, these parameters are poor markers of end-organ perfusion, particularly when considering volume status.[162] The hemodynamic parameters used for GDT are generally SV and CO or their surrogates. Although it remains controversial,[163] a growing body of evidence indicates that in high-risk patients undergoing noncardiac surgical procedures, GDT reduces hospital length of stay,[164] improves postoperative gastrointestinal function,[165] decreases postoperative renal dysfunction,[166] and improves short-term[167] and long-term survival.[168]

The most obvious advantage of echocardiography over other monitors, such as the esophageal Doppler or pulse contour analyzer, is the ability monitor contractility. LV systolic function is extremely complex, with multiple elements beyond EF.[169,170] A normal preoperative EF

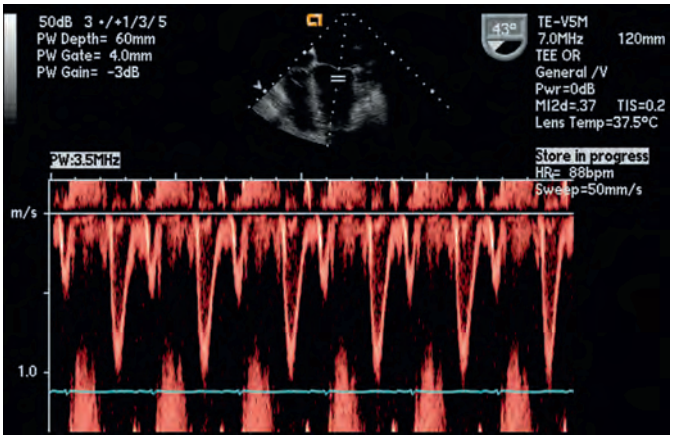

Fig. 46.9 Mitral inflow Doppler echocardiography with E and A waves. *HR,* Heart rate; *PW,* pulsed wave; *TEE,* transesophageal echocardiography.

may not predict intraoperative contractile performance, particularly as loading conditions change.[171] Subtle systolic dysfunction can be unmasked by anesthesia, surgical procedures, or some other hemodynamic disturbance. Thus hypocontractility must remain on the differential diagnosis for hemodynamic instability regardless of initial assumptions. The LV SAX view is an easy and effective way to estimate LV function qualitatively. In addition, it provides simultaneous information on contractile performance and loading conditions, which are interdependent. Frequent assessment of the LV SAX allows for both a rapid estimation of preload, afterload, and contractility in the setting of hemodynamic instability, as well as the effects of any intervention performed to alleviate the disturbance.

Volume therapy in GDT focuses on changes in SV after volume administration. The method used to assess this change is similar to that used to monitor dynamic changes in SV with positive-pressure ventilation. Baseline values are obtained for LVOT, VTI, and LV SV. Volume is then administered, and these parameters are reassessed. An increase in SV of more than 10%[172,173] indicates *volume responsiveness,* which warrants further volume loading and reassessment. An increase of less than 10% suggests that the patient will not benefit from further volume loading, and an alternate method to improve hemodynamics should be sought. Large volumes of fluid are not necessary. As little as 100 mL of colloid can be used, with a sensitivity of 95% and a specificity of 78%.[172] Alternatively, passive leg raise can be used to test volume responsiveness[174] by placing the bed at 45 degrees of semirecumbency and then tilting the bed so that the upper body is horizontal and the legs are at a 45-degree angle.[175] Passive leg raise can achieve the same SV increase as a 300-mL volume bolus in fluid responders,[176] with the advantage of being reversible.[177]

TEE is not only able to identify improvements in forward flow, but it also can monitor intracardiac pressures, particularly left atrial pressure (LAP), to aid in preventing elevated filling pressures and pulmonary edema.[178,179] Although an LAP measurement may not reflect intravascular volume status, a large increase in LAP during fluid administration warns of impending edema that may be hastened by further volume. The echocardiographic assessment of LAP involves the use of spectral Doppler to assess diastolic compliance. Placement of the PWD cursor at the mitral leaflet tips during diastole yields two waves, E and A (Fig. 46.9). The E wave represents early diastolic filling as a result of a pressure gradient between the left atrium and the left ventricle. The A wave represents the gradient between the left atrium and left ventricle generated by atrial contraction. Simplifying the diastolic physiology for the sake of clarity, the pressure gradient during the E wave can be produced in one of two ways: (1) a normal LAP in the setting of a low LV end-diastolic pressure (LVEDP) in a compliant myocardium, or (2) a high LAP generated by compensatory mechanisms to overcome a high LVEDP in a noncompliant myocardium. Because both mechanisms can generate the same pressure gradient, the E waves for both may look the same.

The velocity with which the mitral annulus ascends in diastole can help determine how the pressure gradient is established. PWD interrogation of the mitral annulus in the four-chamber view yields early and late diastolic waves termed E′ and A′ (Fig. 46.10). These waves are brighter (because of the high-density tissue) and slower compared with the mitral inflow and require an adjustment of the gain and scale. The tissue Doppler function on the machine optimizes these parameters automatically (see Chapter 15). A relatively fast E′ is a marker for normal diastolic compliance, whereas a slow E′ indicates poor diastolic compliance. Because the E wave is approximately the same for both low and high LVEDP and the E′ wave is reduced with a high LVEDP, the ratio of E to E′ increases as the LVEDP (and the LAP) increases. An elevated E/E′ ratio correlates with LAP in septic shock,[180] heart failure,[181] and ventilated patients in the intensive care unit,[182] and it may be a better marker of high pressures than brain natriuretic peptide.[183] No universally accepted values for E/E′ and LAP have been established. Based on the available data, an E/E′ ratio greater than 18 is most likely associated with an elevated LAP, whereas an E/E′ ratio of less than 12 most likely rule outs elevated pressures.[181] In addition, Bouhemad and associates[180] showed a statistical correlation between pulmonary capillary wedge pressure (PCWP) and E/E′ by using the following formula: $PCWP = 0.97 \times E/E' + 4.34$.

PWD interrogation of the pulmonary venous inflow is another method to assess diastolic compliance and LAP. In a left ventricle with normal compliance, the LAP is lowest during systole because of the descent of the mitral annulus. The pressure gradient between the pulmonary vein (PV) and the left atrium is greatest during this period and generates the most blood flow. As the left atrium fills, the gradient decreases and blood flow slows. The MV then opens, releasing the pressure in the left atrium and reestablishing a gradient between the PV and the left atrium. Blood flow from the PV to the left atrium resumes, although at a lower velocity and flow distance (ie, VTI) as a result of a smaller gradient. PWD interrogation of a PV throughout the cardiac cycle yields waves in systole (PVs) and diastole (PVd), with the maximum velocity and VTI in systole greater in normal LAP (Fig. 46.11). In a left ventricle with poor diastolic compliance, the gradient between the PV and the left atrium is reduced in systole. The majority of blood flow therefore occurs in diastole after the MV opens, to yield a PVs with a lower maximum velocity and VTI than

the PVd. The PV systolic fraction ($PVs_{VTI}/[PVs_{VTI} + PVd_{VTI}]$) correlates well with the mean LAP,[184] with a value of less than 0.4 predicting a PCWP greater than 12 mm Hg with a positive predictive value of 100%.[185] Additionally, the deceleration time (ie, the time from peak velocity to baseline) of the PVd wave (DTd) correlates very well with LAP (Figs. 46.12 and 46.13). A DTd of less than 175 milliseconds has a 100% sensitivity and 94% specificity for a mean LAP of greater than 17 mm Hg, and a DTd greater than 275 milliseconds predicts a mean LAP of 6 mm Hg or less with a sensitivity and specificity of 88% and 95%, respectively.[186]

Suggested Method

For the purposes of general intraoperative hemodynamic monitoring and GDT, use of the limited examination mentioned earlier with the addition of spectral Doppler assessments of mitral inflow, mitral annular, and pulmonary venous inflow velocities is suggested (Box 46.6). At the start of the monitoring period, the entire limited examination should be performed. This should include baseline values for E, E, PVs, PVd, and DTd, as well as an estimation of the LAP using an approximation of the equation noted in the report by Bouhemad and colleagues[180]:

$$PCWP = 0.97 \times E/E' + 4.34 \approx E/E' + 4$$

After this assessment, the focus of continued monitoring should be on the following views:

1. Four-chamber view for RV and LV systolic function and calculation of LAP

TABLE 46.5 Echocardiographic Findings in the Most Commonly Encountered Hemodynamic Abnormalities

Abnormality	*SV*	*Potential Other Findings*
↓ Contractility	↓	↓ Ejection fraction ↓ Segmental or global wall thickening
↓ Volume	↓	↓ End-diastolic area ↓ End-systolic area ↑ SV variability
↓ Afterload	↑	Hyperdynamic systolic function ↓ End-systolic area Normal end-diastolic area
↑ Afterload	↓	↑ End-systolic area ↓ Ejection fraction ↓ Segmental or global wall thickening ↑ Mitral or aortic valve regurgitation
Sinus bradycardia	↓	Bradycardia Normal end-diastolic area
Sinus tachycardia	↓	Tachycardia ↓ End-diastolic and end-systolic areas

SV, Stroke volume; ↑, increased; ↓, decreased.

TABLE 46.6 Echocardiographic Changes Following a Hemodynamic Intervention That Indicate the Success of the Intervention

Intervention	*Successful*	*Consider Alternative*
Inotrope	↑ SV, CO ↑ EF ↑ RV, LV contractility	No change in SV or CO Arrhythmia, ischemia[a] ↑ LAP[b]
Volume	↑ SV, CO ↓ SV variation ↑ EDA, ESA	No change in SV or CO ↑ LAP[b] ↓ EF
Pressor	↑ ESA Normalized left ventricle	↓↓ SV, CO[c] ↑ LAP[b]
Vasodilator	↑ SV, CO ↓ ESA ↑ EF, contractility ↓ LAP[b]	No change in SV or CO Hyperdynamic right ventricle, left ventricle
(+) Chronotrope	↑ SV, CO	↓ SV, CO ↑ LAP ↓ EDA Arrhythmia, ischemia[a]
(−) Chronotrope	↑ SV, CO	↓ CO ↑ LAP[b]

[a]For echocardiographic signs of ischemia, please see above.
[b]Echocardiographic parameters of ↑ LAP consist of ↑ E/E′ wave ratio, ↓ pulmonary vein in systole velocity-time integral, and/or ↓ deceleration time of the pulmonary vein in diastole. Echocardiographic parameters of ↓ LAP would be the opposite.
[c]A reduction in SV is an appropriate response to pressor administration in the setting of low afterload. An excessive reduction, however, may mean that the increase in SVR with the pressor is too much for this particular contractile state.
CO, Cardiac output; *EDA,* end-diastolic area; *EF,* ejection fraction; *ESA,* end-systolic area; *LAP,* left atrial pressure; *LV,* left ventricular; *RV,* right ventricular; *SV,* stroke volume; ↑, increased; ↓, decreased.

2. Transgastric SAX view for estimation of LV contractility, volume, and afterload
3. Deep transgastric view for spectral Doppler evaluation of the LVOT for SV and SV variation

Interventions to optimize SV should then be based on the TEE findings. For general hemodynamic monitoring, the main hemodynamic abnormalities encountered are poor contractility, hypovolemia, or low afterload. However, arrhythmias and high afterload must also be considered. Malignant arrhythmias obviously require emergency intervention to reestablish CO. Less acute arrhythmias, particularly sinus bradycardia and tachycardia, are far more common and can significantly compromise CO. Elevated afterload can also affect CO, even in the setting of high normal or only slightly elevated blood pressures. This finding highlights the interdependency of contractility and loading conditions. Mildly elevated afterload in a patient with normal systolic function may have little effect on CO, but it may have a significant effect in a patient with compromised systolic function. Table 46.5 lists the echocardiographic findings in the most commonly seen hemodynamic abnormalities.

The appropriate intervention should then be performed, and the foregoing parameters should be reevaluated by TEE. With the exception of pressor administration, all interventions should lead to an increase in SV. Although pressor administration reduces SV in a hyperdynamic left ventricle, a large reduction in SV may indicate that pharmacologic vasoconstriction is not the appropriate response. Echocardiographic parameters of LAP should also be assessed, particularly when volume or pressors have been given. An increase in E/E′ ratio, a reduction in PV systolic fraction, and a reduction in DTd suggest an acute increase in LAP. Further volume or pressor administration may result in pulmonary edema. RV and LV contractility, LV SAX assessment of preload and afterload, SV and SV variation, and LAP should be continuously monitored. Interventions should be tailored to the acute cardiac physiologic features with the goals of maintaining perfusion pressure, improving SV, and preventing pulmonary edema. Additional TEE parameters suggesting that an intervention is appropriate or potentially inappropriate are listed in Table 46.6.

Transthoracic Echocardiography

The preceding discussion focuses on the application of TEE to the noncardiac surgical patient. TEE is safe and has repeatedly been shown to add value to intraoperative management. However, as noted by Markin and associates,[4] cardiac assessment does not begin and end in the operating room, even in the emergency setting. The utility of TEE in the awake patient is obviously limited. TTE provides the anesthesiologist with additional noninvasive windows to aid in cardiac diagnosis and monitoring. The images acquired from TTE are the same as those in TEE, but at a different angle. Technically speaking, the "window" differs, but the "view" does not. The information and interpretation are the same. All the hemodynamic assessments listed earlier can be performed with TTE using similar views. The following discussion reviews the value and application of TTE by anesthesiologists, including how to perform a basic examination.

Value of Perioperative Transthoracic Echocardiography

The American College of Cardiology guidelines give a class I recommendation to preoperative echocardiography in patients "with clinically suspected moderate or greater degrees of valvular stenosis or regurgitation" and a class IIa recommendation in patients with dyspnea of unknown origin.[187] Although these recommendations apply to a significant number of preoperative patients, the ASE also encourages the use of echocardiography in the following situations[188]:

- When symptoms or conditions are potentially related to a cardiac disease
- When results from previous testing (electrocardiogram, chest radiograph, biomarkers) are concerning for heart disease
- To reevaluate known structural heart disease with a change in clinical status
- When pulmonary hypertension is suspected
- With diagnoses of atrial fibrillation
- When hypertensive heart disease is suspected

Given that preoperative patients frequently meet these criteria and the information obtained from TTE is recognized to add value to the long-term care of these patients, it seems reasonable to apply these broader criteria to preoperative echocardiography when feasible.

Preoperative cardiac assessment involves diagnosing CV dysfunction, predicting the effects of anesthesia on CV function, and attempting to mitigate the risks through preoperative optimization. Resting preoperative TTE predicts postoperative cardiac complications[189] better than does clinical risk assessment alone,[190] and it is as sensitive as but more specific than dipyridamole thallium scanning.[191,192]

Equally important is how the information on cardiac pathophysiology obtained through echocardiographic studies can guide anesthetic care. Anesthesia encapsulates a wide range of care options, and perioperative CV risk cannot be assumed to be the same across all potential anesthetic cases. Physiologic optimization is an ongoing process that carries through the preoperative, intraoperative, and postoperative periods. In the immediate perioperative period, acute cardiac physiologic status guides this care. Cardiac physiology, from systolic and diastolic function to valvular regurgitation, depends on loading conditions that can quickly vary. A preoperative TTE examination is well suited to define the *current* CV state and allows the anesthesiologist to adjust care appropriately. Numerous studies have shown that point-of-care TTE in the hands of anesthesiologists alters intraoperative care.[193–197] Preoperative point-of-care TTE has also been linked to improved outcomes including a reduction in mortality rates.[105] The information obtained through echocardiography is beneficial above and beyond the history and physical examination. The sensitivity of symptoms of heart failure (including orthopnea, paroxysmal nocturnal dyspnea, and dyspnea with 4 metabolic equivalents of activity) is less than 35%, and even including physical findings of lower extremity edema, jugular venous distention, and an S_3 gallop, the sensitivity is still only approximately 50%.[198]

The utility of TTE is not limited to the preoperative period. The advantages of TTE over TEE in the awake postoperative patient are obvious. TTE also plays an important role intraoperatively. Twenty percent of the TTE examinations performed to assess hemodynamic instability in the perioperative patients in the report by Markin and associates[4] were performed in the operating room. In the report by Shillcut and colleagues,[3] more than 80% of the TTE examinations were performed intraoperatively. Intraoperative TTE is most commonly used when TEE is contraindicated, when a TEE probe cannot physically be placed, or when TEE images are not adequate as a result of technical difficulties.

How to Perform a Basic Transthoracic Echocardiography Examination

Investigators have repeatedly shown that noncardiologist providers can successfully be trained in bedside TTE. This group of providers includes medical students,[199,200] internal medicine residents,[201] emergency medicine physicians,[202] critical care physicians,[47] internists,[203] and anesthesiology residents.[6] Kobal and associates[9] showed that first-year medical students using bedside ultrasound to diagnose cardiac disease were significantly more likely to reach accurate diagnoses than were attending cardiologists who were not using ultrasound. The teachability of point-of-care TTE is likely related to a paradigm shift with regard to image acquisition and interpretation. Because of the size and complexity of the original ultrasound machines, there use was limited to practitioners with specialized training. Current technology, conversely, has yielded small, easily portable units geared toward decision making in real time. A detailed analysis of the images is not required to make immediate decisions on prognosis and hemodynamic management. Similar to the echocardiographic assessment of hemodynamic emergencies with TEE, perioperative TTE requires only a qualitative analysis, thus reducing the training required for competency.

With adequate training an anesthesiologist can be credentialed to perform TTE and potentially bill for their studies. Although currently no standard exists for training or credentialing anesthesiologists to perform TTE, guidelines are in place for other specialties. The American College of Cardiology guidelines on training in echocardiography suggest that cardiologists with level II training in TTE who want to incorporate TEE into their practice should perform at least 50 examinations before being considered competent.[204] An argument could be made that similar criteria should apply to anesthesiologists with level II training in TEE when seeking proficiency in TTE. With training in basic image acquisition and interpretation and 50 supervised studies, an anesthesiologist should be considered competent to perform a TTE examination.

Fig. 46.14 How to obtain the parasternal long-axis echocardiographic view. The patient is in the left lateral decubitus position to position the heart on the chest wall. The probe is placed in the third or fourth intercostal space with the marker toward the right shoulder.

The following are instructions for acquiring TTE images. As noted by Shillcutt and associates[3] and Markin and colleagues,[4] a limited examination should be performed, focusing of the pertinent images that aid in perioperative care.

1. Equipment: A phased-array probe is necessary for this examination. Any machine that is used to perform TEE should also have TTE capabilities. Point-of-care devices can also acquire adequate images for qualitative analysis.
2. Positioning: When imaging is done from the parasternal and apical windows, the patient should be in the full left lateral decubitus position with the left arm resting under the head to help spread the ribs. To access the LV apex, it is necessary to move the patient to the very edge of the bed or stretcher or to tilt the patient slightly back from a true left lateral position. Although the left lateral position is preferred, it is also possible to perform the entire examination with the patient supine. The subcostal window is accessed with the patient supine and the legs slightly bent to relax the abdominal muscles.
3. Basic technique and assessment
   a. Parasternal LAX view (Video 46.16):
      i. Technique: The probe should be positioned at the third or fourth intercostal space, just to the left of the sternum, with the "indicator" pointing toward the left shoulder (Fig. 46.14).
      ii. Assessment: This view is one of the easiest to perform, even in supine or morbidly obese patients. It provides information on RV size and function, AV function, left trial size, and LV function, size, and thickness.
   b. Parasternal SAX view (Video 46.17):
      i. Technique: From the LAX, the probe is rotated approximately 90 degrees clockwise until the indicator points toward the patient's right shoulder (Fig. 46.15). The probe should then be tilted until the appropriate LV cross-section is obtained.
      ii. Assessment: With angulation of the probe, the basal, middle, and apical cross-sections showing the 16 LV segments can be assessed for wall motion abnormalities. Global LV function and filling can be assessed as well. By angling the probe to look more anteriorly (angling the "tail" toward the apex), an SAX view of the AV can be seen.
   c. Apical four-chamber (Video 46.18):
      i. Technique: The apical window can be found by placing the probe at the point of maximal impulse (Fig. 46.16). The indicator should point toward 5 o'clock. The apex

Fig. 46.15 How to obtain the parasternal left ventricular short-axis echocardiographic view. The probe is turned clockwise approximately 90 degrees.

Fig. 46.16 How to obtain an apical four-chamber echocardiographic view. Ideally the probe would be placed at the point of maximal impulse in the axilla with the marker pointing toward the floor. This placement is often difficult with the beds used in the preoperative period. Placement of the probe under or near the nipple often produces adequate images.

of the left ventricle will appear directly under the probe with minimal foreshortening and without showing the coronary sinus or LVOT.

ii. Assessment: This view shows global and regional LV and RV function, chamber sizes, and mitral and tricuspid valve function. The valves can be interrogated with CFD. Spectral Doppler can be used to assess right-sided pressures with continuous-wave Doppler through any tricuspid regurgitation. Assessment of diastolic function can be performed with a combination of PWD interrogation of mitral inflow and tissue Doppler evaluation of septal and lateral mitral annulus motion in diastole. Slight angling of the tail of the probe toward the feet will reveal the five-chamber view. PWD interrogation of the LVOT yields LVOT VTI and thus allows for SV calculation.

d. Subcostal four-chamber (Video 46.19):

i. Technique: The patient should be placed supine for these images. It is useful to have the patient bend the knees or place a pillow under the knees to relax the abdominal musculature. The probe is placed just below or slightly left of the xiphoid process, with the indicator pointed to the patient's left and with the probe nearly horizontal (Fig. 46.17).

Fig. 46.17 How to obtain a subcostal four-chamber echocardiographic view. The probe should be positioned near the xyphoid process with the marker toward the right side of the patient's body.

ii. Assessment: The right ventricle is seen very well, allowing for evaluation of thickness, function, and size. Pericardial effusions can be seen here, as well as evidence of tamponade (ie, compression of the right atrium or right ventricle). The left ventricle and atrioventricular valves can also be evaluated.

Conclusion

Echocardiography, using either TTE or TEE modalities, is extremely useful to the perioperative physician by aiding in both diagnosis and management. Because of its portability and ease of use, it is the diagnostic tool of choice in the setting of hemodynamic instability. Echocardiography is not limited to emergencies; it provides a significant amount of information as a general hemodynamic monitor. With numerous complementary tools at the examiner's disposal, echocardiography is also the ideal monitor for goal-directed therapy. Finally, limited preoperative echocardiographic assessment, even in the hands of noncardiologists, significantly alters intraoperative and postoperative anesthetic management and may even reduce perioperative mortality rates.

Goal-Directed Fluid Therapy, Enhanced Recovery, and the Perioperative Surgical Home for Cardiac Patients in Noncardiac Surgery

GERARD R. MANECKE, Jr, MD

TEACHING POINTS

1. The costs of health care are escalating, and the increase is unsustainable. Goal-directed fluid therapy, enhanced recovery programs, and the perioperative surgical home are ways to control costs while improving quality.
2. Goal-directed fluid therapy is an integral part of enhanced recovery programs, and both fall under the general umbrella of the perioperative surgical home.
3. The traditional approach to perioperative fluid management has no sound evidence base and causes perioperative fluid and salt overload. *Zero fluid balance* is recommended, using a goal-directed approach. Enhanced recovery programs emphasize the avoidance of salt and water overload.
4. Administering goal-directed fluid therapy involves cardiovascular monitoring such as minimally invasive cardiac output and the application of an algorithm or guidelines specific to fluid and hemodynamic management.
5. Goal-directed fluid therapy and enhanced recovery programs increase quality by decreasing variability in practice with evidence-based management. Decreased cost results from less perioperative morbidity and streamlined care delivery.
6. Various monitors may be used for goal-directed fluid therapy, ranging from invasive (pulmonary artery catheter) to noninvasive (finger cuff cardiac output). The choice of monitor is based on the clinical situation and the individual or institutional preference. The most common monitors used are esophageal Doppler and arterial pulse wave analysis systems.
7. Goal-directed fluid therapy algorithms may be based on cardiovascular performance (eg, cardiac output) or preload responsiveness (eg, stroke volume variation). Algorithms that incorporate both are likely to be the most effective.
8. Enhanced recovery programs are multidisciplinary, multifactorial care pathways. They incorporate optimal preoperative preparation, careful intraoperative management of fluid status, temperature, antibiotic administration, minimally invasive surgery, multimodal pain relief, postoperative nausea and vomiting control, and early mobilization.
9. Perioperative surgical homes are becoming popular constructs for delivering streamlined, coordinated care.
10. Anesthesiologists can enhance their value to their health systems by becoming involved in the development, implementation, and management of perioperative surgical homes.

With recent advances in expensive diagnostic and treatment modalities, the costs of health care have skyrocketed.[1] The need to care for increasing numbers of patients undergoing diagnostic and therapeutic procedures while controlling the cost has pushed health care systems to devise increasingly efficient ways to deliver care. The *throughput* of patients is often stymied by prolonged hospital stays and readmission after procedures. Inefficient systems, inconsistent care, and perioperative complications cause delays, poor patient and provider satisfaction, and high costs.

Goal-directed fluid therapy (GDT), enhanced recovery programs (ERPs), and the perioperative surgical home (PSH) are three related approaches to patient care that have emerged to provide optimal outcomes for patients undergoing surgery. GDT refers to fluid and hemodynamic management targeting optimal cardiovascular performance and using monitoring beyond standard noninvasive monitors. ERPs are designed to incorporate patient management processes, such as preoperative optimization, multimodal pain management, and early mobilization after surgery so as to facilitate recovery. PSH is a construct consisting of a coordinated, multidisciplinary team using best-evidence guidelines and protocols to guide patients through the entire perioperative experience as seamlessly as possible. Fig. 47.1 shows GDT as a component of enhanced recovery, and both are under the PSH umbrella.

Goal-Directed Fluid Therapy

Traditional, liberal fluid management of patients undergoing major surgery has entailed a type of *cookbook* approach (Box 47.1). This methodology involves the calculation of maintenance fluid requirement based on body weight, calculation of a deficit based on the period

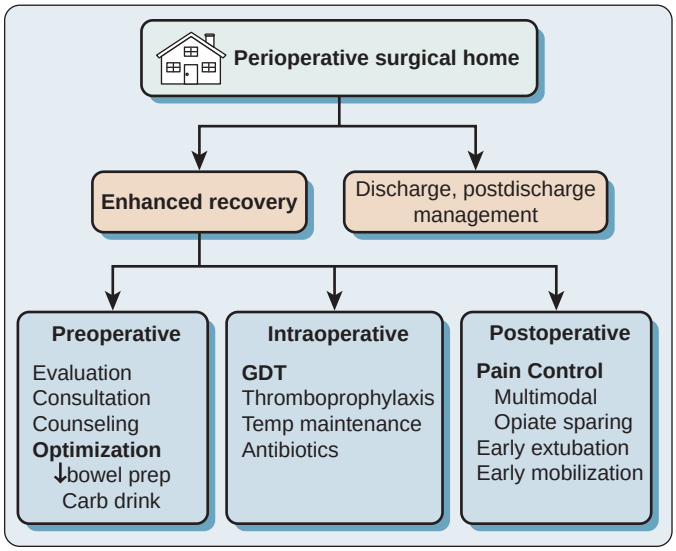

Fig. 47.1 Goal-directed fluid therapy (GDT) is part of enhanced recovery programs that are under the perioperative surgical home umbrella.

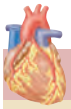

BOX 47.1 GOAL-DIRECTED FLUID THERAPY

- Standardizes fluid and hemodynamic management.
- Aims to avoid fluid and salt overload while avoiding hypovolemia.
- Is based on parameters beyond heart rate and blood pressure, such as:
  - Minimally invasive or invasive cardiac output
  - Stroke volume variation (SVV)
  - Pulse pressure variation (PPV)
  - Doppler corrected flow time (FTc)
  - Central venous oxygen saturation
- Many algorithms have been used successfully.
- Algorithm should have physiologic basis and be easy to use.

during which the patient has not had any fluid by mouth, presumed effects of a bowel preparation, and the estimation of *third space* losses based on the invasiveness of the surgery. Typically, for major abdominal surgery, 6, 8, 10, or even 12 mL of crystalloid/kg per hour would be administered to replace insensible losses and a loss to the third space. The concept of the third space grew out of a radionuclide study by Shires and associates,[2] and the massive amounts of fluid to replace losses were suggested by Jenkins and colleagues.[3] Subsequently, the methodology and clinical ramifications of this work have been called into question—specifically, if the third space exists at all.[4,5] It is highly likely that what has been referred to as fluid loss to the third space represents translocation of administered fluid out of the vascular space, resulting in intracellular and extracellular edema.

Excess salt and fluid in the perioperative period is now generally accepted as harmful. Lowell and associates[6] studied postoperative critical care patients and found that perioperative weight gain (fluid excess) was associated with a dramatic increase in mortality. Fluid and salt excess can lead to airway edema, increased lung water, tissue edema, and cardiac failure. Improved outcomes associated with relative fluid restriction (as compared with the traditional approach) have been found in prospective studies of general surgical patients published in the surgery[7] and anesthesiology[8] literature. Shorter hospital lengths of stay, improved wound healing, fewer surgical infections, and fewer cardiovascular and pulmonary complications have all been associated with relative fluid restriction and are supported by a metaanalysis.[9] It could be argued that excess perioperative fluid and salt are acceptable

Fig. 47.2 Fluid and salt overload can cause airway problems, increased lung water, congestive heart failure, renal failure, skin breakdown, and vision problems.

because, with time, the patient will mobilize the fluid. However, the potential pulmonary problems, prolonged ventilation, increased complication rate, and extra time in recovery associated with excess fluid and salt administration are no longer necessary or acceptable (Fig. 47.2). The avoidance of fluid and salt overload in major surgery is now a standard component of ERPs (Fig. 47.3).

Over-aggressive fluid restriction can have negative consequences as well, with hypovolemia leading to hypotension, tachycardia, organ ischemia, and vital organ failure. Morbidity rates are higher in the setting of either hypovolemia or hypervolemia (Fig. 47.4).[10] Targeting no perioperative change in body weight, *fluid restriction* protocols do allow modest fluid administration with a background rate (eg, 1–4 mL/kg per hour)[8] and fluid boluses to maintain hemodynamic stability.[7] Likewise, blood products are used as needed to maintain adequate hemoglobin concentration and coagulation.

History, Development, and Outcomes of Goal-Directed Fluid Therapy

A goal-directed, protocol-based approach to fluid and hemodynamic management has grown out of accumulating evidence that optimizing hemodynamic status improves outcome and that accurate assessment of volume and hemodynamic status using only standard, noninvasive monitors is often impossible. Certainly, for example, tachycardia, hypotension, and oliguria can result from either hypovolemia or hypervolemia (heart failure). GDT adoption has also resulted from the recognition that decreasing variability of practice using a best-evidence approach improves outcome. Decreasing process variability is essential to creating high-performance systems.[11]

Shoemaker and colleagues[12] used pulmonary artery catheter data to provide *supranormal* hemodynamics in high-risk surgical patients, reporting improved outcomes. Rivers and associates[13] applied early, aggressive fluid and hemodynamic management to septic patients admitted to the emergency department, showing dramatic improvements in mortality rate. This work, published in 2001, revolutionized the initial management of sepsis, such that the vast majority of tertiary care centers now have a sepsis protocol that incorporates an early goal-directed approach.

In 2002, Gan and colleagues[14] studied 100 patients undergoing major elective surgery, randomly assigning them to receive either standard therapy or GDT, based on esophageal Doppler parameters. The goal-directed group experienced shorter hospital stays (5 ± 3 days vs 7 ± 3 days), less nausea and vomiting, and earlier return of bowel function. The algorithm, based on corrected flow time (FTc) and

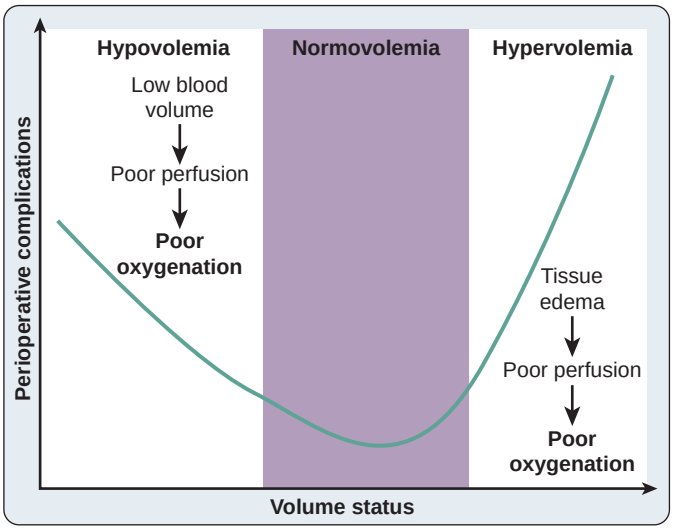

Fig. 47.4 Either hypervolemia or hypovolemia may cause impaired tissue perfusion and poor outcome. *(From Bellamy MC. Wet, dry or something else?* Br J Anaesth. *2006;97:755–757. Used with permission.)*

increases in stroke volume (SV) from colloid fluid boluses, is shown in Fig. 47.5. Numerous studies of a wide variety of surgical populations using various GDT algorithms and monitors showed benefits for the vast majority of patients.[15–21] Hamilton and associates[22] in 2011 performed a metaanalysis of 29 studies over the previous 30-year period, revealing reductions in mortality and morbidity associated with a goal-directed approach. The odds ratio for mortality was 0.48 (95% CI 0.33–0.78), and the odds ratio for surgical complications was 0.43 (95% CI 0.34–0.53). Corcoran and associates[9] performed a meta-analysis in 2012 comparing traditional with goal-directed approaches, showing improved outcomes associated with GDT. In a 2014 multi-institutional study of 734 high-risk gastrointestinal surgery patients (OPTIMISE Trial) conducted by Pearse and colleagues[23] survival and major complication benefit did not reach statistical significance. However, when this study data were included with a 38-study meta-analysis, decreased perioperative morbidity was observed (relative risk 0.77; 95% CI 0.71–0.83).[23]

Goal-Directed Fluid Therapy and Cost Reduction

With its decreased morbidity and hospital lengths of stay, it is anticipated that GDT will reduce costs. Financial benefits have been demonstrated with GDT, although the available studies are not recent and the pulmonary artery catheter was used.[24,25] Relatively little recent research in this area has been reported. Perioperative complications, in addition to being distressing to patients and health care delivery teams, dramatically increase health care costs. This increased cost results from an increased use of expensive resources (intensive care unit [ICU] and hospital beds, diagnostic tests, medical and surgical therapies), and the loss of opportunity (fewer patients can be cared for in the system). Volanthen and associates,[26] studying abdominal surgery, showed that patients with an uneventful course had a mean cost per case of $27,946, whereas patients with one or more complications had an *added* cost of $34,446. Boltz and colleagues,[27] who studied abdominal and vascular surgery, showed that for patients with one, two, or three perioperative complications the excess costs were $6,358, $12,802, and $42,790, respectively. In this large study, the average cost difference among patients who did and did not suffer complications was $22,398.

A recent study of the University HealthSystem Consortium (UHC) database, consisting of 120 academic medical centers and 300 of their affiliated hospitals, projected cost savings associated with GDT by applying the odds ratio of complications in high-risk surgeries from a recent metaanalysis to the actual costs of complications recorded in the UHC database.[28] The conservative projected direct cost savings per patient treated was $569 to $970, and $43 to $73 thousand for the entire UHC system per year. The mortality rate, hospital lengths of stay, and direct costs for patients with at least one complication versus those with no complications is presented in Table 47.1.

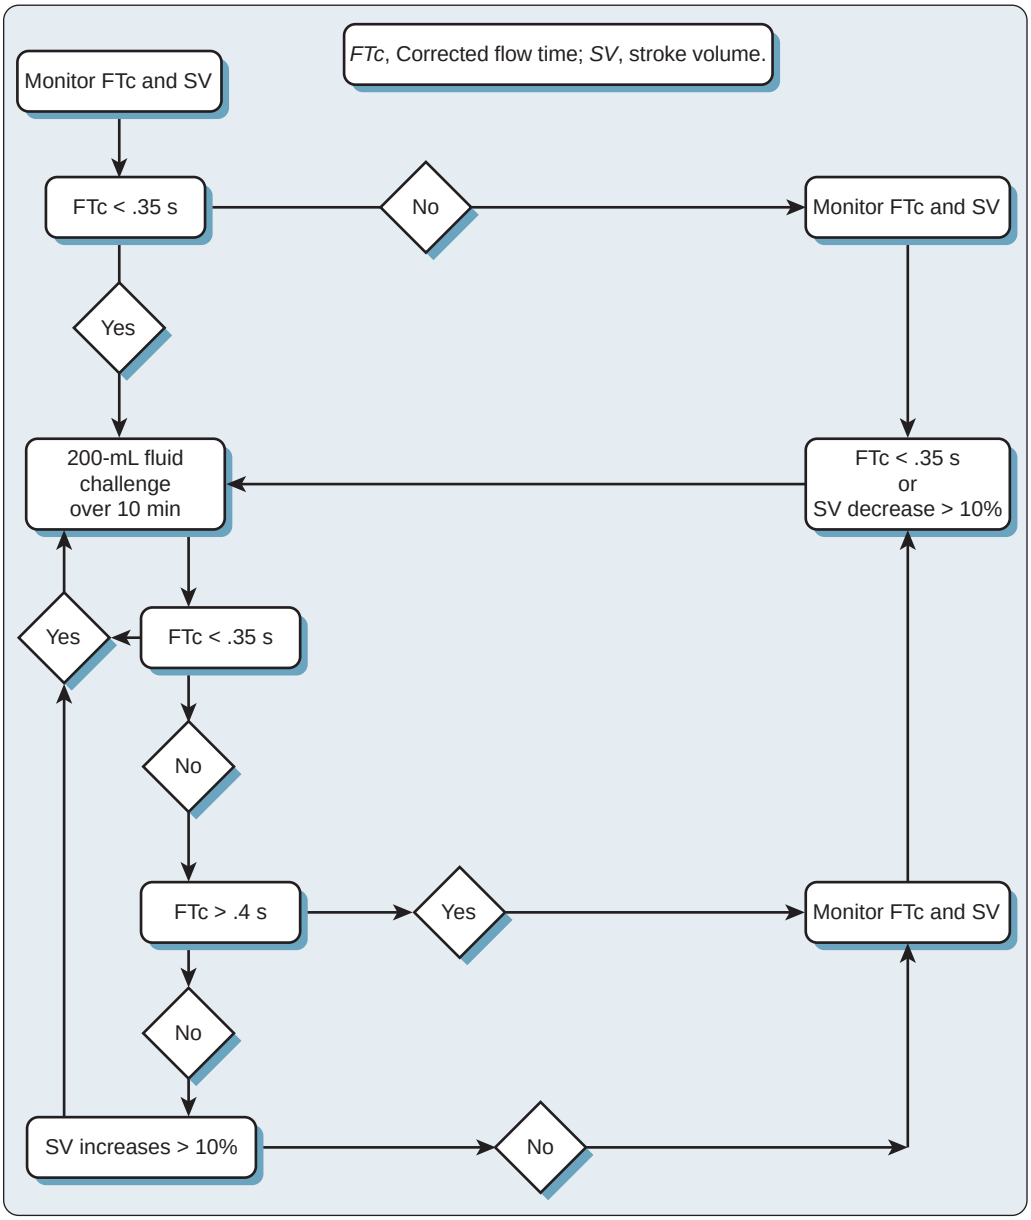

Fig. 47.5 Goal-directed fluid therapy algorithm. *(From Gan TJ, Soppitt A, Maroof M, et al. Goal-directed intraoperative fluid administration reduces length of hospital stay after major surgery. Anesthesiology. 2002;97:820–826. Used with permission.)*

TABLE 47.1 Mortality Rate, Hospital Length of Stay, and Direct Costs of Patients With No Surgical Complications Versus One or More Complications

	No Complications	*≥1 Complication*	*P Value*
Mortality rate	1.4%	12.4%	<0.001
Hospital LOS (days)	8.1 ± 7.1	20.5 ± 20.1	<0.001
Direct Costs (mean)	$17,408 ± $15,612	$47,284 ± $49,170	<0.001

LOS, Length of stay.

Monitoring for Goal-Directed Fluid Therapy

Various monitors have been used successfully in GDT, ranging from invasive (pulmonary artery catheter)[12] to noninvasive (finger plethysmographic waveform).[29] The data provided complement standard monitoring (heart rate, blood pressure) with parameters tracking overall cardiac performance such as cardiac output and SV, and/or indices of potential fluid responsiveness such as stroke volume variation (SVV), pulse pressure variation (PPV), arterial pulse wave analysis systems), and FTc esophageal Doppler. Monitoring of central venous oxygenation has been used to assess adequacy of the circulation.[13] Assessment of tissue perfusion by means of gastric tonometry has been used in GDT,[30] and attempts at evaluating tissue oxygenation (near-infrared spectroscopy) have been made as well[31] (see Chapter 13).

Each monitoring system has strengths and weaknesses, and their use should be tailored to individual situations and institutional preference. Although the accuracy of minimally invasive cardiac output monitors such as arterial waveform systems and esophageal Doppler has been questioned, the ability of the systems to assess and trend cardiovascular performance appears to be adequate for perioperative GDT. Of course, in critically ill or unstable patients, invasive monitors such as a pulmonary artery catheter and transesophageal echocardiography should be considered. Monitors used for GDT are presented in Table 47.2.

TABLE 47.2 Monitors for Goal-Directed Fluid Therapy (GDT)

Invasiveness	*Technology*	*Device*	*Parameters for GDT*	*Strengths*	*Weaknesses*
Invasive	Thermodilution cardiac output Pulmonary artery Central venous pressure	Pulmonary artery catheter	Cardiac output	Clinical gold standard for measuring cardiac output Vast amount of potentially useful data, including RV function	Is invasive Requires central venous access
	Transpulmonary thermodilution	PiCCO (PULSION Medical Systems) Central arterial catheter	Pulmonary artery and central venous pressure	Vast amount of potentially useful data, including thoracic blood volume and extravascular lung water	Is invasive Requires central arterial access
	Fiberoptic oximetry	Precep Catheter (Edwards Lifesciences)	Mixed venous and venous oxygen saturation	Assessment of global oxygen balance and extraction ratio	No direct information concerning cardiac performance or fluid responsiveness
Minimally Invasive	Doppler flow measurement Descending aorta	CardioQ (Deltex Medical)	Cardiac output	Most common monitor successfully used for GDT	Requires skill (placement)
	—	—	Corrected flow time (preload, afterload)	Newer systems incorporate arterial pressure wave	Inaccurate information concerning aortic cross-clamping, aortic aneurysm, aortic regurgitation
	Pressure wave pulsatility	Vigileo/FloTrac (Edwards Lifesciences)	Cardiac output Stroke volume variation (fluid responsiveness)	Easy to use Stroke volume variation be a powerful parameter combined with cardiac output	Inaccurate information concerning aortic cross-clamping, aortic regurgitation, cirrhosis, sepsis
Noninvasive	Finger cuff	ClearSight system (Edwards Lifesciences)	Cardiac output Stroke volume variation (fluid responsiveness)	Noninvasive	Potential accuracy issues Relatively unstudied in GDT
	Finger plethysmography	Pulse oximetry	Waveform variation	Noninvasive	Potential accuracy issues Relatively unstudied in GDT No cardiac output data
	Thoracic electrical impedance Bioreactance Velocimetry	NICOM (Cheetah Medical) ICON (Cardiotronics)	Cardiac output	Noninvasive	Potential accuracy issues Relatively unstudied in GDT

RV, Right ventricular.

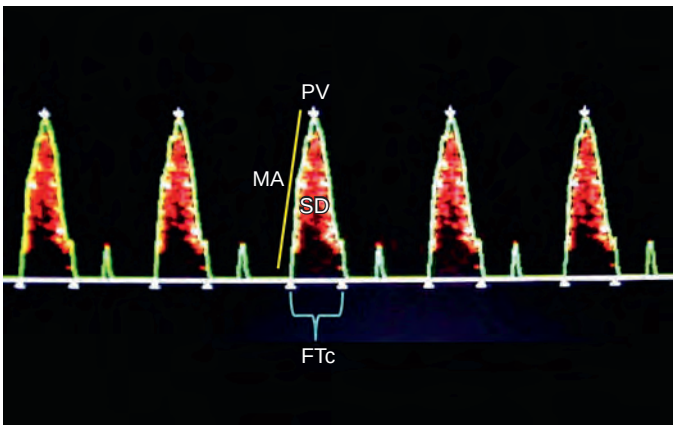

Fig. 47.6 Esophageal Doppler velocity-time waveform. *FTc*, Corrected flow time; *MA*, mean acceleration, *PV*. peak velocity.

The esophageal Doppler (CardioQ, Deltex Medical, Greenville, SC) is the most studied monitor for GCT. This system consists of a small probe placed in the esophagus that insonates the descending thoracic aorta. An estimation of the cross-sectional area of the aorta is made based on patient characteristics (age, height, gender, and weight) and the area under the velocity-time is calculated, with the terms velocity-time integral (VTI) and stroke distance (SD) used interchangeably. SD is multiplied by the aortic cross-sectional area to obtain SV:

$$SV = SD \times \text{Aortic cross-sectional area} \qquad \text{Eq 47.1}$$

Because of its common use (particularly in the United Kingdom) and its track record of utility in GDT, a number of algorithms have been developed for use with the esophageal Doppler monitor. These may use SV and FTc for volume responsiveness and afterload (see Fig. 47.5). Other potentially useful parameters include peak velocity and mean acceleration (contractility assessment) (Fig. 47.6).[32] Experienced

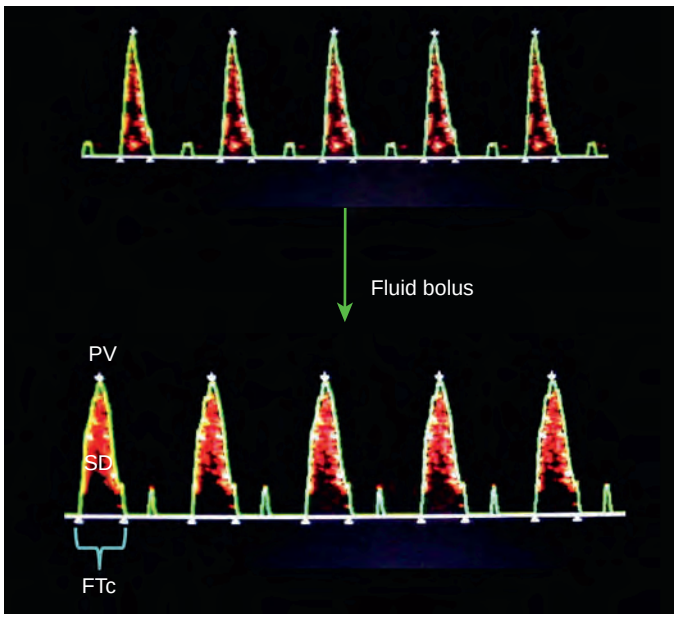

Fig. 47.7 Visual waveform inspection reveals a positive response to a fluid bolus, with increases in peak velocity (PV), corrected flow time (FTc), and stroke distance (SD).

users are able to recognize waveform changes that reflect changes in hemodynamics (Fig. 47.7). Newer esophageal Doppler systems can incorporate arterial pressure waveform analysis when an arterial catheter is used, allowing the added assessment of SVV and PPV. Proper placement and use of the esophageal Doppler system requires some practice, particularly in optimizing the velocity-time waveform. Approximately 15 practice sessions are required to gain facility.

The FloTrac/Vigileo (Edwards Lifesciences, Irvine, CA) sensor-monitor system is the most commonly used arterial pressure–based system used for GDT. An arterial catheter is required, and the arterial wave is digitized by a proprietary transducer. The SV is determined by the pulsatility of the wave (standard deviation of the arterial wave), and a *resistance-compliance* factor, K, is calculated using patient characteristics and characteristics of the waveform:

$$SV = K \times Pulsatility \qquad \text{Eq 47.2}$$

A list of potential monitors for GDT is presented in Table 47.2.

Noninvasive cardiac output monitoring systems are also available, using pressure waveform analysis from either the finger or the wrist.[33,34] A promising concept, these systems do not involve intravascular catheters or esophageal probes. Electrical impedance and cardiometry devices are available as well. Their use for GDT has yet to be firmly established, but it is likely that they will undergo further development.

In certain situations, particularly in critically ill patients, minimally invasive systems are inadequate to provide the detailed information that invasive methods such as pulmonary artery catheterization with thermodilution, transpulmonary thermodilution, and transesophageal echocardiography can provide. These advanced monitors provide the necessary information for GDT and allow for complex hemodynamic and cardiac problem-solving solutions as well (see Chapters 13 through 16).

Patient Selection for Goal-Directed Fluid Therapy

GDT is recommended for major procedures during which substantial blood loss or fluid shifts are anticipated. These may include major general, vascular, urologic, or orthopedic surgeries such as pancreatectomy, open colectomy, radical cystectomy (Box 47.2). Major patient comorbidities such as cardiac disease or a debilitated state may prompt the use of GDT as well. GDT has been studied in cardiac surgery with some positive results. Certainly cardiac anesthesiologists and surgeons apply goals, hemodynamic monitoring, and interventions in managing their patients perioperatively, but GDT as discussed in this chapter has not been widely adopted.

Algorithms in Goal-Directed Fluid Therapy

Numerous algorithms have been used successfully in GDT, with application of SV and preload responsiveness parameters such as PPV, SVV, and FTc. An algorithm based solely on the patient's SV response to fluid bolus is attractive because of its simplicity (Fig. 47.8) but has been associated with fluid overload in aerobically fit patients.[35] Algorithms based solely on SVV have been used, but application of SVV as a primary parameter are limited to patients without significant arrhythmias, receiving controlled positive-pressure ventilation.[36] Likewise, Doppler FTc has been used successfully as a primary parameter.[14] A synthesis of these approaches, with the use of blood pressure as an additional parameter to facilitate hemodynamic problem solving, is currently under study (Fig. 47.9).

A physiologic approach to GDT and hemodynamic problem solving can be achieved using a four-quadrant plot of blood flow (*x*-axis) versus blood pressure (*y* axis) with chosen target hemodynamics in the center of the plot. Deviations from the target zone, depending on the quadrant, are associated with a differential diagnosis and recommended management. This approach facilitates understanding of the hemodynamics leading to accurate, prompt diagnosis and management (Fig. 47.10).[37]

With all the effective algorithms available, the most important conclusion from the GDT literature is that using a logical, physiologically sound algorithm in a thoughtful way results in better outcomes than not using one at all. The choice of algorithm depends on the monitors available, the clinical situation, and the practitioner and institutional preferences. Evidence strongly suggests that using a systematic approach to fluid and hemodynamic management, with particular emphasis on avoiding fluid and salt overload, is indicated for patients undergoing major surgery.

Enhanced Recovery

Enhanced recovery after surgery (ERAS) programs have gained acceptance as a multifactorial, evidence-driven multidisciplinary way of managing patients undergoing surgery (Box 47.3). The primary goal of these programs is to facilitate rapid, complete, and comfortable recovery after procedures by minimizing physiologic perturbations and stress response. *Care pathways* for a variety of surgeries, primarily general and orthopedic, have been shown to achieve this goal, and emphasis is placed on minimizing the invasiveness of the surgery such as laparoscopic or small incision surgery. ERAS programs not only decrease complications but facilitate the return to baseline function even in the absence of complications. The primary components of ERAS programs are careful preoperative optimization; improvements in intraoperative management, particularly with regard to fluid and temperature management; multimodal opiate-sparing pain management; and early mobilization (see Fig. 47.3).

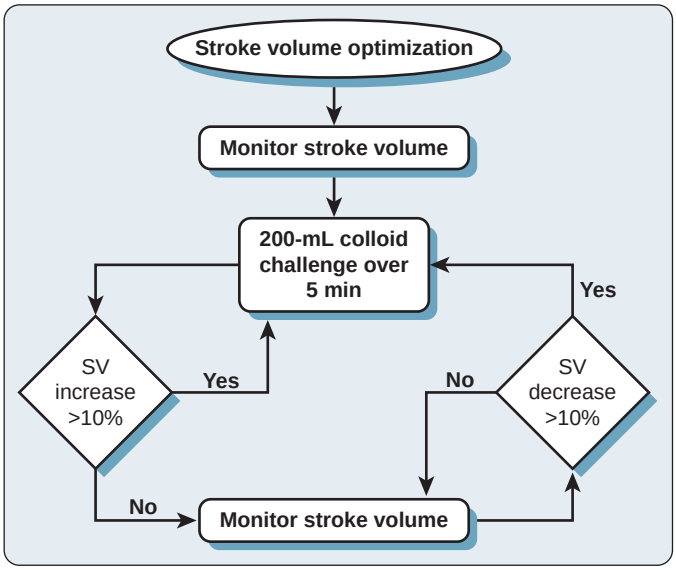

Fig. 47.8 A simple goal-directed fluid therapy algorithm based on responses to fluid bolus. *SV*, Stroke volume.

BOX 47.2 SURGERIES DURING WHICH GOAL-DIRECTED FLUID THERAPY IS RECOMMENDED[28]

- Exploratory laparotomy
- Resection bowel large; colectomy
- Whipple pancreatoduodenectomy
- Hepatectomy
- Splenectomy
- Kidney transplant
- Dissection of radical neck
- Aortofemoral, popliteal, or axillary bypass
- Total open abdominal hysterectomy or bilateral salpingo-oophorectomy
- Hyperthermic intraperitoneal chemotherapy
- Laminectomy fusion with instrumentation (>3 levels)
- Arthroplasty hip, knee, or elbow
- Excision burn
- Cystoprostatectomy with ileal conduit
- Radical cystectomy

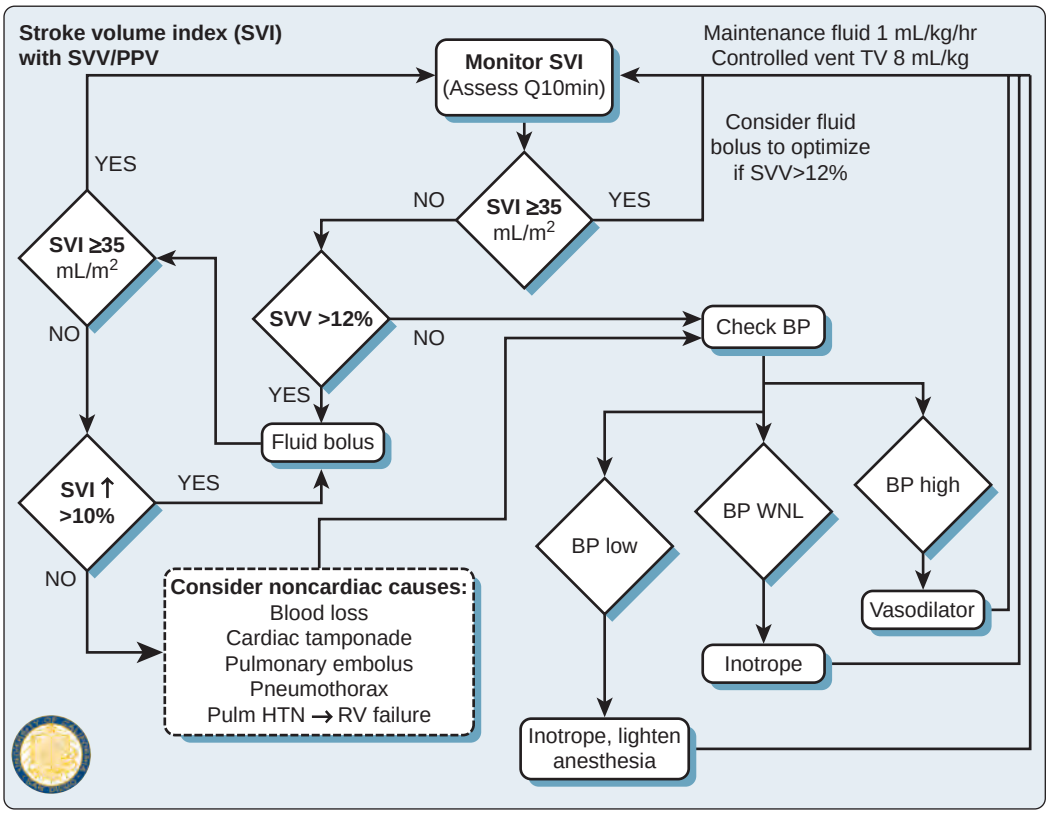

Fig. 47.9 Goal-directed therapy algorithm used at the University of California, San Diego. Stroke volume index (SVI) is the primary parameter, and the values of the targets can be adjusted according to clinical circumstances. Corrected flow time (FTc) can be substituted for stroke volume variation (SVV) for esophageal Doppler use, and an algorithm for use when SVV or FTc cannot be applied is available as well. *BP*, Blood pressure; *HTN*, hypertension; *RV*, right ventricular; *TV*, tidal volume; *WNL*, within normal limits.

BOX 47.3 ENHANCED RECOVERY PROGRAMS

- Preoperative optimization
- Minimally invasive surgery
- Avoidance of fluid and salt overload, goal-directed fluid therapy
- Careful temperature management
- Avoidance of perioperative nausea and vomiting
- Multimodal, opiate-sparing pain relief
- Early removal of catheters and drains
- Early mobilization

BOX 47.4 PERIOPERATIVE SURGICAL HOME REQUIREMENTS

- Multidisciplinary, coordinated effort
- Team leader
- Understanding and navigation of organizational complexities and politics
- Understanding the surgical and medical aspects of care
- Integration of enhanced recovery pathways
- Maintenance and close quality monitoring

ERP preoperative fasting guidelines call for fasting periods of 2 hours for clear liquids, 6 hours for a light meal, and a preoperative carbohydrate drink shortly before surgery. These feedings, along with reduced bowel preparation, result in improved volume and metabolic status at the time of surgery. Multimodal analgesia can be achieved with infiltration of the wound with a local anesthetic, regional techniques, intravenous (IV) or oral acetaminophen, nonsteroidal anti-inflammatory medications, dexmedetomidine, intravenous lidocaine infusion, gabapentinoids agents, and steroid administration. Although opiates should be available for break-through pain, their use should be minimized to facilitate a return of bowel function, decrease nausea and vomiting, and reduce the risk of respiratory depression.

Significant evidence suggests that ERPs decrease complication rates and the lengths of hospital stay. A recent metaanalysis of 16 randomized trials of ERP in colorectal surgery revealed a reduction in morbidity (relative risk, 0.60; 95% CI 0.46–0.76) and shortened hospital stays by 2.28 days, 95% CI 1.47–3.09.[38] Enhanced recovery quality improvement projects at institutional and national levels are now common, with the National Health Service Enhanced Recovery Partnership in the United Kingdom being an example.[39]

Perioperative Surgical Home

The PSH is an organizational umbrella under which ERPs may function (Box 47.4). Emphasizing the continuum that is required in ERPs and seamless care before, during, and after surgery, PSHs are now being formed as part of quality improvement and cost containment strategies. PSH has the strong backing and support of national organizations such as the American Society of Anesthesiologists, with large national meetings held on the subject.[40] Challenges in creating PSHs

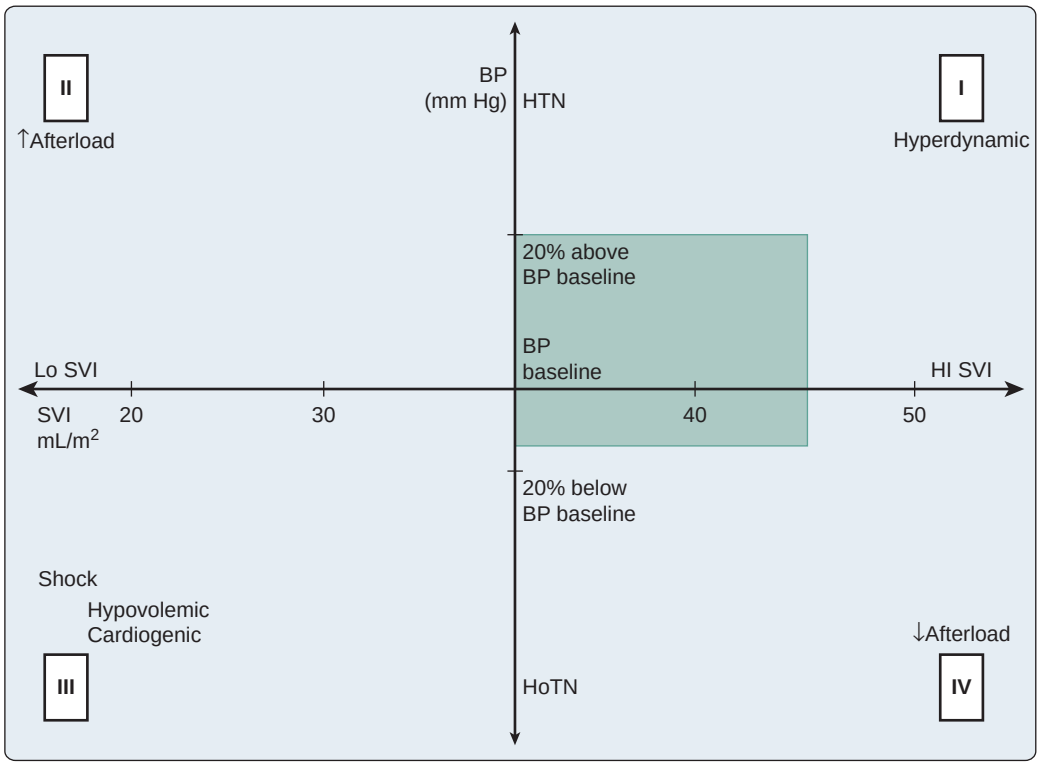

Fig. 47.10 A four-quadrant plot can be created by plotting the stroke volume index (SVI) on the *X* axis and mean arterial pressure (MAP) on the *Y* axis. A target zone (dark area) can be created, and deviations from the target zone are associated with hemodynamic aberrations specific to each quadrant. Point-of-care guidance for each quadrant can be provided. *BP*, Blood pressure; *HoTN*, hypotension; *HTN*, hypertension.

include the complexity of the perioperative care, communication and coordination between many team members, and institutional resistance to change. Anesthesiologists, with their wide scope of influence and organizational skills, will likely enhance their value to their health systems by increasing their involvement in the implementation and management of ERPs and PSHs.[41]

Vascular Surgery: Endovascular and Open Surgery

ELIZABETH A. VALENTINE, MD | E. ANDREW OCHROCH, MD, MSCE

KEY POINTS

1. Patients who present for cerebrovascular, aortic, or peripheral arterial interventions are at elevated risk for concomitant coronary artery disease.
2. A thorough preoperative assessment for cardiovascular disease and medical optimization of any comorbid conditions is essential prior to elective vascular surgery. This preoperative process is typically not possible for emergency vascular procedures.
3. The most significant risk factor for future stroke in the setting of carotid stenosis is the presence of recent symptomatic neurologic symptoms. Symptomatic high-grade carotid stenosis should undergo repair. The benefit of intervention for patients with symptomatic but moderate stenosis, or in asymptomatic patients with high-grade stenosis, is statistically significant although less robust.
4. Because of the high rates of mortality and morbidity associated with emergent repair, abdominal aortic aneurysms should be repaired if increasingly symptomatic, if rapidly expanding, or the aneurysm diameter exceeds 5 cm.
5. With aggressive medical management and lifestyle modifications, the natural history of claudication related to peripheral arterial disease is generally indolent and relatively benign. A small subset will progress to critical disease. In general, critical limb ischemia mandates surgical intervention. Timing for intervention in intermittent claudication should take into account severity and tolerability of the symptoms as well as patient-specific risk factors.
6. Endovascular interventions have become a mainstay of treatment for vascular disease. In general, short-term morbidity and mortality are improved with endovascular repair, although the early preoperative benefit is not always maintained in long-term follow-up.
7. Endovascular interventions have unique complication profiles and often warrant repeat intervention and life-time surveillance.

Cardiovascular disease (CVD) is common and clinically important. It is the leading cause of death both in the United States and worldwide.[1,2] Based on data from the Framingham Heart Study, the lifetime risk of developing CVD has been estimated to be greater than 50% in men and nearly 40% in women.[3] A metaanalysis of 18 cohorts across a larger patient demographic found similar results.[4] Although the total number of deaths attributable to cardiovascular events has declined over the past decade, CVD still accounts for nearly one in every three deaths in the United States.[5]

Among the various disease processes that can lead to CVD, atherosclerosis is the most common. (CVD is discussed in detail in Chapter 7.) The process of atherosclerotic plaque formation is both complex and dynamic, involving lipid deposition, smooth muscle proliferation, and an inflammatory milieu (Fig. 48.1). Autopsy studies have demonstrated fatty streaks visible to the naked eye first evident in childhood; the severity of disease increases with age and risk factors.[6] In adulthood, these lesions progress into fibrous plaques prone to rupture, erosion, and hemorrhage. The end result is a narrowed intravascular lumen that creates the potential for downstream ischemia due to mismatch between oxygen supply and demand.

CVD can be grouped into four major categories: coronary artery disease (CAD), cerebrovascular disease, aortic disease, and peripheral arterial disease (PAD). Depending on the location of the lesion, this can result in ischemia or infarction of the heart, brain, abdominal viscera, or limbs. Noncoronary atherosclerotic disease is considered a CAD equivalent and confers a risk of a major adverse cardiac event equivalent to CAD.[7] The 10-year risk of developing CAD in this patient population is greater than 20%.

Some risk factors for CVD, such as age, gender, ethnicity, and family history, are not modifiable. Others are controllable by lifestyle and pharmacologic measures. A large, international study identified nine potentially modifiable risk factors that contributed to greater than 90% of the patient attributable risk of a cardiovascular event: hypertension, dyslipidemia, diabetes, smoking, abdominal obesity, regular physical activity, daily consumption of fruits and vegetables, regular alcohol consumption, and psychosocial factors.[8] These associations were found across both sexes, at all ages, in all regions. Many of the risk factors for CAD and noncoronary atherosclerotic disease overlap, and patients with atherosclerotic disease in one area are at increased risk of vascular disease in other major vascular beds (Table 48.1). Thus, it is common to see significant CAD in patients undergoing major noncardiac vascular surgery, and vice versa.

General Considerations in Perioperative Management for Vascular Surgery

The goal of the preoperative assessment of the patient is to delineate the extent of underlying cardiac and noncardiac disease and medically optimize any underlying conditions. It is vital for the anesthesiologist to assess each organ system for underlying pathophysiology and the subsequent likelihood of leading to perioperative complications. Perioperative management must be tailored to the individual patient to protect any at-risk organ system. Because of the significant association of CAD, cerebrovascular disease, aortic degenerative disease, and PAD, a major focus of the preoperative assessment is to detect, evaluate, and optimize preexisting vascular comorbidities.

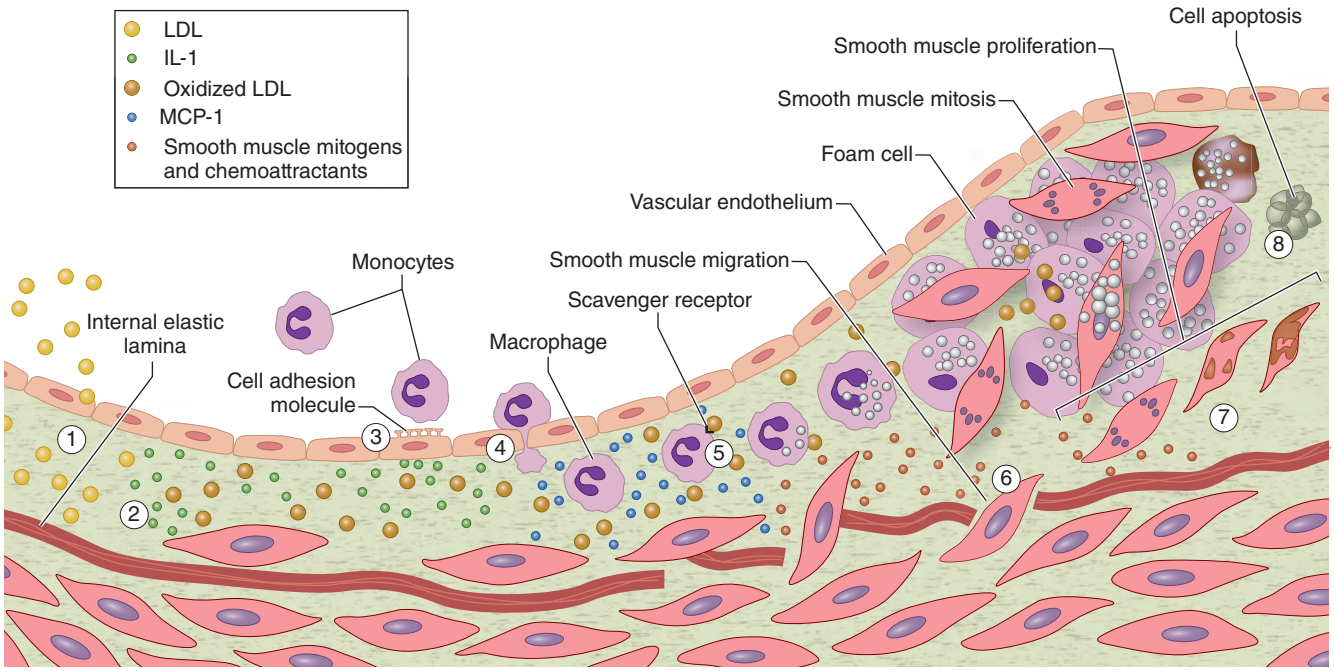

Fig. 48.1 Evolution of atherosclerotic plaque formation. *1,* Accumulation of lipoprotein in the intimal layer; *2,* oxidative stress; *3,* cytokine induction with expression of adhesion molecules; *4,* infiltration of inflammatory cells; *5,* development of foam cells and propagation of inflammatory mediators; *6,* smooth muscle migration; *7,* smooth muscle proliferation; *8,* calcification. apoptosis, and fibrosis. *IL-1,* Interleukin 1; *LDL,* low-density lipoprotein; *MCP-1,* monocyte chemoattractant protein 1. *(Redrawn from Libby P. The vascular biology of atherosclerosis. In: Mann DL, Zipes DP, Libby P, et al, eds.* Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine. *10th ed. Philadelphia: Saunders; 2015:873–890.)*

TABLE 48.1 Concomitant Rates of Atherosclerotic Disease in Major Vascular Beds

	Cerebrovascular Disease	*Abdominal Aortic Disease*	*Peripheral Artery Disease*
Coronary artery disease	8–40%	30–40%	4–40%
Cerebrovascular disease	—	9–13%	17–50%
Abdominal aortic disease	—	—	7–12%

Significant overlap exists in risk factors for coronary, cerebrovascular, aortic, and peripheral arterial disease. As many as 50% of patients with atherosclerotic disease in one vascular bed will have concomitant disease present in at least one other vascular distribution.

Data from references 195, 199, 249.

Preoperative Assessment

The preoperative assessment should evaluate for coronary and noncoronary atherosclerotic disease or risk factors. Because of the risk of anemia, as well as a significant risk for blood loss, a complete blood count to assess preoperative levels of hemoglobin and hematocrit should be obtained. A metabolic panel to assess baseline renal function is reasonable because of the likelihood of underlying renal insufficiency as well as risk for postoperative renal dysfunction. Coagulation studies should be considered for any patient who has been on anticoagulation and are mandatory if considering neuraxial manipulation either for anesthesia (eg, spinal or epidural) or therapeutic intervention (spinal drain—see Chapter 23). A preoperative electrocardiogram (ECG) is often useful to serve as a baseline for evaluation of a perioperative insult. A preoperative echocardiogram is reasonable to assess baseline function for any patient with cardiovascular risk factors undergoing vascular surgery, particularly if the patient has new or worsening symptoms.

The American College of Cardiology (ACC) and American Heart Association (AHA), in collaboration with the American Society of Anesthesiologists (ASA), Society of Cardiovascular Anesthesiologists (SCA), American College of Surgeons, and Society for Vascular Medicine, have released well-known guidelines regarding the perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery (see Chapters 1 and 43).[9] The most recent recommendations from these guidelines simplify previous risk stratification prior to elective surgery (see Fig. 43.4). The first step is to evaluate whether a clinical emergency exists; if so, the patient should proceed to surgery without delay with best medical optimization. The second step evaluates whether the patient has an acute coronary syndrome, which should be evaluated and optimized according to guideline-directed medical therapy before nonemergent surgery is performed. Subsequent steps rely on a combination of surgical risk calculators,[10,11] patient functional capacity,[12,13] and clinical decision making to determine if further cardiac evaluation is warranted prior to surgery. In general, patients undergoing vascular surgery represent at least an intermediate (>1%) risk for an adverse perioperative cardiac event and may benefit from additional testing if it will change perioperative management (see Chapter 43 for further details).

Several observational studies previously suggested that preoperative cardiac revascularization improves the outcomes of patients undergoing high-risk noncardiac surgery.[14,15] The Coronary Artery Revascularization Prophylaxis (CARP) study was the first and only randomized controlled trial to evaluate outcomes following prophylactic cardiac revascularization prior to major vascular surgery.[16] This study found no difference in outcomes in patients undergoing major vascular surgery who underwent routine revascularization by either coronary artery bypass grafting or percutaneous coronary intervention. A subsequent analysis found that patients with unprotected left main coronary artery disease may be the only subset of patients who benefits from prophylactic revascularization.[17] Subset analyses found

that of the cohort randomized to prevascular surgical intervention, patients who underwent coronary artery bypass grafting had a lower incidence of perioperative myocardial infarction (MI) and shorter length of stay (LOS) than those that underwent percutaneous coronary intervention.[18] This difference was attributed to better overall revascularization. In large part because of the results of the CARP trial, cardiac revascularization is not typically recommended before surgery unless otherwise indicated according to current practice guidelines.[19,20]

Preoperative Medication Management

It is incumbent on the anesthesiologist to work with the patient's surgical and medical teams to ensure medical optimization prior to surgery, including appropriate management of preoperative medications. As such, it is critical that the anesthesiologist recognize the potential benefits and risks of maintaining, stopping, or initiating medications in the perioperative period (see Chapter 43).[9]

As a general rule, most antihypertensive medications should be continued in the perioperative period.[9] Perhaps no medication has been as extensively studied or widely debated as perioperative β-blockade. Kaplan and colleagues first reported the safety of continuation of β-blockade in the 1970s.[21] Shortly thereafter, Slogoff and coworkers demonstrated an increase in myocardial ischemia in patients on chronic β-blockade when withdrawn before surgery.[22] The preponderance of evidence suggests that patients on chronic β-blockers should be continued on the medication in the perioperative period.[23–26] β-Blockers not should be instituted as new therapy on the day of surgery because of an increased risk of stroke and death.[9,27] It is reasonable to consider β-blockade in high-risk vascular patients prior to surgery, according to the latest ACC/AHA guidelines.[9] This decision should be made in conjunction with the surgical and medical teams caring for the patient.

Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers are generally considered to be beneficial in patients with CVD.[9] They have also been associated with perioperative myocardial and renal protection in adult cardiac surgical patients.[28–30] On the other hand, a large, retrospective observational study in the cardiac surgery population demonstrated that perioperative angiotensin blockade was significantly associated with found vasoplegia, atrial fibrillation, renal failure, and death.[31] Although further randomized controlled trials are warranted, current guidelines suggest it may be reasonable to continue them in the perioperative period.[9,32,33] A reasonable compromise may be to withhold these medications for about 24 hours prior to anesthetic induction to minimize the risk of perioperative vasoplegic hypotension.[34]

The statins have also enjoyed considerable interest because of their known beneficial pleiotropic effects.[35,36] Multiple trials have demonstrated that statins are effective in stroke prevention, independent of their lipid lowering effect.[37–39] Perioperative statin therapy has also been associated with the reduction of perioperative cardiac morbidity and mortality in vascular surgical patients.[40–44] Current guidelines recommend that statin therapy should be continued in the perioperative setting and that it may be reasonable to initiate statin therapy in patients undergoing vascular surgery.[9]

Management of antiplatelet agents must balance the risk of stopping medications versus the risk of bleeding in the perioperative period, particularly in the setting of recent percutaneous coronary intervention with coronary stents.[9] This decision must be made in consultation with the surgical and medical teams managing the patient. In general, it is reasonable to continue aspirin if the risk of adverse cardiac event outweighs the risk of bleeding.[9,45] Management of anticoagulation must be tailored to the individual patient and surgical risks. Patients on anticoagulation deemed high risk may benefit from hospital admission for bridging therapy with heparin and/or antiplatelet therapy before entering the operating room[9] (see Chapters 43 and 44). No guidelines exist to guide management of diabetic medications in the perioperative setting. It may be prudent to hold oral hypoglycemics to prevent unintended hypoglycemic episodes, particularly under general anesthesia. Metformin, in particular, may pose a risk for lactic acidosis in the setting of hypovolemia and iodinated contrast agents frequently used in vascular surgery.[46] Insulin dosing should be adjusted in the setting of preoperative fasting. Blood glucose should be monitored closely in the perioperative setting and covered appropriately with insulin therapy, although recent evidence does not support tight control.[47,48]

Premedication for Anxiolysis and Analgesia

The major goals of premedication for the vascular surgical patient are to reduce anxiety and to provide analgesia for any painful procedures prior to induction of anesthesia. In addition to meeting these basic goals, management of pain and anxiety in the patient with CVD has the distinct benefit of reducing sympathetic stimulation and the risk of myocardial ischemia. Because these patients may also be exquisitely sensitive to narcotics and anxiolytics, these agents should be titrated slowly to clinical effect. When receiving sedation, patients should receive supplemental oxygen and be continuously monitored with pulse oximetry, electrocardiography, and noninvasive blood pressure measurements.

Intraoperative Anesthetic Management

The primary anesthetic used during vascular surgery will depend on factors such as the patient, the surgeon, anatomic considerations, and invasiveness of the surgical procedure. As such, anesthetic techniques are discussed in subsequent sections. On arrival to the operating room, all patients should be placed on standard ASA monitors, including regular noninvasive blood pressure measurement, pulse oximetry, and continuous electrocardiography. Lead V_5 is usually cited as the most sensitive for diagnosing acute myocardial ischemia, although its sensitivity is not perfect, ranging from 66–85%.[49,50] The combination of multiple precordial leads increases the sensitivity to 80–85%, and the addition of lead II increases the sensitivity to higher than 95%.[49,50] It is prudent to place an arterial catheter for invasive blood pressure monitoring for all but the most minor of vascular procedures because of the inherent risk for rapid hemodynamic changes. Patient comorbidities, cross-clamping on major vascular structures, and potential for hemorrhage all contribute to the hemodynamic instability frequently observed during these procedures. Invasive arterial monitoring also allows for frequent blood sampling to assess ventilation and oxygenation, ongoing blood loss and resuscitation needs, and overall metabolic milieu. Because induction of general anesthesia and endotracheal intubation are among the more hemodynamically labile periods, placing the arterial monitoring prior to induction of general anesthesia is wise.

Invasive monitoring with central venous or pulmonary arterial cannulation is not routine for most vascular procedures. Common exceptions include open aortic procedures or when patient comorbidities dictate utility. Large-bore intravenous access, either peripheral or central, is mandatory for any major vascular procedure because of the inherent risk of blood loss and need for resuscitation. Active type and screen and adequate blood product availability should be confirmed before any major vascular procedure is performed.

Although transesophageal echocardiography (TEE) is the most sensitive method for detecting intraoperative myocardial ischemia, it has not supplanted clinical assessment and routine electrocardiography for determination of patients at risk for myocardial ischemia during noncardiac surgery.[9,50–52] The ASA, in conjunction with the SCA, has released practice guidelines for the intraoperative use of TEE.[52] In general, expert opinion has recommended that TEE should be considered in noncardiac surgery in the following circumstances: when the patient has cardiovascular disease that may result in significant clinical compromise, when life-threatening hypotension is anticipated, and when persistent unexplained hypotension and/or hypoxia occurs.[52] Furthermore, these practice guidelines recommend that TEE be strongly considered for major open abdominal aortic procedures and that TEE does not have a routine role during endovascular aortic and distal procedures.[52]

Postoperative Management

In general, patients can undergo tracheal extubation uneventfully in the operating room and recover in the postanesthesia care unit following most vascular surgical procedures. Patients undergoing major abdominal aortic procedures may benefit from close surveillance and management in an intensive care unit setting where mechanical ventilation is frequently continued after initial admission to the unit. In this case, sedation and analgesia should be provided with short-acting agents to facilitate rapid emergence and serial neurologic assessments. Common complications following major vascular surgery include myocardial ischemia, hemodynamic lability, stroke, coagulopathy, renal failure, respiratory failure, coagulopathy, hemorrhage, hypothermia, delirium, and metabolic disturbances.

Carotid Artery and Cerebrovascular Disease

Stroke is important because it is common and clinically serious. An imbalance between blood supply and demand to the brain can result in permanent cerebral infarction (stroke) or transient ischemic attack (TIA), conventionally defined as a focalized neurologic deficit lasting less than 24 hours with no evidence of permanent infarction. Strokes can be defined as ischemic, characterized by disruption of blood flow through a vessel, or hemorrhagic, characterized by bleeding into the brain parenchyma or surrounding spaces.[53] Approximately 87% of strokes in the United States are ischemic in origin.[53] Ischemic strokes can be further subcategorized into five subtypes: cardioembolic strokes, large vessel disease strokes, small vessel disease strokes, strokes related to unusual causes, and strokes of undetermined cause.[54] At least 20% of ischemic strokes are related to extracranial atherosclerotic disease such as carotid stenosis.[55,56]

Clinical Features and Natural History

Stroke is a leading cause of permanent disability and death worldwide.[5,57,58] It is estimated that more than 6 million Americans have suffered a clinical stroke for an overall prevalence of nearly 3% and that the prevalence of clinically silent strokes is 2- to 10-fold higher.[58–61] The global burden of stroke is staggering, accounting for about 10% of deaths worldwide and billions of dollars in stroke-related medical costs.[62,63]

The prevalence of carotid artery disease rises with age, male gender, and racial minorities.[64–69] Although TIAs resolve, they are clinically important because they are a strong predictor of clinical stroke in the near future.[70,71]

Major Milestones in Carotid Artery Intervention

Fisher first described the link between extracranial carotid disease and cerebrovascular disease in 1951.[72,73] Soon thereafter, in 1953, DeBakey described the first successful carotid endarterectomy (CEA) with significant disease-free long-term follow-up.[74] The popularity of CEA has subsequently increased as a result of strong evidence supporting carotid disease as a risk factor for stroke and death.[75–77] Further randomized trials after 1990 repeatedly demonstrated clinical benefit of CEA for both symptomatic and asymptomatic carotid atherosclerosis.[78–84] Mathias first described percutaneous angioplasty of the carotid artery in 1977.[85] Although balloon expandable stents were first introduced in 1989, their use disseminated after the introduction of embolic protection devices that reduced the risk of stroke in the early 1990s.[86,87] Since then, multiple high-quality trials, including meta-analyses, have compared carotid artery stenting (CAS) to CEA.[88–92]

The determination of when and how to intervene to treat carotid atherosclerotic disease is complex. The stroke risk related to the disease itself must be balanced with the stroke risk associated with the chosen intervention. Furthermore, surgical decision making must also take into consideration patient-specific risk factors and risk factors for open (CEA) versus endovascular (CAS) management.

Symptomatic Carotid Atherosclerotic Disease: Indications for Intervention

Symptomatic carotid disease is defined as the onset of sudden and focal neurologic symptoms, either temporary or permanent, that are ipsilateral to the carotid pathology. The most important indicator of future stroke risk is the presence of symptoms within the previous 6 months. Three landmark clinical trials have investigated the benefit of CEA versus medical management for patients with symptomatic carotid disease.[78,80,93]

The North American Symptomatic Carotid Endarterectomy Trial (NASCET) was a prospective, multicenter, randomized trial of more than 650 patients with TIA or nondisabling stroke with either moderate (30 to 69%) or severe (70–99%) degree of occlusion of the ipsilateral carotid artery.[78,79] Patients were randomized to either best medical therapy or best medical therapy plus CEA. The study was prematurely terminated in the severe disease group because of overwhelming evidence that surgery was beneficial in this cohort. Although risk of stroke or death was higher at 30 days for the surgical group, longer term outcomes related to stroke and death at 2 years were significantly improved in the surgical cohort. Subsequent study of patients with moderate symptomatic carotid stenosis demonstrated a potential, albeit more modest, degree of benefit in patients with 50–69% stenosis.[79] Patients with stenosis less than 50% did not benefit from surgery. Long-term follow-up in the severe cohort has continued to favor CEA.[94]

The European Carotid Surgery Trial (ECST) was a multicenter, prospective, randomized trial enrolling more than 3000 patients with symptomatic carotid disease to medical management versus medical management plus open surgical intervention.[80] Demonstrable benefit for CEA was found for symptomatic carotid stenosis above 80% for the primary outcome of major ipsilateral stroke or death. Because different methods of measurement of stenosis were used in these two trials, it must be remembered that the carotid stenosis category of 80% in the ECST is approximately equivalent to the 70% category defined by the NASCET criteria.

The Veterans Affairs Cooperative Studies Program (VACSP) trial was a prospective, randomized, multicenter trial of 16 Veterans Affairs Medical Centers. Individuals with angiographically identified carotid stenosis greater than 50% presenting within 120 days of stroke or TIA were randomized to CEA plus best medical therapy versus best medical therapy alone.[93] At a mean follow-up of almost 1 year, a significant reduction in stroke or crescendo TIA was demonstrated in the surgical arm. This benefit was most pronounced in patients with greater than 70% stenosis. An important limitation to this study is that only men were enrolled.

Subsequent pooled analyses of the combined data from the NASCET, ECST, and VACSP trials have been performed.[95,96] A consistent benefit was demonstrated for patients with greater than 70% stenosis, with a number needed to treat (NNT) of 6.3 to prevent one stroke over 5 years. A benefit was also demonstrated in patients with moderate (50–69% stenosis), although less robust. The NNT to prevent one stroke over 5 years in this population was 22. There was no significant benefit of CEA in patients with near total occlusion of the internal carotid artery. CEA also was not beneficial in patients with less than 50% carotid stenosis and was found to be harmful for patients with less than 30% stenosis. Taken together, these studies suggest a clear benefit to CEA for patients with high-grade stenosis.

Asymptomatic Carotid Atherosclerotic Disease: Indications for Intervention

Three major trials have evaluated the utility of CEA in patients with asymptomatic carotid disease.[81–84] The Veterans Affairs Cooperative Studies Program (VASCP) was a prospective, multicenter, randomized

trial of more than 400 men with asymptomatic carotid stenosis of greater than 50% as assessed by angiography, assigned to best medical therapy or best medical therapy plus CEA.[84] A statistically significant reduction in the incidence of ipsilateral neurologic events was noted in the surgical group; however, the combined incidence of 30-day stroke and death showed no benefit from operative intervention.

The Asymptomatic Carotid Atherosclerosis Study (ACAS) was a prospective, multicenter, randomized trial of more than 1600 asymptomatic patients with carotid stenosis greater than 60%, randomized to best medical therapy alone versus best medical therapy and CEA.[81] The primary end point was stroke in the distribution of the study artery or any stroke or death in the perioperative period. After more than 2 years of follow-up, the rate of stroke or death was reduced by more than 50% in the surgical group compared with the medical group.

The Asymptomatic Carotid Surgery Trial (ACST) is the largest prospective, multicenter, randomized trial in the asymptomatic population.[82,83] Asymptomatic patients with greater than 60% stenosis were randomized to immediate CEA versus deferral and medical management until symptoms occurred. All remaining medical management was left to the discretion of the treating physicians. The net 5-year risk for all strokes or perioperative death was reduced in the surgical arm by nearly half. Similar results were found in fatal or disabling stroke. The benefit of CEA was statistically significant for contralateral as well as ipsilateral stroke; improved collateral flow via the circle of Willis is the speculated mechanism for contralateral stroke reduction.

A metaanalysis of these three trials demonstrated a small absolute risk reduction of about 3% for the outcome of any stroke for patients with asymptomatic carotid disease who underwent CEA.[97] The NNT to prevent one stroke at 3 years was approximately 33. The net benefit to CEA in asymptomatic patients is delayed because of perioperative morbidity; the early perioperative morbidity outweighs the modest reduction in stroke risk until 2 years or more after surgery. Thus, asymptomatic patients with between 50% and 70% stenosis must be carefully selected to have at least a 5-year expected survival to benefit from surgical intervention.

Carotid Artery Stenting

Carotid artery angioplasty and stenting (CAS) is an alternative to open surgical intervention for patients with carotid atherosclerotic disease, particularly for patients considered to be poor candidates for surgery or anesthesia. Proponents of this minimally invasive technique cite the apparent ease, speed, and comfort for patients over traditional open repair with CEA. Accumulating evidence suggests similar long-term outcomes between CEA and CAS. Significant differences in short-term morbidity and mortality have been found between the two procedures. Furthermore, the ability to predict which patients may be at high risk for adverse outcomes following open repair has been challenged; although better patient selection has been associated with decreased perioperative complications with CAS, most data were not adequately powered to detect treatment differences between different patient groups.

Endovascular treatment of carotid disease has been extensively studied. The Carotid Revascularization Endarterectomy versus Stenting Trial (CREST) is the largest randomized controlled trial to date comparing CEA with CAS. The physicians enrolled more than 2500 standard-risk patients with either symptomatic or asymptomatic carotid artery disease.[88–92] This study failed to show a difference in composite end point of stroke, MI, or death at 30 days, plus any ipsilateral stroke during long-term follow-up.[88] However, several significant differences were found between CEA and CAS. The rate of adverse events in patients age 70 and older significantly favored CEA over CAS; stenting appears to be more beneficial for younger patients whereas CEA may be more appropriate for older patients.[91] Thirty-day stroke and stroke/death rates were significantly higher in the CAS arm. Thirty-day MI rates were significantly higher in the CEA group. At 1 year after intervention, quality of life was found to be significantly diminished for patients who developed stroke, even minor stroke, compared with those who suffered an MI.[88,90] Stroke complications were associated with poorer long-term survival, with an estimated 4-year mortality after any periprocedural stroke of 21.1% versus 11.6% for patients without stroke.[98] However, the importance of periprocedural MI must not be discounted: subsequent analysis found the mortality rate at 4 years was significantly higher for both patients who developed MI and those with asymptomatic cardiac biomarker increase only, a difference that persisted with adjustment for baseline risk factors.[92]

Multiple metaanalyses have evaluated the use of CAS compared with CEA to treat carotid disease.[99–103] The most recent review was performed by Bonati and associates and included 16 trials involving 7572 patients.[99] In patients with symptomatic carotid stenosis with standard surgical risk, CAS was associated with a greater risk of periprocedural stroke or death, death or any stroke or MI, and any stroke. In subgroup analysis, this difference was significant only in patients aged 70 or older. The end point of death or any stroke up to 30 days after treatment or ipsilateral stroke during long-term follow-up was greater in the CAS group, but the rate of ipsilateral stroke after the initial 30-day perioperative period did not differ between treatments groups, suggesting that beyond the immediate risk, results are similar between the two groups. CAS was favored in terms of risk of MI and cranial nerve palsy. The remainder of recent meta-analyses generally agree that the early risk of stroke or death is increased with CAS versus CEA, whereas long-term outcomes are similar between the two groups. The increased risk is generally noted in patients older than 70 years, suggesting that CAS may be a more reasonable alternative in a younger population. Periprocedural rates of MI are increased following CEA compared to CAS.[100,101] The main caveat of these metaanalyses is that data from early stent trials may introduce bias because of the changes in stent technology and practitioner expertise.

Additional Factors Influencing Surgical Decision Making

Carotid intervention may also depend on factors beyond symptom status and degree of stenosis. Both plaque progression and contralateral carotid disease have been associated with an increased stroke risk.[104–107] The Oxford Plaque Study histologically graded the stability of carotid plaque and noted that inflammatory changes were most commonly seen in symptomatic unstable lesions.[108] Plaque characteristics such as ulceration and echolucency also appear to be unstable and increase stroke risk.[109,110] Unstable carotid plaque has also been associated with clinically silent microembolic strokes that are related to substantial risk of clinically significant stroke.[111]

Patient factors such as age and gender may also influence the decision for carotid intervention.[112] Older patients appear to be at higher risk for adverse events with CAS compared to CEA, as outlined earlier. In both symptomatic and asymptomatic trials of CEA versus medical management, the benefit of CEA appears to be greater for men than for women, particularly in asymptomatic patients.[78–82] Rockman and investigators found that women were at higher risk of stroke following CAS compared to CEA for both symptomatic and asymptomatic patients.[113] This may be due to a greater embolic potential in female carotid plaque.[114] In general, women tend to derive less benefit from carotid intervention than do men, particularly with CAS and in the absence of symptoms. Medical management may be considered for female patients unless symptomatic disease is present.

Adverse factors such as excessive patient comorbidity, scar tissue from previous neck surgery or radiation, and the presence of a tracheal stoma are typically associated with high surgical risk and are indications for CAS. Carotid lesions above the second cervical vertebra or below the clavicle are also less amenable to surgical intervention. Alternatively, severe aortic arch atheroma or significant carotid tortuosity typically increase the rate of complications in patients undergoing CAS and are indications for CEA. The complication rate of the surgeon must also be taken into account when weighing the risk and benefits of carotid intervention for the individual patient.

Finally, the significant advances in best medical therapy for cerebrovascular disease since the early trials of carotid intervention may challenge the role of carotid intervention in patients with asymptomatic disease.[115,116] Further randomized controlled trials are required to define the role of carotid intervention in the modern era of medical management.

Anesthetic Considerations and Management for Carotid Artery Intervention

Preoperative Evaluation and Preparation

Because the risk factors for cerebrovascular and coronary disease overlap significantly, CAD is common and important in patients with carotid artery stenosis.[117] Up to 50% of patients with large vessel cerebrovascular disease have abnormal stress tests despite no known underlying cardiac disease: the underlying CAD is frequently severe.[118] Carotid intimal thickness has also been associated with the clinical extent of CAD.[119] Because CAD is prevalent in patients with carotid arterial disease, it is a primary focus of the preoperative evaluation prior to carotid revascularization.[120] Patients should be risk stratified according to current ACC/AHA guidelines (see Chapter 43).[9]

Intraoperative Anesthetic Technique

Carotid revascularization can be performed under general anesthesia or under local anesthesia. The primary advantage of local anesthesia is the ability to continuously monitor neurologic function in an awake patient, which may more reliably detect cerebral ischemia than the neuromonitoring methods utilized under general anesthesia. Because the need for intraoperative intervention in the awake patient may be detected more promptly and reliably, it can minimize the risks of intervention such as embolic risk of shunt placement. Local anesthetic techniques may also avoid hemodynamic extremes and cardiorespiratory morbidity associated with general anesthesia. General anesthesia, on the other hand, has the benefits of increased patient comfort, decreased patient anxiety, and airway control. It also avoids the need for emergent intraoperative conversion consequent to complications such as seizure and airway compromise.

A recent survey at major academic centers demonstrated a wide divergence in perioperative practice for carotid surgery, indicating a lack of consensus about best practices.[121] Patient outcomes following general versus local anesthesia has been the subject of extensive study.[122–125] The largest and best known study is the General Anaesthesia versus Local Anaesthesia for carotid surgery (GALA) trial that randomized more than 3500 patients undergoing CEA, at 95 medical centers in 24 countries, to either general anesthesia or local anesthesia.[123–125] In this investigation, there were no differences in major adverse events between the two groups with respect to death, stroke, MI, LOS, and quality of life.[123–125] Patients undergoing general anesthesia were more at risk for hemodynamic instability and perioperative cognitive dysfunction. A subsequent study, however, demonstrated that intraoperative shunting was the main risk factor variable associated with perioperative cognitive dysfunction.[126] A recent large meta-analysis ($N = 4596$; 14 randomized clinical trials) demonstrated that anesthetic technique had no effect on death, stroke, MI, postoperative cardiopulmonary complications, hospital LOS, or patient satisfaction after CEA.[122] In this meta-analysis, the use of intraoperative shunting was more common in the general anesthesia group.[122] In summary, the available literature does not support the use of one anesthetic technique over another for carotid surgery. The decision for general versus local anesthesia should consider both patient and surgeon preferences as well as unique patient characteristics that might favor one technique over another. Regardless of technique, the goals of the anesthetic are the same: maintain hemodynamic norms and ensure smooth, rapid recovery from anesthesia to allow for early neurologic assessment.

Local Anesthesia Technique for Carotid Endarterectomy

Local anesthesia is performed with or without a nerve block, usually in conjunction with intravenous sedation to minimize patient discomfort and anxiety. It is important to limit sedation so as to maintain the ability to monitor the neurologic status. Local anesthetic options include cervical epidural injection or superficial cervical plexus block with or without deep cervical plexus block. Superficial cervical plexus block, with or without deep plexus block, is more commonly used because it has demonstrated a significantly lower rate of complications.[127] A superficial cervical plexus block has been found to be as effective as a deep or combined block and can avoid the complications of a deep cervical plexus block such as subarachnoid injection, phrenic nerve blockade, Horner syndrome, and increased risk of conversion to general anesthesia.[128–130]

The ability to rapidly convert to a general anesthetic must be ensured before CEA is performed under local anesthesia. Despite concerns, the rate of conversion to general anesthesia has been reported to be relatively low, occurring in only 4% of patients in the GALA trial.[123] Indications for conversion to general anesthesia include patient intolerance or request, accidental subarachnoid injection with brainstem anesthesia, seizure (related to intravascular injection of local anesthetic), airway compromise (from surgery or oversedation), or other hemodynamic or surgical complication. Patient selection is key to the success of local anesthesia. The patient cannot be claustrophobic (drapes are immediately adjacent to and across the patient's face) and must be able to lay flat and still for the duration (arthritis, chronic obstructive pulmonary disease [COPD], heart failure, and other comorbidities may make this difficult for patients).

General Anesthetic Technique for Carotid Endarterectomy

A major goal during the induction and maintenance of a general anesthetic is to avoid hemodynamic extremes such as the lows (during induction with agents with vasodilatory effects) or the highs (during periods of intense sympathetic stimulation, such as intubation and surgical incision). To this end, a variety of anesthetic agents can and have been used. Typically, a balanced anesthetic technique is employed. Induction of general anesthesia should involve the slow titration of a short-acting hypnotic agent, titrated to effect. The addition of a short-acting opioid may blunt the hemodynamic response to endotracheal intubation. General anesthesia can be maintained effectively with either volatile or intravenous agents.[131] Anesthetics must be titrated to minimize interference with any intraoperative monitoring techniques such as electroencephalography.

In general, endotracheal intubation is preferred because of limited access to the airway during the procedure and the greater ability to manipulate ventilation. The use of a laryngeal mask airway has been described and may avoid some of the complications associated with endotracheal intubation (sympathetic stimulation, coughing with suture line disruption and/or hematoma).[132] Normocapnia should be maintained during the procedure to avoid both a decrease in cerebral blood flow associated with hyperventilation and vasoconstriction, as well as potential intracerebral "steal" during permissive hypercapnia.

Intraoperative Hemodynamic Monitoring

Invasive arterial blood pressure monitoring should be considered because there is potential for sudden hemodynamic changes as a result of anesthesia or surgical manipulation.

Stroke during carotid intervention may result from inadequate cerebral perfusion due to hypotension, thrombosis, embolism, and/or carotid clamping in the setting of insufficient collateral flow from the circle of Willis. Cerebral ischemia can be mitigated if the insult is detected in timely fashion and appropriate interventions are made. An intact neurologic examination in an awake patient remains the gold standard for neurologic monitoring and provides a rationale for carotid intervention under local anesthesia. In this setting, a baseline neurologic assessment is performed before sedative medication is administered. Thereafter, the sedation is titrated to achieve both patient comfort and cooperation with serial neurologic evaluations during the procedure, especially during carotid manipulation and

clamping. A change in neurologic function may require interventions to restore cerebral perfusion; these interventions might include shunt placement and/or permissive systemic hypertension to augment collateral flow via the circle of Willis.

If a general anesthetic technique is chosen, a variety of neuromonitoring techniques are available to monitor for cerebral ischemia during carotid intervention; these techniques include EEG, carotid stump pressure, somatosensory-evoked potentials (SSEPs), transcranial Doppler, and cerebral oximetry[133] (see Chapter 18). Intraoperative EEG is a commonly used neuromonitoring modality. Unprocessed EEG is preferred over processed EEG (eg, bispectral index) because bispectral index monitoring has not been reliably shown to predict cerebral ischemia in this patient population.[134,135] Significant alterations during carotid intervention in the electroencephalographic tracings, such as complete signal loss, a 50% decrease in background activity, and/or an increase in delta wave activity, may indicate intraoperative ischemia and the need for intervention. The clinical studies supporting the utility of routine EEG monitoring during carotid intervention are limited and not conclusive.[136,137] Because both intravenous and volatile anesthetic agents may affect the electroencephalographic tracings, close communication between the anesthesia and neuromonitoring teams remains essential to minimize this anesthetic interference and to maximize both the sensitivity and specificity of EEG to detect cerebral ischemia during the carotid procedure.

Although an intraoperative carotid stump pressure less than 50 mm Hg may predict for stroke after carotid intervention, it has limited utility as the sole method for detecting intraoperative cerebral ischemia and the need for interventions such as shunting.[136,137] A recent meta-analysis ($N = 4557$; 15 prospective and retrospective studies) evaluated the diagnostic value of SSEPs in carotid intervention.[138] A change in SSEPs during carotid intervention had a strong pooled specificity of 91% (95% confidence interval [CI], 86–94), but a weak sensitivity of 58% (95% CI, 49–68).[138] Furthermore, a change in SSEP profiles during carotid intervention significantly raised the risk of perioperative stroke (pooled odds ratio, 14.39; 95% CI, 8.34–24.82).[138]

Transcranial Doppler measures blood velocity in the middle cerebral artery to aid in the detection of significant intraoperative microemboli. This alert may prompt the surgical team to avoid further carotid manipulation that could lead to stroke.[139] Although transcranial Doppler can detect cerebral ischemia, it is not always accurate.[140,141] Cerebral oximetry uses near-infrared spectroscopy to detect cerebral oxygen saturation; however, data to support its use for carotid surgery are mixed.[142–144] Given the current neuromonitoring choices for detection of stroke during carotid intervention under general anesthesia, it is clear that no technique is perfect. Recent meta-analysis has suggested that a combination of stump pressure with EEG or SSEP has the best diagnostic power for detection of cerebral ischemia in this setting.[141] The role for neuromonitoring during CEA with the patient under general anesthesia is prominent when it guides the decision for selective shunting. In the setting of routine shunting for CEA, there is less of a role for these modalities, given that the shunt maintains cerebral perfusion despite the clamped segment of the carotid artery. Ultimately, the choice of neuromonitoring technique, and whether to routinely use neuromonitoring at all, is left to the discretion and expertise of the operative team.

Anesthesia for Carotid Artery Stenting

CAS is a minimally invasive procedure that can usually be performed under local anesthesia or monitored anesthesia care. Sedation is carefully titrated to allow for continuous neurologic examination throughout the procedure. If a general anesthetic technique is employed, short-acting agents are typically administered to allow for a rapid emergence and neurologic evaluation. Because peripheral endovascular access is obtained rather than direct surgical manipulation of the head and neck, a laryngeal mask airway may be chosen rather than endotracheal intubation to attenuate the hemodynamic lability encountered on induction and emergence of general anesthesia.[145] As with any endovascular technique, it may become necessary to convert to open repair. As such, monitoring and vascular access should be planned accordingly.

Intraoperative Challenges

Both CEA and CAS may be associated with hemodynamic lability of both heart rate and blood pressure because of altered baseline carotid baroreceptor sensitivity as well as intraoperative manipulation of the carotid baroreceptors. Carotid baroreceptor manipulation, either directly or endovascularly, may result in a profound parasympathetic response with bradycardia and hypotension. Periods of significant stimulation, such as endotracheal intubation or surgical dissection, can lead to increased sympathetic outflow with resultant hypertension and tachycardia.

Carotid cross-clamping may precipitate ipsilateral cerebral ischemia from decreased carotid blood flow and inadequate collateral flow via the circle of Willis. Blood pressure should be maintained in a normal to slightly higher than baseline range prior to cross-clamping in order to optimize cerebral blood flow. Carotid unclamping may be complicated by impaired autoregulation and disrupted baroreceptor function, resulting in increased cerebral blood flow.[146]

Issues may arise during CAS such as stent kinking, stent thrombosis, carotid dissection, and/or atheroembolism. Technical issues with the stent may often be amenable to observation or additional stent placement, whereas acute thrombosis typically necessitates immediate conversion to open CEA. The incidence of clinically important embolization has significantly decreased with the use of embolic protection devices.[146] In the event of significant distal embolization, management options include catheter-directed thrombolysis, aspiration thrombectomy, and/or aggressive anticoagulation.[146]

Postoperative Complications

Ongoing hemodynamic lability may continue into the postoperative period as a result of continued altered baroreceptor function. Uncontrolled postoperative pain may also contribute to hypertension. Although the risk of MI is substantially lower after CAS compared with CEA, it nevertheless remains a leading cause of perioperative death after carotid intervention.[147,148]

Cerebral hyperperfusion syndrome is a rare but clinically important complication, usually occurring several days following carotid intervention and resulting from impaired cerebral autoregulation after relief of high-grade stenosis.[149] Clinical presentation may progress from severe headache to seizures or, at worst, intracerebral hemorrhage.[149] Management is supportive, with strict control of blood pressure to minimize the risk of intracerebral hemorrhage.[147,149]

Postoperative hematoma following CEA is usually a result of diffuse oozing following heparin administration and concurrent antiplatelet therapy. Although a relatively uncommon occurrence, with reported incidence of approximately 0.5–3%, postoperative hematoma can lead to life-threatening airway compromise.[132] Injury to the recurrent or superior laryngeal nerve may result in paralysis of the ipsilateral vocal cord. Additional complications related to vascular access during CAS are encountered in 3–5% of cases and include infection; bleeding, hematoma, or retroperitoneal hemorrhage requiring transfusion; pseudoaneurysm or arteriovenous fistula formation; and vessel thrombosis or dissection with resultant limb ischemia.[146] The use of iodinated contrast agents may precipitate renal dysfunction, particularly in patients with underlying renal disease.

Abdominal Aortic Disease

The aorta is the major arterial conduit from the heart to the systemic circulation and provides vascular inflow to all of the major abdominal and pelvic organs as it traverses the abdomen.[150] The abdominal aorta is a retroperitoneal structure that begins at the diaphragmatic hiatus and ends at the level of the fourth lumbar vertebra, where it bifurcates into the common iliac arteries.[150]

Abdominal Aortic Aneurysm

An aneurysm is typically defined as a greater than 50% dilation of the expected normal arterial diameter.[150] The aorta tapers gradually from the thorax to the abdomen such that its normal diameter at the level of the renal arteries is approximately 2.0 cm.[151] Although factors such as age, gender, race, and body surface area may influence normal aortic diameter, an abdominal aortic diameter greater than 3.0 cm is considered aneurysmal.[150] Aortic aneurysm occurs most commonly in the abdominal aorta.[152] Aneurysms of the thoracic and thoracoabdominal aortas occur far less commonly (for further details refer to Chapter 23).

Abdominal aortic aneurysms (AAAs) are classified by location as infrarenal (originating below the level of the renal arteries), juxtarenal (originating at the level of the renal arteries), or suprarenal (originating above the renal arteries). This distinction is important because it dictates the complexity of the surgical repair and the potential for hemodynamic derangements, particularly with open intervention and the accompanying aortic cross-clamp. The majority of AAAs are infrarenal, whereas approximately 5–15% involve the suprarenal aorta.[153]

It has recently been recognized that the process of aneurysm formation is a distinct degenerative progression with features such as vessel wall infiltration by macrophages, destruction of elastin and collagen, loss of smooth muscle cells, and neovascularization.[154,155] While inflammation and macrophage infiltration are common to both atherosclerotic and aneurysmal disease, atherosclerosis is primarily noted within the intima and media, whereas aneurysmal disease typically affects the media and adventitia.[154] Although the overwhelming majority of AAAs are caused by degenerative disease, less common causes include infection, inflammatory diseases, trauma, and congenital conditions.

Clinical Features and Natural History

AAAs are typically seen in older adults with an incidence that increases significantly after age 50.[150] The occurrence of AAA is also more common in men and Caucasians.[156,157] Although population-based screening studies estimate an overall AAA prevalence of about 5%, this prevalence is decreasing, perhaps as a result of better risk factor modification.[158,159]

The nonmodifiable risk factors for AAA include age, gender, and family history.[156] Modifiable risk factors include smoking, obesity, hyperlipidemia, hypertension, and atherosclerotic arteriopathy (including CAD).[150,156] Smoking is the modifiable risk factor most strongly associated with AAA.[156,157] Regular exercise and a healthy diet are associated with a decreased risk of AAA.[156] In contrast to most vascular pathophysiology, diabetes mellitus is associated with a reduced risk of AAA.[156] A possible explanation for this protective effect of diabetes against AAA may be the consequent vascular stiffness and calcification, preventing aneurysm formation.[160]

Most AAAs are asymptomatic and are often discovered incidentally.[150] Occasionally, patients may present for vague abdominal pain and/or may note a pulsatile abdominal mass. Rarely, a large AAA may be secondary to a mass effect on related structures, such as vomiting from gastrointestinal compression, urinary symptoms from ureteral compression, or venous complications from iliocaval compression. Most aneurysms eventually become symptomatic secondary to growth or rupture. Rupture of an AAA is most often lethal with a mortality rate of at least 75%. In this setting, of the 50% of patients who reach the hospital alive, about 50% will survive to hospital discharge.[161–163] Given these high mortality rates from rupture and emergency surgery in patients with AAAs, a major management goal is to identify and treat AAAs before they rupture.[150] Current European and North American guidelines recommend ultrasound screening for AAAs in high-risk circumstances, such as for adults older than 64 years and adults with a family history of AAA.[150,164,165] Furthermore, the frequency of surveillance imaging for patients with known AAA is a function of aneurysm size.[164,165]

Indications for Abdominal Aortic Aneurysm Intervention

The single greatest risk factor for aneurysm rupture is size.[150,164,165] Current evidence-based guidelines suggest repair when aneurysm diameter exceeds 5.0–5.5 cm.[150,161,164,165] Rapid aneurysm growth, defined as greater than 10 mm per year, is also an indication for intervention.[150,164] Furthermore, urgent repair is recommended in the setting of symptomatic nonruptured AAA, regardless of size.[150,164,165] Finally, in the setting of excessive perioperative risk, medical rather than surgical management may be considered in patients with multiple significant comorbidities.[150,164,165]

Dubost and colleagues first described open AAA repair in 1951.[166] Although AAA repair is still considered a high-risk surgical procedure, clinical outcomes have steadily improved as a result of ongoing refinements in perioperative management, including advances in anesthetic and surgical techniques.[161] Current estimates of perioperative mortality rates for open AAA repair range from 1.5 to 5.8%.[167–170] A recent meta-analysis demonstrated a perioperative mortality rate of 4.2% for open repair.[171] Endovascular aortic repair (EVAR) for AAA was pioneered by Volodos in 1986 and Parodi in 1991.[172,173] With ongoing improvements in endovascular technology and proceduralist skill, the procedure has become a mainstay of treatment for AAA.[161,164,173,174] Recent epidemiologic studies suggest that more than 50% of AAAs undergo EVAR in the contemporary era.[175,176] High-quality randomized controlled trials comparing endovascular to open abdominal aortic repair have demonstrated a significant perioperative survival benefit due to EVAR with no significant difference in mid- to long-term mortality between AAA repair techniques.[177–184] Whereas open AAA repair has proven long-term durability,[185] EVAR carries a risk of repeat endovascular intervention.[182–184] Ultimately, the decision for open versus endovascular repair for the individual patient depends on multiple factors, such as aortic anatomy, urgency, patient preference, and surgical expertise.

Randomized Trials of Endovascular Versus Open Abdominal Aortic Aneurysm Repair

The UK Endovascular Aneurysm Repair 1 (EVAR 1) trial was a multicenter prospective study ($N = 1252$) of patients with large AAAs who were randomized to either open or endovascular repair.[177,180,182] The 30-day operative mortality rate was reduced by two-thirds in the endovascular cohort, although the need for secondary interventions was also higher in this group.[177] The early survival benefit of EVAR was lost by 2 years.[180] The increased morbidity remained substantial in the EVAR cohort through the long-term follow-up, with new endograft-related complications and reinterventions.[182]

The Dutch Randomized Endovascular Aneurysm Repair (DREAM) trial similarly compared both perioperative and long-term outcomes in patients who underwent endovascular versus open AAA repair.[178,181,182] The DREAM trial was a multicenter trial studying 351 patients with AAA who were randomized to either open or endovascular repair. Trial end points such as perioperative death and a composite of death and major morbidity favored EVAR.[178] At 2-year interim analysis, the survival advantage associated with EVAR was already lost,[181] and at a median of 6 years of follow-up, survival rates remained comparable between cohorts.[182] Similar to the EVAR 1 study, the need for long-term reintervention was significantly higher in the EVAR cohort, most often for graft-related complications such as graft migration or endoleak. The quality of life at 6 months and 1 year was also lower in the EVAR cohort.[186]

The Open Versus Endovascular Repair (OVER) Veterans Affairs Cooperative Study Group was a third multicenter prospective trial of 881 patients with AAAs, medically fit for either type of intervention, who were randomized to endovascular or open repair.[179,184] Short-term analysis demonstrated a significant reduction in 30-day mortality and in-hospital mortality in the endovascular group.[179] Consistent with trials such as EVAR 1 and the DREAM, this initial EVAR survival advantage was lost within 3 years of follow-up. The lack of survival benefit beyond the perioperative period held true for high-risk subgroups, including patients with larger aneurysms, older age, higher

surgical risk, or known CAD. No significant difference in device failure, need for reintervention, or 1-year major morbidity was noted between the two groups. In contrast to the DREAM results, no difference in quality of life was noted between the two groups at mid-term analysis. Patients were followed for up to 9 years following intervention with a mean of 5.2 years.[184] Comparable survival rates were again noted between the two groups. Aneurysm rupture after repair, although uncommon, was only associated with EVAR. The rates of secondary procedures and number of postrepair hospitalizations were comparable between cohorts.

The Anévrisme de l'aorte abdominale: Chirurgie versus Endoprothèse (ACE) trial was a multicenter, prospective randomized trial evaluating open versus endovascular AAA repair in patients deemed at low-to-moderate risk for surgery.[187] A total of 299 patients with aneurysms 5.0 cm or greater in diameter were enrolled. In contrast to the aforementioned trials, the ACE trial found no significant difference in perioperative mortality, major morbidity, or reintervention. In long-term follow-up (median 3 years), the endovascular group was more likely to have undergone reintervention with a trend toward higher aneurysm-related mortality.[187] No significant difference was found in overall major or minor morbidity between the two groups, although the open repair group was more likely to have suffered cardiac complications.[187]

Taken together, the results of these trials suggest a short-term survival benefit but no long-term survival benefit with endovascular as compared to open repair. A recent meta-analysis of these four major trials confirmed a significantly lower short-term mortality (1.4% vs 4.2%; $P < .0001$) with EVAR that was not sustained at intermediate or long-term follow-up.[171] There was no difference in either cardiac or aneurysm-related mortality between groups at either intermediate- or long-term follow-up. There was a significantly higher rate of reintervention in the endovascular group, although the majority of these reinterventions were endovascular-based procedures associated with a low mortality rate.

Additional Factors Influencing Surgical Decision Making

In the current era, open repair of AAA tends to be reserved for patients who are not candidates for EVAR. Anatomic constraints pose the greatest barrier to EVAR. A hostile proximal aortic neck is a major indication for open AAA repair.[188,189] A proximal aortic neck may be hostile and compromise adequate endovascular seal because of factors such as short length, excessive angulation, heavy calcification, or high thrombus burden.[150,188,189] Multiple studies have demonstrated an increase in graft-related complications in this setting.[190–192] In a similar fashion, challenging iliac artery anatomy such as calcification, aneurysm, and/or stenosis may be problematic for both adequacy of distal endovascular seal and safety of arterial access. Involvement of the abdominal visceral aortic segment is not necessarily a contraindication to EVAR because current techniques allow for branched, fenestrated, or snorkeled grafts to maintain patency of visceral vessels such as the renal arteries.

Several additional vascular scenarios may mandate open repair. Complications related to previous EVAR (such as endoleak or migration) that are not amenable to further endovascular intervention require open repair. Long-term conversion rates from endovascular to open repair are approximately 1–2%.[193] In general, infection of either the native aorta or aortic graft calls for open intervention. Finally, patients with unique vascular anatomy, such as anomalous renal arteries or in whom the inferior mesenteric artery is paramount for intestinal perfusion, may be better served with open repair.

Anesthetic Considerations and Management for Abdominal Aortic Aneurysm Intervention

Preoperative Evaluation and Preparation

Patients with AAAs are very likely to have high-risk comorbidities.[150] Many risk factors for AAA, such as age, sex, hypertension, hyperlipidemia, and smoking, also increase the risk for CAD, which is the most common cause of both early and late mortality following AAA repair. Both open and endovascular aneurysm repair are associated with an elevated risk for an adverse perioperative cardiac event. In a large study of patients ($N = 1000$) scheduled for peripheral vascular surgery, preoperative coronary angiography demonstrated that only 6% of patients with AAA had normal coronary arteries.[194] In this study, 94% of patients had angiographically identified CAD that was categorized as follows: mild to moderate in 29%, advanced but compensated in 29%, severe but correctable in 31%, and severe yet uncorrectable in 5%.[194]

COPD is also a frequently encountered comorbidity because smoking is a major risk factor for both disease processes. Multiple studies have highlighted that COPD is a significant predictor for increased morbidity and mortality after AAA repair.[195–197] In addition to coronary and pulmonary disease, preoperative renal dysfunction is also an important predictor of perioperative morbidity and mortality.[195,198,199] Therefore, preoperative assessment for AAA repair should delineate the extent of underlying cardiovascular, pulmonary, and renal disease, given their outcome importance. Although EVAR has been associated with lower perioperative morbidity and mortality, the inherent risk of conversion from an endovascular to open aortic approach necessitates a thorough preoperative evaluation for both populations.

Baseline hemoglobin and hematocrit levels are essential because of the risk of major hemorrhage during AAA surgery. Adequate blood product availability must be ensured before any elective repair is performed. Coagulation studies should be considered, particularly in the setting of planned neuraxial instrumentation or drugs that interrupt normal coagulation. A baseline assessment of renal function is essential to evaluate perioperative renal reserve. A baseline ECG is important for diagnosis of new perioperative myocardial injury. Further cardiac testing for this high-risk surgical procedure should be stratified according to current guidelines (see Chapter 43). Although COPD is an important perioperative risk predictor, preoperative pulmonary function testing such as spirometry and arterial blood gases are typically not predictive and are not routinely indicated.[197]

Statin therapy should be continued perioperatively because it may be of particular benefit to patients undergoing AAA repair.[40,200,201] Aggressive attempts to achieve smoking cessation 4–6 weeks before aortic intervention are worthwhile, according to recent trials that have demonstrated consequent significant reductions in perioperative cardiovascular and respiratory complications.[202,203]

Intraoperative Anesthetic Technique

Open Abdominal Aortic Aneurysm Repair

Although regional techniques have been described for high-risk patients, general anesthesia is the most commonly employed technique for open abdominal AAA repair.[204] Surgical exposure is obtained by either a midline transabdominal or lateral retroperitoneal incision. Given the extensive incision and frequency of COPD, epidural analgesia should be considered in this setting to facilitate high-quality pain control, to limit the side effects of parenteral narcotics, and to preserve respiratory function.[205,206] A recent meta-analysis has suggested that this strategy can decrease major complications in AAA repair such as postoperative mechanical ventilation, MI, gastrointestinal morbidity, and renal injury.[207]

Although general anesthesia can be induced by a variety of agents, particular consideration is given to maintaining the patient's baseline hemodynamics in order to maintain adequate end- organ perfusion (typically within 20% of baseline values), while minimizing sympathetic stimulation to noxious events such as endotracheal intubation and placement of invasive monitors. Moderate doses of narcotics and/or intravenous lidocaine on anesthetic induction may prove useful in this regard.[208] Volatile and/or intravenous anesthesia may be utilized for maintenance of general anesthesia. Although recent evidence suggests a cardioprotective effect of volatile agents in cardiac surgery, this benefit is less clear in the context of AAA repair.[209–211]

Invasive blood pressure monitoring is mandatory for tight control of blood pressure during periods of hemodynamic instability and rapid blood loss. Consideration should be given to placement of an arterial catheter before the induction of general anesthesia to guide titration of induction agents to ensure steady hemodynamics during this labile period. Large-bore intravenous access is a necessity and should also be present prior to surgical incision. Adequate blood product availability and assisted means for expeditious transfusion should be available as needed. Cell-saving techniques may decrease the amount of autologous blood needed and mitigate the risks of transfusion.[212] Central venous access should be obtained to facilitate monitoring of overall volume status and to ensure rapid and reliable administration of vasoactive drugs. Invasive monitoring of cardiac output, by PAC or TEE, is reasonable, especially in high-risk patients or patients undergoing complicated surgical repairs requiring high or prolonged aortic cross-clamp times.[52]

Endovascular Abdominal Aortic Aneurysm Repair

EVAR can be successfully performed under local anesthesia, neuraxial anesthesia, or general anesthesia. Although no randomized controlled trials have compared anesthetic techniques, a recent meta-analysis (cumulative $N > 13{,}000$; 10 observational trials) showed no difference in 30-day mortality between techniques but did demonstrate a significantly shorter hospital LOS, lower risk of intensive care unit admission, and reduced perioperative complications in the local group.[213]

Both surgeon and patient preference should also be considered when choosing an anesthetic technique. Certain patient populations are unsuitable candidates for local or neuraxial anesthesia, including patients with significant anxiety, medical comorbidities that preclude their ability to lie flat, and patients with whom communication is limited (such as baseline cognitive dysfunction or language barrier). Currently, EVARs are frequently performed under local anesthesia. The risk of intraoperative conversion from local to general anesthesia (usually precipitated by surgical complication) is less than 1%.[214,215]

Local and Neuraxial Anesthesia Technique for Endovascular Repair

In addition to the postoperative benefits discussed earlier, local or neuraxial anesthesia has several potential intraoperative benefits. Avoiding the myocardial depressant effects of general anesthetic agents and the potentially stimulating periods of induction and emergence may afford better intraoperative hemodynamic stability. Pulmonary outcomes may be improved by avoiding mechanical ventilation and maintaining baseline respiratory mechanics. An awake, conversant patient may also serve as an "early monitor" for complications such as anaphylactic reactions to iodinated contrast agents (eg, pruritus or dyspnea) or arterial rupture (eg, sudden retroperitoneal pain) that may not be immediately evident in an unconscious patient.

Surgical access to the femoral or iliac arteries is obtained either by surgical cutdown or a percutaneous technique. Skin infiltration with local anesthetic, frequently supplemented by ilioinguinal and iliohypogastric nerve blocks, provides adequate anesthesia for arterial access.[216] Neuraxial techniques such as single-dose spinal, continuous spinal, epidural anesthesia, and combined spinal-epidural techniques have all been described as successful.[216–218] Regardless of neuraxial technique, medications should be dosed to obtain an adequate level of regional anesthesia from dermatomal levels T6 through L3 for a period of 3–4 hours. Providers must be prepared to promptly treat hypotension caused by sympathetic blockade that may be encountered with neuraxial anesthesia.

Either local or neuraxial techniques may require supplementation with titrated sedation. Small doses of short-acting agents should be titrated carefully to provide adequate cooperation, sedation, analgesia, and anxiolysis. Care must be taken to avoid oversedation, airway obstruction, and hypoxemia. The ability to convert rapidly and safely to a general anesthetic remains important in the case of either surgical or anesthetic misadventure.

General Anesthesia Technique for Endovascular Repair

General anesthesia eliminates concerns regarding patient comfort, anxiety, and/or the ability to lie immobile and flat for a prolonged duration. It also obviates emergent conversion to general anesthesia. Further advantages of general anesthesia such as dampened bowel peristalsis and precise control of respiration enhance the quality of intraoperative imaging to facilitate accurate stent deployment.

Intraoperative Hemodynamic Monitoring for Endovascular Repair

With the endovascular approach there is typically less hemodynamic instability than with an open aortic intervention because the need for aortic cross-clamping is avoided. Thus, from this perspective, the requirement for invasive arterial blood pressure monitoring is less imperative for EVAR. The ability, however, to place an arterial catheter rapidly in an emergency situation is limited in EVAR because both arms are usually tucked to allow intraoperative fluoroscopy and both groins are usually surgically accessed for the repair. Given these constraints, elective direct arterial blood pressure monitoring is often selected as a precaution in case of arterial rupture and conversion to open repair.

Although EVAR has a lower risk of bleeding and transfusion compared to open aortic intervention, large-bore peripheral intravenous access is still preferred because of the small, but real, risk of conversion to an open approach.[178,179] Central venous access is typically not required unless a significant need for vasoactive medication is anticipated or reliable large-bore peripheral access cannot be established.

Intraoperative Neurologic Monitoring for Abdominal Aortic Aneurysm Repair

Spinal cord ischemia is a feared complication following aortic surgery. Blood flow to the spinal cord is provided by the single anterior and paired posterior spinal arteries, which arise from the vertebral arteries and posterior circulation.[219] The anterior spinal artery typically supplies the anterior two-thirds of the spinal cord and the posterior spinal arteries supply the posterior one-third.[219] Radicular arteries arising from the ascending cervical, deep cervical, intercostal, lumbar, and sacral segmental arteries, as well as hypogastric collaterals, provide additional blood flow to the spinal cord. The thoracolumbar spinal cord is a watershed region with a clinical vulnerability to significant ischemia.[219] The most important segmental artery in this region is the arteria radicularis magna, or artery of Adamkiewicz. This large radicular artery is typically located between T9 and T12 and thus is not at risk of sacrifice for most patients undergoing abdominal aortic repair, although it may originate higher or lower from the aorta.

A major risk factor for spinal cord ischemia during AAA repair is previous thoracic aneurysm repair with exclusion of large high thoracic feeding arteries to the anterior spinal artery, thus making the spinal cord far more dependent on the artery of Adamkiewicz (see Chapter 23),[220,221] Additional risk factors for spinal cord ischemia during AAA repair include prolonged hypotension, anemia, emergency surgery, aortic rupture, and aortic dissection.[219]

Because of the relatively limited length of replacement for isolated AAA repair and the low likelihood of sacrifice of the artery of Adamkiewicz, spinal cord ischemia due to vascular exclusion is a relatively rare occurrence for isolated AAA repair. The incidence of spinal cord ischemia following open AAA repair is generally less than 1%.[198] A recent literature review noted only six reported cases of spinal cord ischemia after EVAR.[222] In patients who have undergone previous descending thoracic aortic injury, the risk of spinal cord ischemia after delayed EVAR does not appear to be increased, despite concerns about a compromised spinal cord arterial network.[223] This lack of increased risk likely reflects the ability of the spinal cord arterial collateral network to adapt over time to loss of segmental arterial supply.[219]

If sufficient concern exists for a risk of spinal cord ischemia, a spinal drain may be prophylactically placed. This scenario is unlikely in AAA repair, given the extremely low risk of spinal cord ischemia. The rationale for spinal drain placement is to augment spinal cord perfusion

pressure, calculated as the difference between the mean arterial pressure (MAP) and the cerebrospinal fluid (CSF) pressure. If CSF drainage is used, it is suggested that no more than 10 mL/h should be drained and CSF pressure should be maintained at 10–12 mm Hg.[219,224] The MAP should be maintained at least 70–80 mm Hg to maintain a spinal cord perfusion pressure higher than 60 mm Hg.[224] Intraoperative CSF drainage and permissive systemic hypertension are typically titrated to results of simultaneous spinal cord monitoring with SSEPs, motor-evoked potentials, or both (see Chapter 23).

Inherent risks exist with spinal drain placement and CSF drainage.[225] Because these risks can outweigh potential benefits in AAA repair, a reasonable approach is to insert a spinal drain only if neurologic insult is apparent postoperatively. Neurologic recovery has been reported with spinal cord rescue in this setting with prompt recognition, permissive hypertension, and timely CSF drainage.[226–228] In this situation, titrated CSF drainage is usually supplemented with systemic blood pressure augmentation to a MAP range of 90–110 mm Hg in order to maximize spinal cord perfusion pressure. In this high-risk setting, the goal hematocrit is greater than 25% to provide adequate oxygen delivery.[219,226]

Intraoperative Challenges

Hemodynamic Management of Aortic Clamping and Unclamping

Hemodynamic perturbations during open AAA repair are influenced by factors such as aortic cross-clamping (AXC), rapid blood loss, significant fluid shifts, and acute cardiac dysfunction. The application of an aortic cross-clamp initiates an array of physiologic derangements governed primarily by the level at which the clamp is applied (Fig. 48.2).[229,230] An increase in MAP and systemic vascular resistance (SVR) caused by impeded arterial flow is the most consistent response to AXC, with an increase in arterial pressure of 10% or more with infrarenal aortic cross-clamping.[230] The potential for a substantially greater increase exists if the aorta is clamped at a higher level such as above the celiac axis where flow to the abdominal viscera is also interrupted.

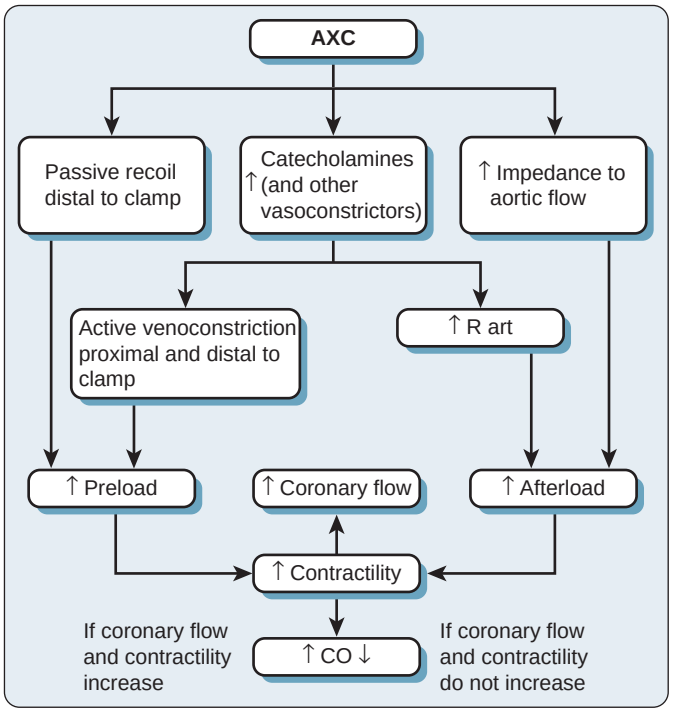

Fig. 48.2 Physiologic changes with aortic cross-clamp placement. Typical hemodynamic response to aortic cross-clamp placement. The level of cross-clamp placement, changes in circulating blood volume, depth of anesthesia and/or anesthetic agents employed, and other physiologic factors may have varying effects. *AXC,* Aortic cross-clamping; *CO,* cardiac output; *R art,* increased arterial resistance. *(Redrawn from Gelman S. The pathophysiology of aortic cross-clamping and unclamping.* Anesthesiology. *1995;82:1026–1060.)*

The hemodynamic effects of an aortic cross-clamp below the level of the celiac axis allows for shifting of blood flow to the splanchnic circulation, which in turn augments its venous capacitance (Fig. 48.3). The typical result of this volume redistribution is little change in venous return and cardiac output, unless major swings in splanchnic venous tone occur. When the clamp is placed above the celiac artery, the splanchnic circulation cannot serve as a reservoir. Rather, venous capacitance below the clamp decreases, expelling blood from the splanchnic system to the central circulation, with resultant increases in filling pressures and venous return. The redistribution of blood volume in this setting is also affected by blood loss, fluid loading, anesthetic depth, and administered vasopressors.[229]

Baseline myocardial contractility reserve may also affect the response to AXC during AAA repair. The increases in preload and afterload acutely increase myocardial work and oxygen demand, particularly with supraceliac clamping. The physiologic response to this increased demand is to increase myocardial perfusion via coronary vasodilation.[229,230] Thus, patients without significant CAD and preserved ventricular function may tolerate these increases in preload and afterload with minimal effect on cardiac output. TEE has demonstrated regional wall motion abnormalities in 33% of patients during suprarenal clamping and in 92% of patients during supraceliac clamping.[231] In the setting of concomitant CAD where the coronary vasculature is already maximally vasodilated and/or there is left ventricular dysfunction, the acute increase in myocardial oxygen demand during AXC may precipitate myocardial ischemia, overt heart failure, or both.

Hemodynamic management during AXC focuses primarily on decreasing afterload and left ventricular wall stress with arteriolar dilators and normalizing preload with venous dilators.[229,230] Typically, short-acting vasoactive agents (such as sodium nitroprusside, nitroglycerin, nicardipine and/or clevidipine) are titrated to achieve these hemodynamic goals in a fashion that adapts rapidly to a changing clinical scenario. Because myocardial ischemia and/or heart failure may present acutely during this critical period, agents to improve myocardial oxygen supply as well as inotropic agents should be available to support ventricular function as necessary. Close communication between the surgical and anesthetic teams is paramount so that pathophysiologic derangements can be anticipated and appropriately managed.

There are several episodes of "aortic clamp release" during open aortic repair (Fig. 48.4). After completion of the proximal aortic anastomosis, the initial superior aortic clamp is then applied lower on the new aortic graft. Even if the initial aortic clamp was supraceliac, the distal aortic anastomosis is commonly infrarenal. The typically brief initial clamp time for the proximal aortic anastomosis results in minor hemodynamic disruption from reperfusion of the celiac and renal vascular territories. In contrast, after completion of the entire AAA repair, release of the distal aortic cross-clamp is frequently associated with dramatic hypotension. The mechanism for hypotension is multifactorial (Fig. 48.5). Distal aortic unclamping results in an immediate and profound (up to 70–80%) decrease in SVR.[232] This distal vasodilation as a result of tissue hypoxia and release of vasoactive mediators promotes sequestration of blood distal to the aortic cross-clamp, resulting in a relative central hypovolemia.[229,230] These vasoactive and inflammatory mediators (such as lactic acid, oxygen free radicals, prostaglandins, endotoxins, and cytokines) promote vasodilation and myocardial depression on release of the aortic cross-clamp. This hypotensive response can be mitigated by surgical techniques such as minimizing ischemic time and releasing the aortic cross-clamp gradually.

Adequate volume loading should be performed during the AXC period in anticipation of the profound vasodilation and relative hypovolemia that accompany clamp removal. Vasodilatory agents during the AXC period may prove useful in this regard. In anticipation of

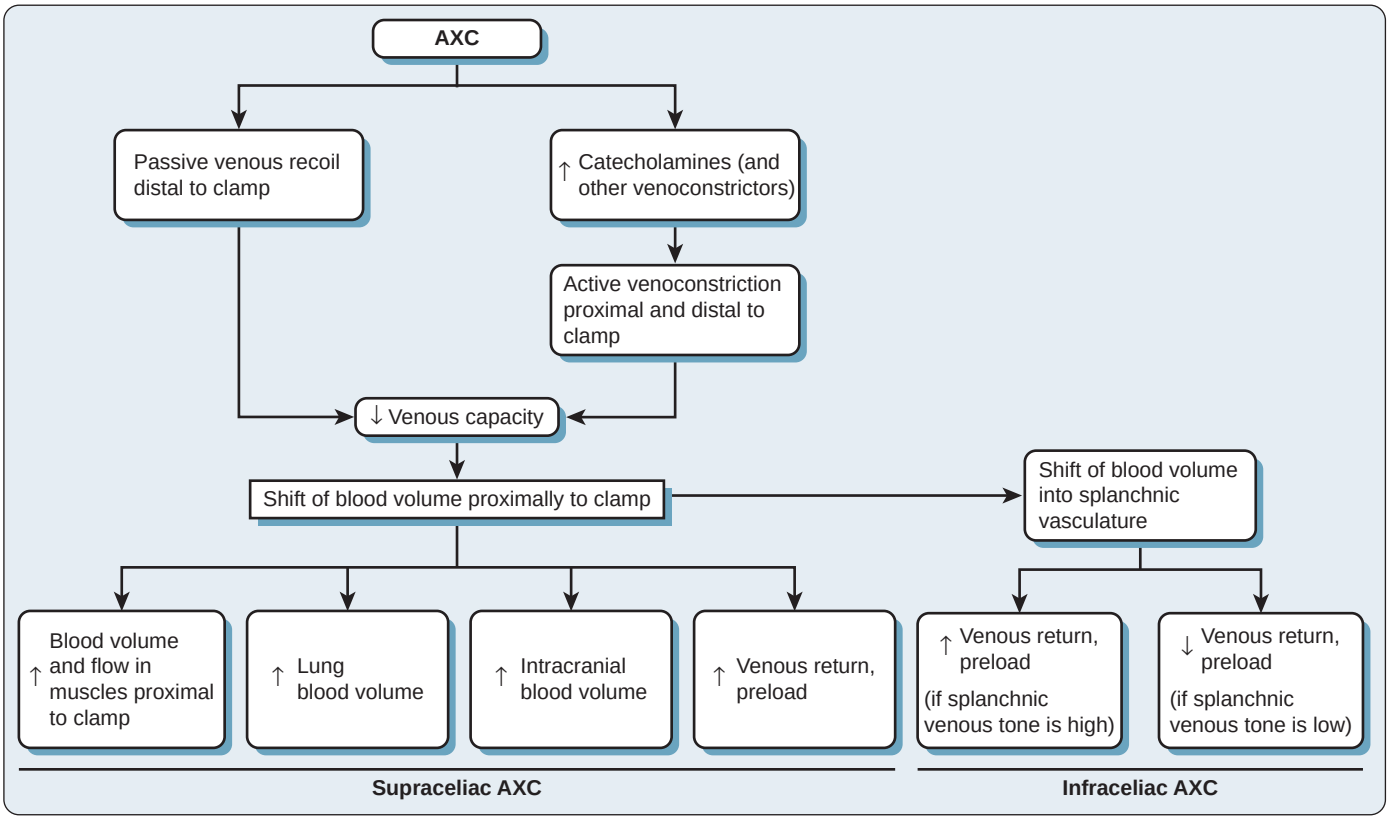

Fig. 48.3 Changes in blood volume distribution during aortic cross-clamping *(AXC)*. The shifting of blood volume with aortic cross-clamping is dependent on the level of cross-clamp placement (supraceliac vs infraceliac), release of catecholamines and administration of vasoactive medications, and overall blood volume. *(Redrawn from Gelman S. The pathophysiology of aortic cross-clamping and unclamping.* Anesthesiology. *1995;82:1026–1060.)*

aortic cross-clamp release, vasodilatory agents should be discontinued and vasopressor agents should be immediately available. A slow release of the aortic cross-clamp and/or opening of iliac artery clamps one at a time may allow for a more gradual metabolic washout with less profound hemodynamic derangements. In case of profound hypotension, the aortic cross-clamp may be reapplied. As with aortic cross-clamp placement, clear communication between the surgical and anesthesia teams is necessary during this critical time.

Hemodynamic Management of Endovascular Stent Deployment

In general, EVAR is associated with fewer extreme hemodynamic perturbations owing to the absence of an aortic cross-clamp. Even though endovascular aortic occlusion during stent deployment may result in transient increases in MAP and afterload similar to those seen with external aortic cross-clamp application, their relative brevity rarely necessitates hemodynamic intervention. Brief deliberate hypotension may be utilized at the time of deployment to position the stent precisely and minimize the risk of distal migration. This can be accomplished by a variety of short-acting vasodilatory agents titrated to effect.[233]

Renal Protection and Function

Postoperative renal dysfunction is a major source of morbidity in AAA repair. During open repair, AXC at all levels reduces renal blood flow. Even infrarenal aortic clamping may decrease renal blood flow by 40%, accompanied by an increase in renal vascular resistance with decreases in renal cortical blood flow and glomerular filtration rate.[230,234] These renal effects are mediated by the renin-angiotensin-aldosterone and sympathetic nervous systems.[229] Renal atheroemboli from AXC may also have a deleterious effect on renal function.

Multiple trials since the 1980s have explored whether agents such as mannitol, furosemide, dopamine, fenoldopam, and *N*-acetyl-L-cysteine are nephroprotective during AAA repair.[235] Although these interventions are still employed, there is inadequate evidence to support this practice.[235] Intraoperative maneuvers such as minimizing AXC time and maintaining adequate hemodynamics are the most prudent measures to limit renal injury during open AAA repair.

Renal dysfunction after EVAR is typically a result of iodinated contrast agents, although atheroemboli and graft impingement of the renal artery ostia may also contribute. In this setting, perioperative maneuvers that minimize the risk of contrast-induced nephropathy include limitation of contrast volume, rehydration with isotonic fluid, and administration of systemic sodium bicarbonate.[236,237]

Postoperative Complications

Despite perioperative advances, complications after AAA repair remain prevalent. The Society for Vascular Surgeons registry has recently reported an 11% perioperative rate of major adverse events after AAA repair, including death, stroke, MI, renal failure, respiratory failure, and paralysis; the overwhelming majority were death and MI.[167] Myocardial injury remains a common and serious complication after AAA repair. A combination of existing risk factors, including CAD and the significant hemodynamic demands discussed earlier, explain the reported perioperative MI rates of 5–10% for open AAA repair, despite careful preoperative assessment (see Chapter 43 for further discussion).[167,238] The relative hemodynamic stability afforded by EVAR likely explains the overall lower rate of perioperative MI, reported at 1.8–5%.[178,238,239]

Pulmonary complications are also common following AAA repair. Mechanical ventilation is commonly continued into the immediate postoperative period for open AAA repair, particularly for more

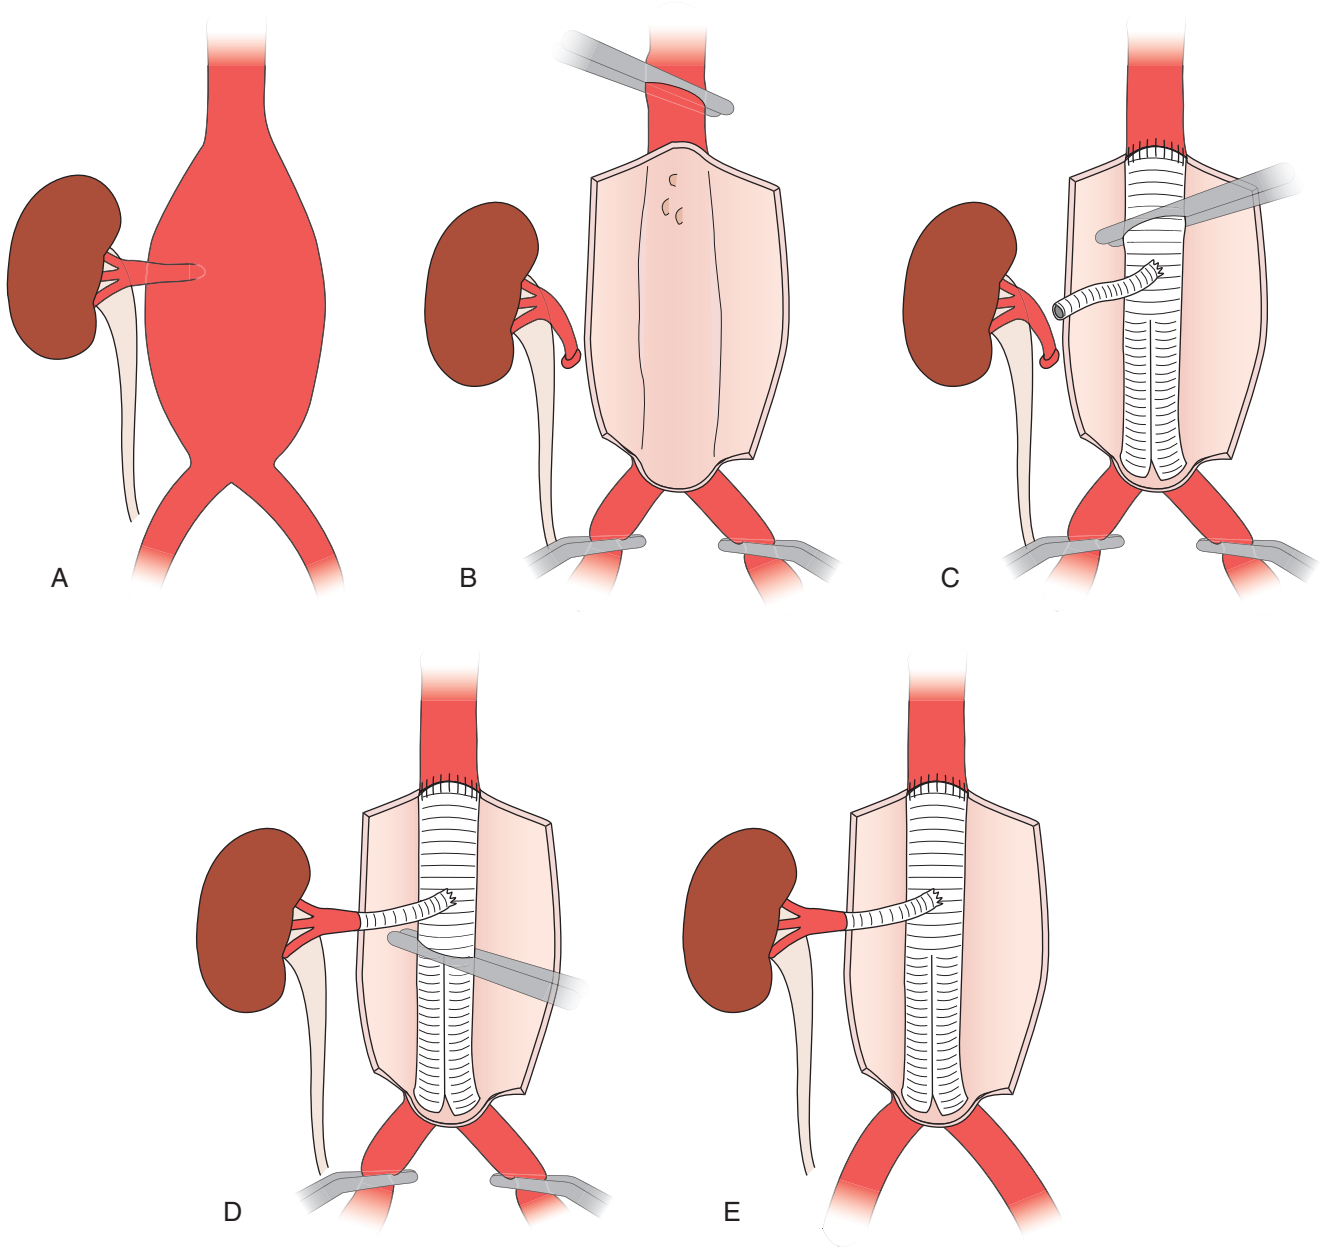

Fig. 48.4 Mobilization of aortic cross-clamp during open abdominal aortic aneurysm repair. To minimize unnecessary ischemic time on visceral organs, the aortic cross-clamp is moved sequentially lower on the graft as each anastomosis is completed. Each cross-clamp release will result in metabolic washout to the previously ischemic organs, although the subsequent quick replacement of the cross-clamp lower on the graft will mitigate some of the hemodynamic alterations. (A) Native aneurysm with right renal artery is shown. (B) Aortal and iliac arteris is clamped. Aneurysm sack is opened and right renal artery is dissected. (C) Aorto-bifemoral graft with separate arterial graft is sewn in. Aortic clamp is moved from native aorta to proximal graft. (D) Right renal artery is anastamosed, with perfusion to right kidney achieve by moving aortic crossclamp distal. (E) Reperfusion of legs: all arterial clamps are removed. *(Redrawn from Woo EY, Damrauer SM. Abdominal aortic aneurysms: open surgical treatment. In: Cronenwett JL, Johnston KW, eds.* Rutherford's Vascular Surgery. *8th ed. Philadelphia: Saunders; 2014:2024–2045.)*

complicated procedures. Frequent ongoing resuscitation needs for the first 24–48 hours following repair may make it prudent to "rest" the patient until hemodynamic stability is achieved, particularly in patients with underlying pulmonary compromise such as COPD. Although most patients are liberated from mechanical ventilation thereafter, pulmonary infection still remains a common postoperative complication, occurring in 17% of patients.[238] In contrast, most patients undergoing EVAR either do not require mechanical ventilation or undergo tracheal extubation in the operating room at the end of the procedure. Consequently, pulmonary complications after EVAR are less common with a reported incidence of 3–7%.[178,187,238] Perioperative interventions such as adequate analgesia, aggressive pulmonary toilet, and early ventilator liberation may all help to minimize pulmonary complications after AAA repair.

Perioperative renal dysfunction has an incidence of 10–20% of patients after open AAA repair with a risk of renal replacement therapy

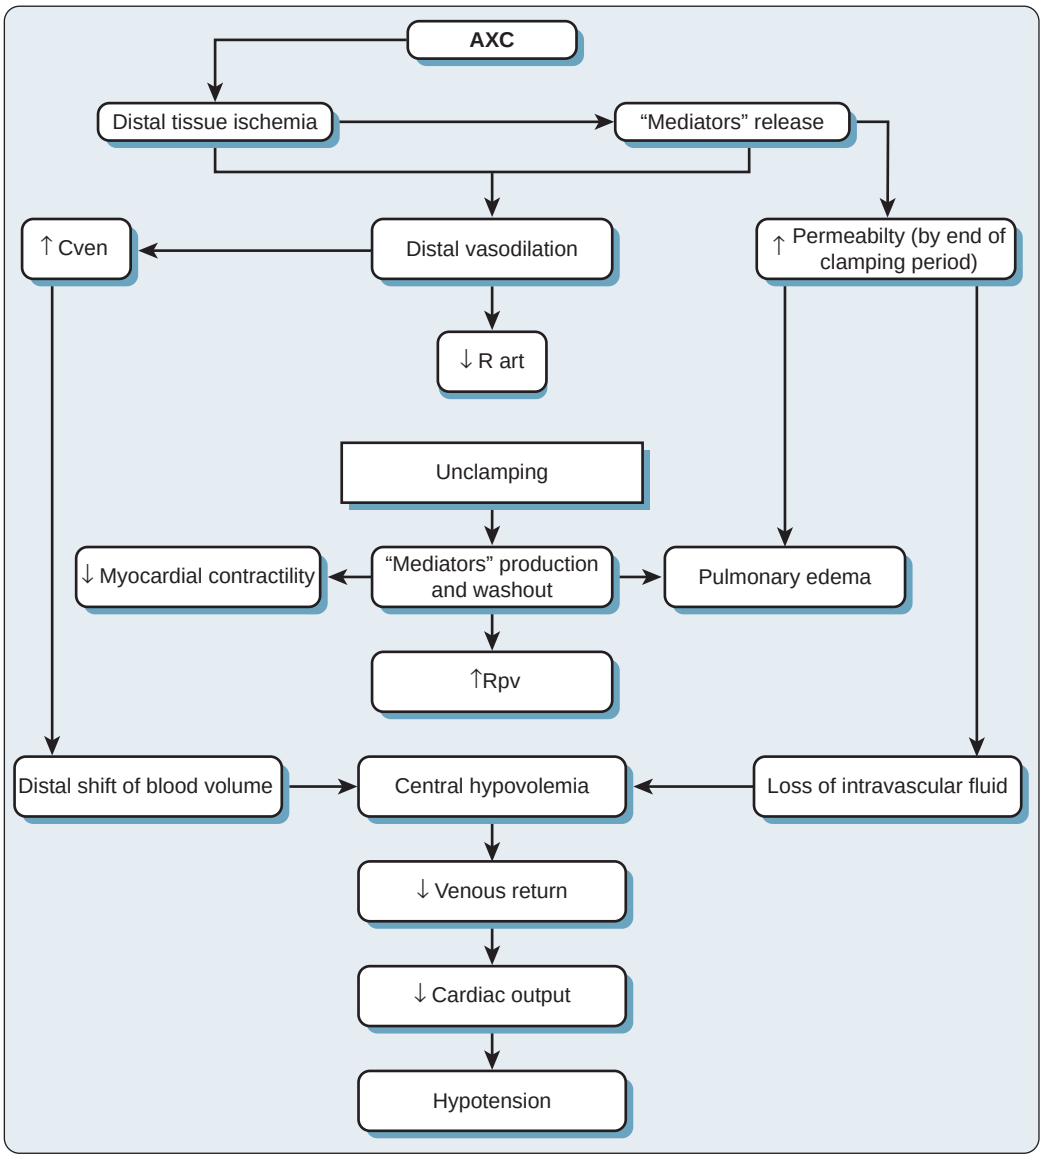

Fig. 48.5 Physiologic changes with aortic cross-clamp release. Typical hemodynamic response to aortic cross-clamp release. *AXC,* Aortic cross-clamping; *Cven,* venous capacitance; *R art,* arterial resistance; *Rpv,* pulmonary vascular resistance. *(Redrawn from Gelman S. The pathophysiology of aortic cross-clamping and unclamping.* Anesthesiology. *1995;82:1026–1060.)*

of 1–3%.[238,240] Although perioperative renal failure after EVAR has a reported incidence of up to 10%, judicious resuscitation with isotonic intravenous fluids, maintenance of normal hemodynamics, and further prophylaxis for contrast-induced nephropathy as previously discussed mitigate the risk for perioperative renal injury.[178,179,238]

Approximately 1% of patients undergoing open AAA repair have complications from bleeding.[238] Bleeding in this setting includes causes such as anastomotic leak, back-bleeding from arterial collaterals, raw-surface oozing, dilutional coagulopathy, hypothermia, and circulating anticoagulants. Meticulous control of surgical bleeding in the operating room and the judicious use of blood product resuscitation, guided by clinical judgment and laboratory values, remain cornerstones of management. Bleeding complications requiring intervention are more common after open as compared with endovascular repair.[238] Vascular events in EVAR include access hematoma, dissection, pseudoaneurysm, arteriovenous fistula, and distal embolization.

Intestinal ischemia remains a serious complication after AAA repair, occurring in about 1–3% of endovascular cases and up to 9% of open cases.[238–243] Despite an extensive collateral arterial network, intestinal ischemia may still result from baseline mesenteric vascular disease, atheroembolization, and/or sacrifice of arterial supply such as the inferior mesenteric artery and hypogastric collaterals.[238,243] Although clinical presentation is variable, early detection remains important; delayed intervention carries a high mortality rate.[244,245] Treatment options range from aggressive resuscitation and broad-spectrum antibiotics for limited disease to emergency bowel resection for full-thickness infarction or evidence of shock.

Spinal cord ischemia is a relatively rare but catastrophic complication of AAA repair. Previous vascular exclusion and length of coverage appear to be the most pertinent factors, although previous aortic surgery, sacrifice of new collateral vessels, aortic cross-clamp duration and location, and perioperative hemodynamic stability are all likely contributors. Spinal rescue in this setting includes permissive systemic hypertension with or without concurrent CSF drainage. Spinal cord ischemia is rare after AAA repair, and these interventions are rarely required.

Lower extremity ischemia is prevalent following both open and endovascular aortic repair. Technical issues with surgical anastomoses,

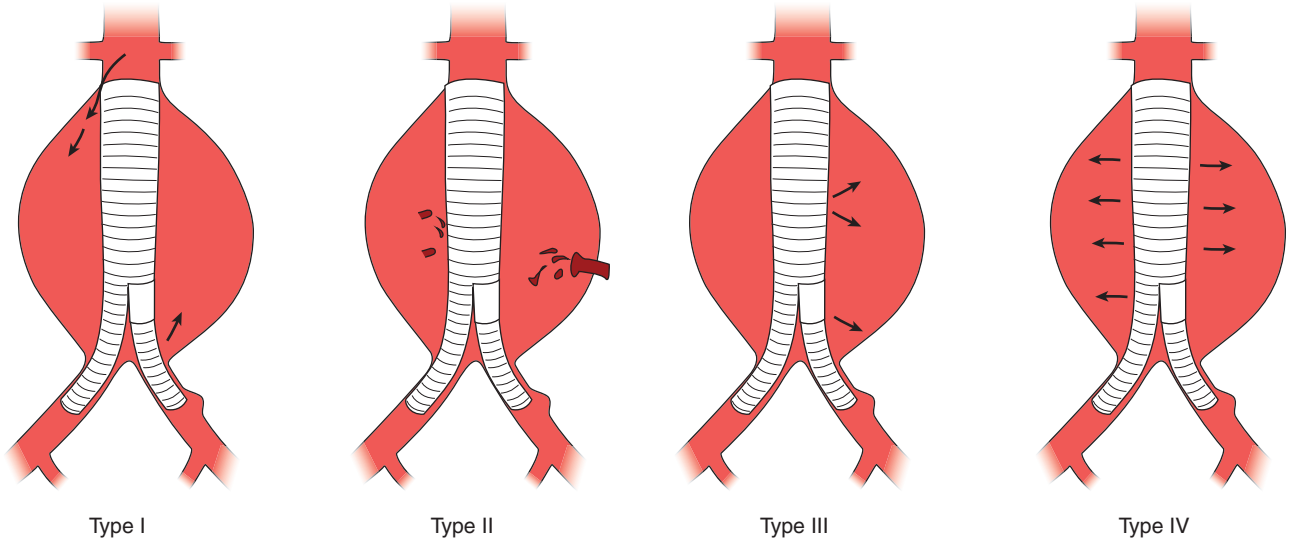

Fig. 48.6 Classification of endoleak. Type I endoleak results from inadequate seal from the proximal or distal end of the endograft. Type II endoleak is caused by inflow from a visceral vessel. Type III endoleak occurs as a result of a defect in the graft, a disconnection of modular graft components, or an inadequate seal. Type IV endoleak occurs as a result of porosity of the graft fabric. Type V endoleak, also known as *endotension*, is an elevation in aneurysm sac pressure without a demonstrable source of endoleak. *(Redrawn from Fairman RM, Wang GJ. Abdominal aortic aneurysms: endovascular treatment. In: Cronenwett JL, Johnston KW, eds.* Rutherford's Vascular Surgery. *8th ed. Philadelphia: Saunders; 2014:2046–2061.)*

acute thrombosis, acute embolic disease, and clamp injury may all be a source for lower extremity ischemia. It is important to confirm adequate distal pulses before leaving the operating room and during the early postoperative period. Adequate intraoperative systemic anticoagulation and meticulous surgical technique are important to reduce the likelihood of this complication.

Unique Complications of Endovascular Intervention

Patients undergoing EVAR are at increased risk for subsequent intervention to manage unique complications.[246–248] Endoleak is defined as a failure to exclude the aneurysm from the circulation after device deployment because of a persistent flow of blood into the aneurysm sac. Endoleaks are important because they pressurize the aneurysm sac for a continued risk of expansion and rupture. Five types of endoleak exist, categorized by location and route of blood flow into the space between the graft and the native aneurysm (Fig. 48.6).[150] Meticulous intraoperative imaging will typically identify the presence of an endoleak requiring immediate intervention. Management options include the placement of additional stents, embolization of feeding vessels, or conversion to open repair.

Endovascular graft kinking has been associated with an increased risk for endoleak, stent migration, stent thrombosis, and acute limb ischemia.[249] Graft kinking is more common following endovascular compared with open AAA repair.[249] Surgical options in this setting include additional stent placement, thrombectomy, and open surgical repair. Because stent complications such as separation and migration typically occur after the perioperative period, follow-up remains essential after EVAR.[150]

Abdominal Aortic Dissection

Aortic dissection is an aortic syndrome characterized by a tear in the intima that may subsequently be propagated by pulsatile blood flow with development of a false lumen between the dissected layers of the arterial wall (see Chapter 23).[150,246]

Aortic dissections are classified both temporally and anatomically. Classically, dissections are labeled acute when clinical symptoms have lasted for 14 days or less and chronic if symptom duration exceeds 2 weeks. Recent work, however, suggests four distinct time periods: hyperacute (symptom onset less than 24 hours), acute (2–7 days), subacute (8–30 days), and chronic (>30 days) with risk of mortality that continues to increase significantly even into what is traditionally considered the chronic phase.[250] The majority of late deaths are from rupture of the false lumen, as its long-term patency sets the stage for aneurysmal dilation and rupture.[251]

Anatomically, two classification systems are used to describe aortic dissections (Fig. 48.7). DeBakey first identified variations in aortic dissection based on both the origin of the initial tear as well as the extent of aortic dissection.[252] The Stanford classification system simplifies the schema by entry site only, with Stanford type A dissection originating in the ascending aorta and Stanford type B dissection originating in the descending aorta.[253] In this chapter, discussion of aortic dissection is limited to abdominal aortic dissections. For an in-depth discussion of thoracic and thoracoabdominal aortic dissection, please refer to Chapter 23.

Acute type B dissections are responsible for approximately one-third of all aortic dissections.[247] Isolated dissection of the abdominal aorta is rare; most commonly, the intimal tear originates within a few centimeters of the left subclavian artery. Isolated abdominal aortic dissection is uncommon with an incidence in the International Registry of Acute Aortic Dissection (IRAD) of 1.3%.[254–255] This rare presentation of aortic dissection is frequently associated with hypertension, aortic atheroma, and aortic aneurysm.[254,255]

The clinical presentation of isolated abdominal aortic dissection may vary depending on end- organ compromise: abdominal pain, visceral ischemia, acute renal failure, and limb ischemia have all been reported.[254-257] The initial intimal tear in isolated abdominal aortic dissection is typically infrarenal, although the proximal entry tear site is not always apparent.[254–257]

Medical therapy was employed in two-thirds of patients in the IRAD analysis, while surgery was performed in one-third.[254] Indications for surgery included rupture, visceral or limb ischemia, acute renal failure, refractory pain, and/or uncontrollable hypertension. The majority of surgical repairs were open with better outcomes than in thoracic aortic

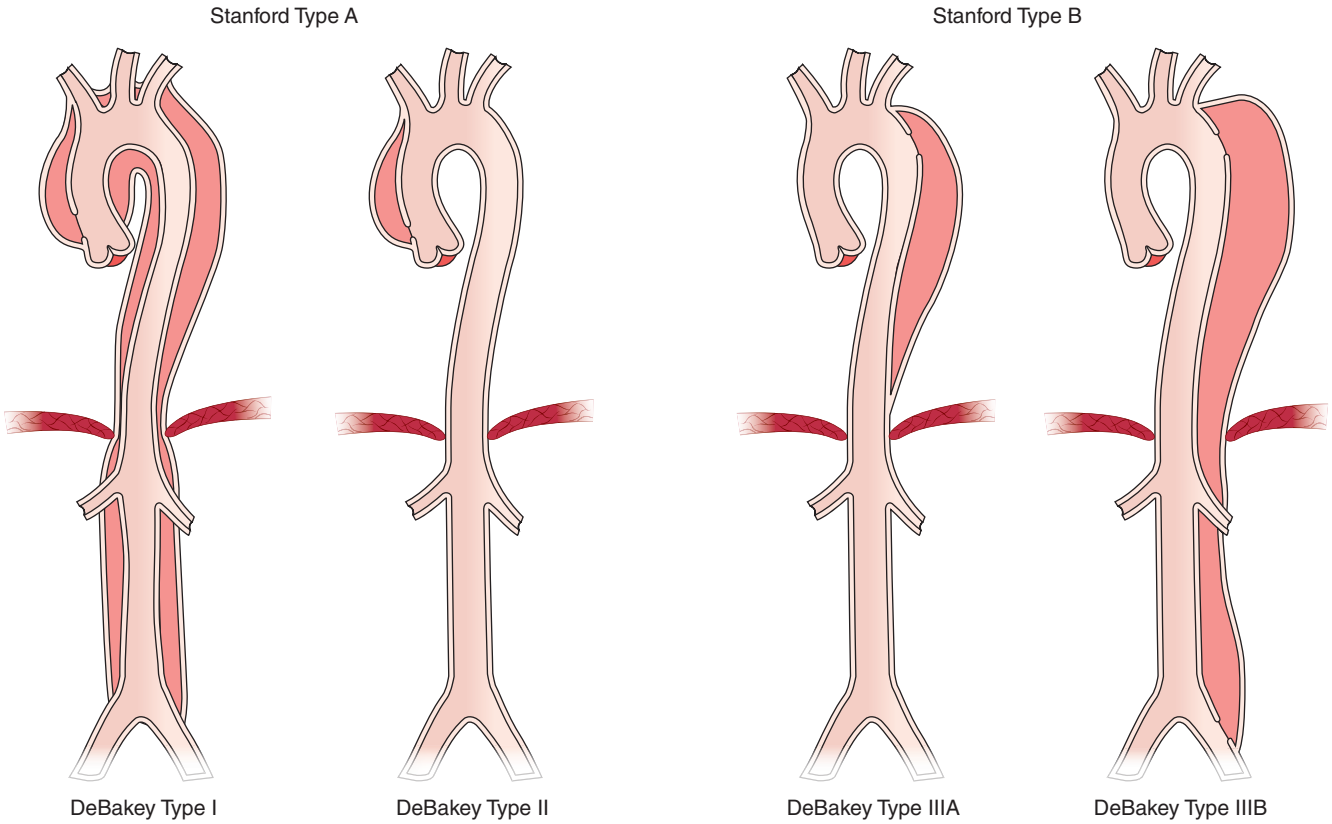

Fig. 48.7 Classification of aortic dissection. Aortic dissections can be classified based on both location of the proximal tear and extent of the dissection (DeBakey) or by the location of the proximal tear alone (Stanford). *(Redrawn from Conrad MF, Cambria RP. Aortic dissections. In: Cronenwett JL, Johnston KW, eds.* Rutherford's Vascular Surgery. *8th ed. Philadelphia: Saunders; 2014:2169–2188.)*

dissection.[254] In this rare abdominal aortic presentation, individual management should be tailored to the clinical situation. Anesthetic considerations in this patient population are similar to those undergoing AAA repair.

Aortoiliac Occlusive Disease

Aortoiliac occlusive disease is a manifestation of PAD that ultimately results in partial or total vascular occlusion. Atherosclerosis is the most common cause of both PAD and aortoiliac occlusive disease; thus, the risk factors are similar and include smoking, age, family history, diabetes, hypertension, hyperlipidemia, as well as more recently identified risk factors such as hyperhomocysteinemia.[165]

Aortoiliac occlusive disease typically begins in the distal aortic segment and the origin of the common iliac arteries and progresses indolently over time.[258] An extensive collateral circulation, primarily from the lumbar and hypogastric arteries, frequently reconstitutes the infrainguinal vessels in disease limited to the aortoiliac segment. Thus, although isolated aortoiliac disease may lead to claudication symptoms (manifested by intermittent thigh, hip, or buttock pain; or impotence from inadequate flow through the internal pudendal artery), it rarely leads to critical limb ischemia. Such patients may tolerate these symptoms for years with expectant medical management. Unfortunately, disease limited to the aortoiliac segment is the exception rather than the rule; more commonly, patients also have extensive infrainguinal disease. Patients with more extensive or multilevel disease are more likely to have more severe claudication symptoms or critical limb ischemia and, not surprisingly, present a more difficult surgical challenge.

Risk factor modification can improve symptoms of claudication and may stabilize disease progression.[259] Most patients, treated appropriately, will not progress to the point of requiring surgical or endovascular treatment. Indications for intervention include disabling or progressive claudication, ischemic rest pain, and tissue loss. The extent to which claudication is disabling is a somewhat subjective decision made jointly by the surgeon and patient based on symptoms and quality-of-life limitations. Current guidelines recommend endovascular or surgical intervention for patients who have significant functional disability that is vocational or lifestyle limiting, who are unresponsive to medical or exercise therapy, and who have a reasonable likelihood of symptomatic improvement.[165,259]

The Trans-Atlantic Inter-Society Consensus (TASC) classifies aortoiliac occlusive disease by location and severity of disease (Fig. 48.8).[260] In general, TASC types A and B represent relatively localized disease of the distal aorta and iliac arteries that is best managed by endovascular intervention.[260] The TASC guidelines further recommend that types C and D disease patterns reflect a more extensive process that is best managed with open repair.[260] Despite these recommendations, recent advances have rendered endovascular treatment as first-line therapy for both localized and extensive aortoiliac disease with comparable outcomes.[259,261] Given this paradigm shift, the Society for Vascular Surgery guidelines now recommend endovascular intervention as a reasonable first-line intervention for both focal and diffuse aortoiliac occlusive disease.[262]

Despite these recent advances in endovascular technology, open surgical reconstruction remains the gold standard for the treatment of aortoiliac occlusive disease, including both bypass and endarterectomy procedures.[259,262]

Extraanatomic bypass procedures such as axillofemoral bypass are typically reserved for high-risk patients with aortoiliac occlusive disease, but they are less durable with reported patency rates below 80%.[262] Because extraanatomic bypass, by definition, does not involve the aortic segment, the hemodynamic lability is avoided. Consequently,

Type A lesions

- Unilateral or bilateral stenoses of CIA
- Unilateral or bilateral single short (≤3 cm) stenosis of EIA

Type B lesions

- Short (≤3 cm) stenosis of infrarenal aorta
- Unilateral CIA occlusion
- Single or multiple stenosis totaling 3–10 cm involving the EIA not extending into the CFA
- Unilateral EIA occlusion not involving the origins of internal iliac or CFA

Type C lesions

- Bilateral CIA occlusions
- Bilateral EIA stenoses 3–10 cm long not extending into the CFA
- Unilateral EIA stenosis extending into the CFA
- Unilateral EIA occlusion that involves the origins of internal iliac and/or CFA
- Heavily calcified unilateral EIA occlusion with or without involvement of origins of internal iliac and/or CFA

Type D lesions

- Intrarenal aortoiliac occlusioin
- Diffuse disease involving the aorta and both iliac arteries requiring treatment
- Diffuse multiple stenoses involving the unilateral CIA, EIA, and CFA
- Unilateral occlusions of both CIA and EIA
- Bilateral occlusions of EIA
- Iliac stenoses in patients with AAA requiring treatment and not amenable to endograft placement or other lesions requiring open aortic or iliac surgery

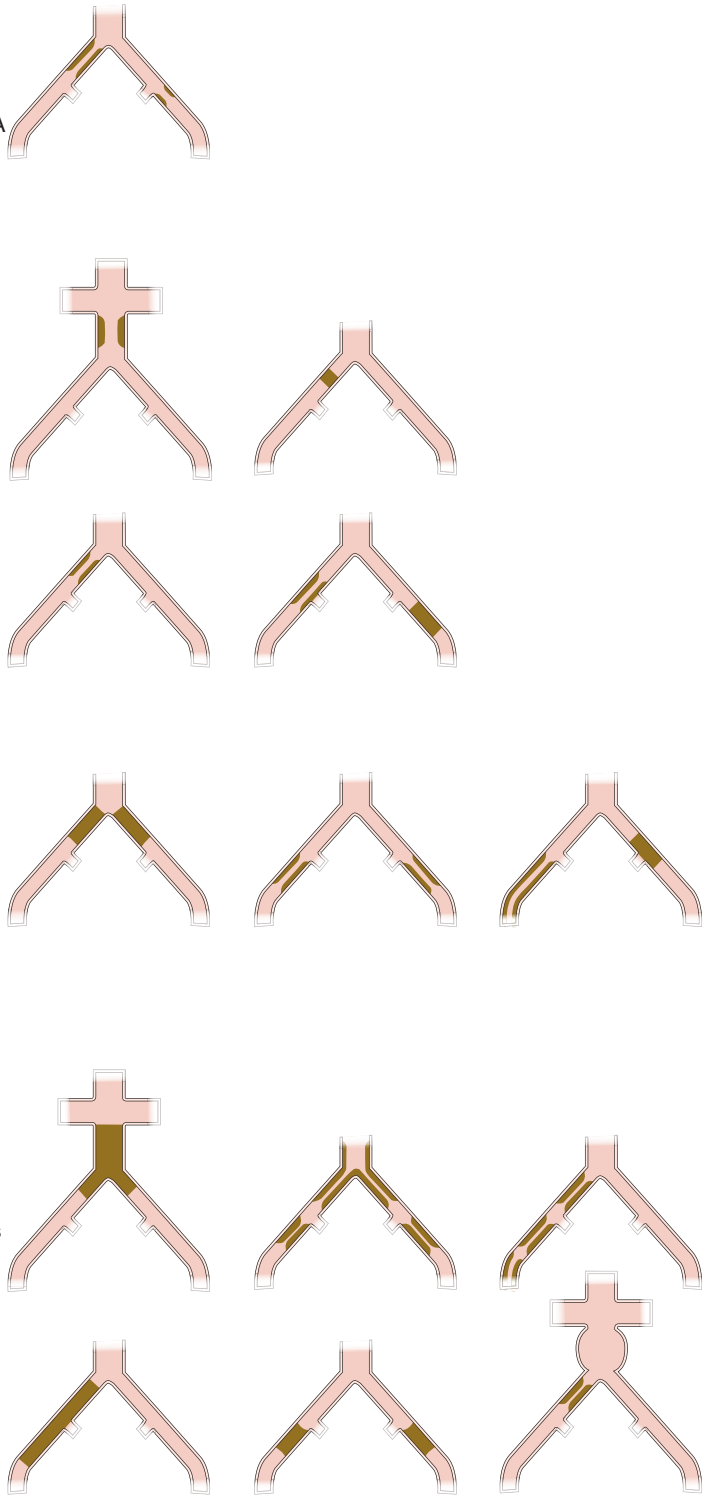

Fig. 48.8 TASC II classifications of aortoiliac disease. Classification of aortoiliac disease based on location, laterality, and disease severity. *AAA,* Abdominal aortic aneurysm; *CFA,* common femoral artery; *CIA,* common iliac artery; *EIA,* external iliac artery. *(Redrawn from Norgren L, Hiatt WR, Dormandy JA, et al. Inter-society consensus for the management of peripheral arterial disease [TASC II].* J Vasc Surg. *2007;45(suppl S):S5–S67.)*

extensive invasive monitoring is typically not required in this setting, unless patient-specific factors suggest benefit. An arterial catheter and large-bore intravenous access are typically still warranted because of excessive comorbidity, risk for hemorrhage, and risk of hemodynamic changes (albeit less severe) with peripheral vascular clamping.

Lower Extremity Arterial Disease

Lower extremity ischemia has a spectrum of clinical presentations, ranging from exertional muscle pain to gangrene and tissue loss. The clinical manifestations of lower extremity arterial disease (LEAD) depend on the location and severity of arterial occlusion as well as the extent of collateral vessels. Because atherosclerosis is the leading cause of LEAD, it is the focus of discussion in this section about the anesthetic considerations for infrainguinal PAD.

Clinical Features and Natural History

Recent metaanalysis has estimated that more than 200 million people worldwide have clinical LEAD and that its prevalence increased by 23.5% in the first decade of the new millennium alone.[263] An estimated 8 to 12 million Americans are affected by LEAD with an economic healthcare burden measured in billions of dollars.[264] The risk factors for LEAD include advanced age, tobacco abuse, hypertension, hyperlipidemia, and diabetes. In addition, race, genetics, chronic renal disease, and homocysteine[262] have also been associated.[262,265]

Although LEAD may be asymptomatic in up to 50% of patients, it remains a sentinel marker for adverse cardiovascular outcomes because it is frequently associated with atherosclerotic CAD.[262,266–268] The annual incidence of an adverse cardiovascular event in patients with LEAD has been estimated at 5–7%.[260] Although management of known asymptomatic LEAD has been aimed at risk factor modification for atherosclerotic disease, the benefits of this approach have not been clearly demonstrated in the asymptomatic patient subgroup.[262] As such, controversy exists in the appropriateness of screening for asymptomatic LEAD. The 2011 ACCF/AHA guidelines recommend screening in patients older than 65 years, or in patients older than 50 years with a history of diabetes or smoking.[269] In contrast, the Society for Vascular Surgery recommendations suggest that no clear benefit is derived from screening for LEAD in asymptomatic patients, unless it may improve risk stratification and medical management.[262] The U.S. Preventative Services Task Force has also recently concluded that there is insufficient evidence to determine the risk and benefit of routine screening for asymptomatic LEAD.[270]

Claudication is the presenting feature of LEAD in up to 35% of patients.[266] Intermittent claudication is defined as a reproducible discomfort in a defined muscle group that is induced by exercise and relieved with rest. In general, claudication in the buttock and hip typically results from aortoiliac occlusion, whereas claudication in the thigh or lower leg results from progressively distal arterial disease.[266] Intermittent claudication is the first and most common symptom associated with PAD.[266] The natural history of PAD is usually a slow, progressive decline in function. With aggressive medical management, lifestyle adjustment, and exercise therapy, the vast majority of patients do not progress to more advanced disease.[260,266]

In a minority of patients, the disease will progress to critical limb ischemia when existing arterial blood flow is insufficient to meet the basic metabolic demands of resting tissue. The clinical presentation in this setting ranges from rest pain to tissue loss (nonhealing ulcers or gangrene). Risk factors that increase the risk for accelerated disease progression include age, diabetes, smoking, and hyperlipidemia.[260,262] Unlike claudication, critical limb ischemia includes a high risk of limb loss resulting from a more aggressive LEAD with multisegmental involvement. Within 1 year, it is estimated that 25% of patients will progress to amputation and 25% will die from cardiovascular mortality.[165,260] Approximately 50% of patients with critical limb ischemia will also have advanced coronary and cerebrovascular artery disease with a higher mortality risk from MI and/or stroke.[260,271] The management of critical limb ischemia involves aggressive risk factor reduction, wound care, and a low threshold for revascularization.

Indications for Lower Extremity Arterial Intervention

Although surgical intervention is typical in critical limb ischemia, it requires an individualized assessment in the context of intermittent claudication.[262,266] First-line therapy for intermittent claudication includes education, aggressive management of comorbid conditions, and lifestyle modification, including smoking cessation and exercise therapy.[262,266] Continued smoking is a major risk factor for amputation, intervention failure, MI, and death in this setting.[272,273] Meta-analysis has demonstrated that exercise therapy for claudicants significantly improves ambulation up to 200%.[274] In clinical terms, however, this increase translated to an absolute increase in walking distance of less than 100 feet.[275] This relatively modest impact may have limited benefit on perceived quality of life.

The indication for surgical intervention in claudication also depends on the patient's subjective perception of disease burden, given that patients have different thresholds for tolerability of symptoms. For example, relatively mild claudication may be perceived as intolerably disabling in a very physically active patient, whereas very similar symptoms may be fairly well tolerated in more sedentary individuals.

Additional Factors Influencing Surgical Decision Making

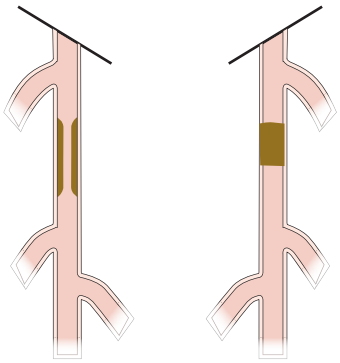
Once the decision has been made for surgical intervention, the selection of open versus endovascular intervention must then also be individualized based on procedural risk, medical comorbidity, overall life expectancy, and expected extent of clinical improvement.[260,262] Open surgical bypass has a long history of success and durability with long-term patency rates greater than 95%.[260,262] Despite this track record, endovascular intervention has become the preferred approach for most patients with LEAD because of low mortality and low morbidity rates. Endovascular procedures, however, have proven less durable in the long term than surgical bypass and have a higher incidence of reintervention.[262]

The TASC II guidelines grade LEAD in four types from type A lesions (relatively short, proximal, and/or localized disease) to type D lesions (long, distal, and/or diffuse or totally occluded disease) (Fig. 48.9).[260] The TASC II guidelines suggest endovascular intervention as the treatment of choice for type A and B lesions and open surgical bypass as the treatment of choice for type C and D lesions, although factors such as operator expertise, patient preference, and patient comorbidities influence the final decision significantly in intermediate lesion types (types B and C).[260] Recent guidelines from the Society of Vascular Surgery recommend endovascular intervention for focal or intermediate length disease of the superficial femoral artery but recommend surgical bypass as an initial strategy for patients with diffuse disease and/or extensive calcification, or for average-risk patients with favorable anatomy for open repair.[260] In general, endovascular intervention for infrapopliteal disease has not been strongly recommended because it has limited benefit.[262]

Because chronic limb ischemia is frequently associated with extensive LEAD, the classic treatment approach has been open repair, which is endorsed by TASC II guidelines.[260] Nevertheless, there is growing support for endovascular intervention because of the higher perioperative morbidity and mortality rates with open repair in this population, although the data are sparse.[276,277] To date, the only randomized, controlled trial to compare open vascular repair to endovascular repair for critical limb ischemia is the Bypass versus Angioplasty in Severe Ischemia of the Limb (BASIL) trial, which enrolled more than 450 patients across 27 centers.[278] Although the perioperative morbidity rate was higher, surgical bypass had a significantly lower immediate failure rate. At 1 year, there was no difference in the primary end point of amputation-free survival, and at 2 years, there was a greater amputation-free survival in the surgical group. Furthermore, patients

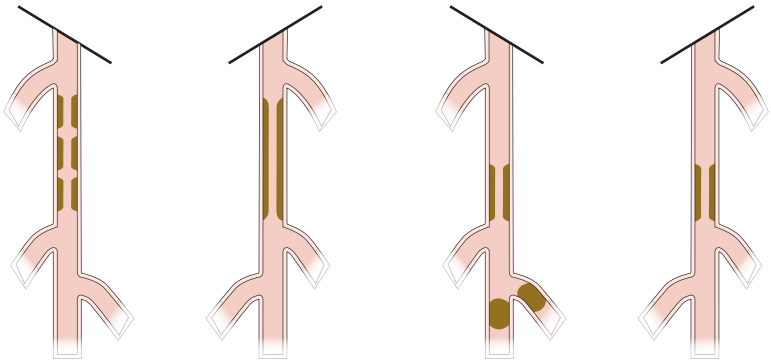
Type A lesions

- Single stenosis ≤10 cm in length
- Single occlusion ≤5 cm in length



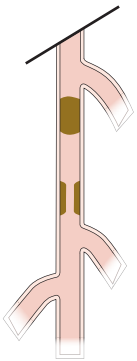
Type B lesions

- Multiple lesions (stenoses or occlusions), each ≤5 cm
- Single stenosis or occlusion ≤15 cm not involving the infrageniculate popliteal artery
- Single or multiple lesions in the absence of continuous tibial vessels to improve inflow for a distal bypass
- Heavily calcified occlusion ≤5 cm in length
- Single popliteal stenosis



Type C lesions

- Multiple stenoses or occlusions totaling >15 cm with or without heavy calcification
- Recurrent stenoses or occlusions that need treatment after two endovascular interventions



Type D lesions

- Chronic total occlusions of CFA or SFA (>20 cm, involving the popliteal artery)
- Chronic total occlusion of popliteal artery and proximal trifurcation vessels

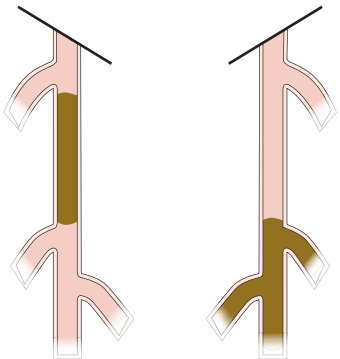


Fig. 48.9 TASC II classifications of femoral popliteal disease. Classification of infrainguinal disease based on location, multiplicity, and disease severity. *CFA,* common femoral artery; SFA, superficial femoral artery. *(Redrawn from Norgren L, Hiatt WR, Dormandy JA, et al. Inter-society consensus for the management of peripheral arterial disease [TASC II].* J Vasc Surg. *2007;45(suppl S):S5–S67.)*

who underwent open limb salvage after failed endovascular repair did worse than patients who underwent bypass as the primary repair.[279] This landmark trial suggests surgical bypass may benefit patients with chronic limb ischemia and that in the setting of limited life expectancy, endovascular intervention may suffice.[278,279]

Anesthetic Considerations and Management for Peripheral Arterial Intervention

Preoperative Evaluation and Preparation

Patients with LEAD are at high risk for perioperative myocardial ischemia, given the high prevalence of concurrent CAD, as already outlined. The preoperative evaluation should evaluate the extent and severity of underlying concomitant conditions, as per current guidelines (see Chapter 43).[9]

Baseline hemoglobin and hematocrit measurements should be taken, given the possibility for sudden and rapid blood loss. As with any vascular repair, adequate blood product must be available. Because renal dysfunction is highly likely, a basic metabolic panel should be obtained prior to surgery. A baseline ECG is helpful to identify any new myocardial injury that may occur during the perioperative period. Further cardiovascular testing should proceed according to current guidelines.[9]

Patients who have diabetes tend to have more aggressive peripheral vascular disease and amputation rates 5 to 10 times higher than in patients without diabetes.[262] A recent single-center clinical trial demonstrated that tight perioperative glucose control significantly decreases wound infections in diabetics with LEAD undergoing surgical bypass procedures.[280] Aggressive attempts should be made in the perioperative period to formulate a smoking cessation plan, given its significant adverse outcomes in this population.[272,273]

Intraoperative Anesthetic Technique

Open Lower Extremity Arterial Bypass

Open lower extremity revascularization procedures are amenable to anesthetic techniques such as regional blocks, neuraxial anesthesia, and general anesthesia. Although studies have suggested that regional and neuraxial techniques enhance hemodynamic stability and decrease catecholamine responses, these differences likely occur primarily during induction and emergence from general anesthesia.[281–284] Careful management of hemodynamics during these critical periods, therefore, may be just as efficacious. Most clinical trials have failed to demonstrate significant outcome benefit from a particular anesthetic technique in patients with LEAD.[281–287] Although regional and neuraxial anesthetic techniques may enhance lower extremity blood flow due to the concomitant sympathectomy, clinical trials have inconsistently demonstrated higher graft patency rates due to anesthetic technique.[288–290] Given that there is currently no compelling evidence to favor a particular anesthetic technique, the literature suggests at least equivalent outcomes. The final choice of anesthetic technique is left to the discretion of the provider, bearing in mind both patient risks and preferences.

A general anesthetic alleviates concerns of patient anxiety, discomfort, and cooperation. No trials have examined the use of one general anesthetic technique over another. The most important consideration when general anesthesia is employed is careful attention to perioperative hemodynamics, particularly during periods of known lability such as induction, intubation, cross-clamp placement or release, and emergence from anesthesia. A variety of agents can be employed to this end. It is prudent to have a variety of short-acting hemodynamic agents readily available to control changes in hemodynamics, including heart rate and blood pressure.

Neuraxial anesthesia is the most commonly used regional technique. Cutaneous innervation of the lower extremity is provided by the lumbar (primarily above the knee) and lumbosacral (primarily below the knee) plexi.[291] The lumbar plexus is composed of the ventral rami from L1–L4 with variable contribution from T12 (ultimately dividing into the femoral, lateral femoral cutaneous, and obturator nerves), and the lumbosacral plexus is composed of the ventral rami of L4–S3 (ultimately forming the sciatic nerve, which branches to become the tibial and common peroneal nerves). In general, local anesthetics are carefully titrated to slowly bring the anesthetic level to approximately T10 to allow for adequate surgical anesthesia while minimizing hemodynamic compromise. Light sedation with short-acting agents may be considered as supplementation to neuraxial or peripheral anesthesia.

Endovascular Lower Extremity Peripheral Arterial Repair

In general, infrainguinal endovascular interventions are very amenable to monitored anesthesia care or local anesthesia. Arterial access can be obtained percutaneously or via small surgical cutdown, typically under local anesthetic block performed by the surgical team. A variety of short-acting agents have been successfully used for monitored anesthesia care. Most commonly, short-acting opioids (such as fentanyl or remifentanil), benzodiazepines, or low doses of sedative agents such as propofol or dexmedetomidine are used in this regard. In general, hemodynamic perturbations and blood loss during endovascular management are minimal. Invasive monitoring is rarely warranted. As always, the anesthesia team must be prepared for rapid conversion to a general anesthetic should complications occur with either the surgical or the anesthetic management. Some patients may be poor candidates for monitored anesthesia care (eg, cannot lie flat or cannot follow commands); in this case, general anesthesia may be a more prudent strategy.

Intraoperative Challenges

Intraoperative challenges during infrainguinal vascular repair are usually secondary to hemodynamic changes related to peripheral vascular clamping and unclamping. In general, compared with AXC, peripheral vascular clamping is fairly well tolerated with relatively mild changes in afterload, hemodynamics, and myocardial wall stress. Release of the peripheral cross-clamp, as with an aortic cross-clamp, may result in hypotension as a result of a decrease in SVR and release of inflammatory mediators. Adequate volume loading, the availability of vasopressor and inotropic support, and close communication with the surgical team can help prevent profound derangements in hemodynamics during this critical period.

Postoperative Complications

Early complications following open infrainguinal bypass primarily involve graft patency, adverse cardiac events, or wound complications. A large multicenter study of more than 1400 patients undergoing open surgical repair for critical limb ischemia reported early complication rates, including graft occlusion (5.2%), wound complications (4.8%), MI (4.7%), amputation (1.8%), and hemorrhage (0.4%).[292] Perioperative mortality was reported to be 2.7%.[292] Complication rates are likely higher in this population than in those undergoing repair for intermittent claudication because of their greater disease burden and more technically challenging repairs. A large review of more than 5700 patients demonstrated an increase in major adverse events, including MI, heart failure, deterioration in renal function, and respiratory complications in patients with critical limb ischemia compared with patients undergoing elective repair.[293] A review of the National Surgical Quality Improvement Program (NSQIP) database found a higher incidence of death and major graft-related complications (graft failure, wound dehiscence, wound infection, and sepsis) among patients undergoing surgery for critical limb ischemia as opposed to claudication.[294]

Complication rates for endovascular interventions continue to decrease as technical skill improves. A review of more than 3700 patients undergoing endovascular repair for lower extremity PAD found complications related to puncture site in 4.0%, angioplasty site in 3.5%, and vessel site in 2.7%.[295] Surgical reintervention was required in 2% and limb loss occurred in 0.2%. Major systemic complications occurred in 0.4% and mortality in 0.2%. A recent systematic review of 23 studies reported complication rates of 8–17%, with most complications being minor and related to hematoma, arterial perforation, and distal embolization.[296] At 1 year of follow-up, clinical success ranged 50–70% with limb salvage rates of 80–90%.[296]

The Cardiac Patient for Thoracic Noncardiac Surgery

PETER D. SLINGER, MD, FRCPC | STEVEN M. NEUSTEIN, MD | EDMOND COHEN, MD

KEY POINTS

1. Cardiac patients or those who have had previous cardiac surgery often present for intrathoracic diagnostic or therapeutic noncardiac procedures. These patients present unique challenges.
2. Patients with coronary artery disease, valvular heart disease, cardiomyopathies, or pulmonary hypertension may require surgery involving lung isolation and one-lung ventilation (OLV) with its subsequent risk of severe hypoxia.
3. Patients with a low cardiac output tend to desaturate during OLV and often require inotropic support for thoracotomy or thoracoscopy.
4. Double-lumen endobronchial tubes and bronchial blockers are used for OLV during thoracic surgery. Bronchial blockers are a useful option for lung isolation in patients who will remain intubated postoperatively. However, double-lumen tubes are used more often because they are stable during surgery and can be suctioned.
5. It is very important for the anesthesiologist to review the chest imaging before any intrathoracic or airway procedure so that an appropriate airway management strategy can be planned.
6. Management of rigid bronchoscopy is fundamental to anesthesia for a lower airway lesion.

Patients with underlying cardiac disease and patients who have had previous cardiac surgery may subsequently present for intrathoracic diagnostic or therapeutic procedures for noncardiac problems. The reader is directed to other sources for basic thoracic anesthesia information.[1] This chapter presents the essential perioperative management considerations for patients with cardiac diseases who require noncardiac thoracic surgery.

Anesthetic Management for Pulmonary Resection in the Patient With Cardiac Disease

Coronary Artery Disease

Because smoking is prevalent among patients presenting for thoracic surgery, these patients are also at risk for having cardiovascular disease, including coronary and peripheral vascular disease. In particular, patients with coronary artery disease (CAD) need to be optimized medically before proceeding with surgery (see Chapters 1, 20, and 43). These patients may be taking β-blockers and statins, which should be continued through the perioperative period, including the day of surgery. Statin use has been shown to reduce perioperative cardiovascular risk in patients undergoing vascular surgery.[2] Patients with CAD should also be taking aspirin, unless contraindicated. If a coronary stent has been placed, aspirin is generally required for life. Most coronary stents are drug-eluting stents and necessitate taking another antiplatelet drug such as clopidogrel for a year. Typically, clopidogrel is stopped at least 5 days before surgery, and preferably 7 days to allow for placement of neuraxial analgesia. Aspirin should be continued both preoperatively and postoperatively. American College of Cardiology guidelines suggest that, if possible, surgery should be delayed for 1 year following drug-eluting stent placement[3] (see Chapters 43 and 44). This delay is not likely to be feasible in the presence of lung cancer that could spread during a prolonged delay. However, one study suggested that the risks after drug-eluting stents were placed were minimal after 6 months (Fig. 49.1).[4] The risk of the stent thrombosing perioperatively generally outweighs the additional risk of bleeding with continuing aspirin therapy. A recent large prospective study of slightly more than 10,000 patients showed that continuing aspirin perioperatively increased bleeding risk, without impacting cardiovascular risk.[5] However, that study excluded patients with drug-eluting stents placed within 1 year.

Intraoperatively, avoiding excessive myocardial oxygen demand ($M\dot{V}O_2$), which could cause myocardial ischemia, is important. Elevated heart rate can be controlled with β-blockade. The short-acting β-blocker esmolol may be useful to acutely control the tachycardia and hypertension that may result from sympathetic stimulation during laryngoscopy, intrathoracic stimulation, and emergence from general anesthesia. The placement of a double-lumen tube (DLT) may be more difficult than placement of a single-lumen tube (SLT), and a prolonged laryngoscopy is more likely to cause sympathetic stimulation. Nitroglycerin can also be useful to treat hypertension in these situations, especially if the heart rate is low and hypertension persists. Nitroglycerin can provide both venodilation and dilation of coronary arteries (see Chapters 11 and 20).

In addition to demand-related ischemia, adequate supply of oxygen to the myocardium must be maintained. A relatively low hemoglobin oxygen saturation, which may occur during one-lung ventilation (OLV), may not be tolerated in patients at risk for myocardial ischemia. The lowered oxygen blood content could contribute toward the development of myocardial ischemia, and arrhythmias. If the oxygen saturation level drops, it may be necessary to reinstitute two-lung ventilation (TLV), or add continuous positive airway pressure (CPAP). During thoracoscopy, it may only be possible to use a limited amount of CPAP without impairing surgical conditions.

The presence of anemia can impact both myocardial supply and demand. A lowered hemoglobin level reduces the oxygen blood content. In addition, the anemia may lead to a compensatory tachycardia, increasing $M\dot{V}O_2$. Anemia, with tachycardia, is not well tolerated, and these patients should undergo transfusion. Patients who are treated with β-blockers intraoperatively also may not tolerate anemia.[6]

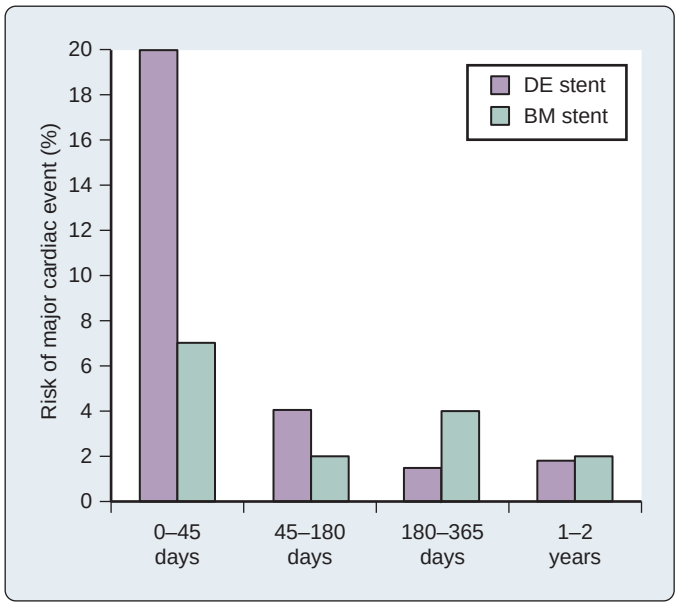

Fig. 49.1 Risk of major 30-day postoperative cardiac events after elective noncardiac surgery in more than 2000 patients after coronary artery stent placement. The risks become minimal after 6 weeks for bare metal *(BM)* stents and after 6 months for drug-eluting *(DE)* stents. *(Based on data from Wijeysundera ND, Wijeysundera HC, Yun L, et al. Risk of elective major noncardiac surgery after coronary stent insertion.* Circulation. *2012;126:1355–1362.)*

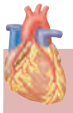
Recovery from a thoracotomy incision is accompanied by more pain than recovery from a thoracoscopy. The pain causes sympathetic stimulation and increases $M\dot{V}O_2$. Effective postoperative pain control is especially important in such patients, and an epidural or paravertebral catheter is recommended, if possible. Advanced planning is needed in the case of a patient taking clopidogrel, such that it is discontinued per the guidelines of the American Society of Regional Anesthesia.[7] Otherwise, the surgery either needs to be postponed or needs to be performed without the benefit of an epidural or paravertebral catheter, which might increase the perioperative cardiovascular and pulmonary risk in patients with severe lung disease.

Patients with a smoking history and significant CAD may have experienced a previous myocardial infarction and have a resulting cardiomyopathy. Such patients may have an internal cardioverter-defibrillator, which will require a perioperative management strategy (see Chapters 4, 5, and 45).

A high inspired oxygen concentration is needed to help tolerate OLV without hypoxemia, limiting the ability to use nitrous oxide. Most commonly, potent inhaled agents are used, although the use of greater than 1 minimum alveolar concentration (MAC) may interfere with hypoxic pulmonary vasoconstriction (HPV). Patients with a low left ventricular ejection fraction may not tolerate the myocardial depressant effects of higher doses of the potent inhaled agents. The concomitant intraoperative use of remifentanil can provide analgesia without vasodilation or myocardial depression and will facilitate a rapid emergence following surgery without prolonged respiratory depression. Its use may allow for a reduction in the amount of potent inhaled agent used. Although higher amounts of the potent inhaled agents can inhibit HPV, the use of sevoflurane has been shown to reduce the level of inflammatory mediators during thoracic surgery, compared with propofol and remifentanil.[8] It may be necessary to infuse a vasopressor concomitantly with the anesthetic agents to maintain an adequate perfusion pressure. If the cardiomyopathy is severe, it may be prudent to place a central venous catheter to provide central access for the administration of norepinephrine or phenylephrine. Strategies to manage the patient with CAD are summarized in Box 49.1.



BOX 49.1 STRATEGIES FOR PERIOPERATIVE MANAGEMENT OF PATIENTS WITH CORONARY ARTERY DISEASE UNDERGOING THORACIC SURGERY

- Maintain preoperative aspirin if a coronary stent is present.
- Maintain preoperative β-blocker.
- Hold clopidogrel 7 days preoperatively, if possible, to allow for neuraxial analgesia.
- Avoid hypoxemia during one-lung ventilation.
- Avoid anemia.
- Avoid tachycardia.
- Maintain adequate perfusion pressure.
- Use epidural or paravertebral postoperative analgesia.

Valvular Heart Disease

Patients with coexisting valvular heart disease also need special consideration when presenting for thoracic surgery. Patients with aortic stenosis in particular, will need maintenance of cardiac preload, systemic vascular resistance (SVR), and myocardial contractility. Such patients may not tolerate higher amounts of potent inhaled agents, due to vasodilation and myocardial depression. Patients with aortic stenosis are likely to have compensatory concentric left ventricular hypertrophy and diastolic dysfunction. Patients undergoing thoracic surgery are prone to atrial arrhythmias, especially with a thoracotomy incision. Patients with aortic stenosis and left ventricular hypertrophy are likely to poorly tolerate such arrhythmias, because of an increased dependence on atrial contraction for ventricular filling. The sympathetic block and vasodilation associated with epidural analgesia also may not be well tolerated. A dilute concentration of local anesthesia should be used, such as 0.1% bupivacaine, and the epidural should be activated gradually. In addition to maintaining adequate hydration and avoiding excessive myocardial depression and vasodilation, it may be necessary to also infuse a vasoconstrictor during the general anesthetic. The addition of intravenous remifentanil may be a beneficial adjunct to provide analgesia without myocardial depression or vasodilation (see Chapters 21, 24, and 27).

In the past, the placement of a pulmonary artery catheter (PAC) would have been indicated in the presence of significant ventricular dysfunction and/or valvular heart disease for monitoring pulmonary artery pressures (PAPs) and measurement of cardiac output (CO). Currently, the vast majority of thoracic operations are done without the use of this monitoring technique, which has not been shown to improve outcome.[9] PACs are also prone to being misused as a result of misinterpretation of data.[10] However, the presence of severe pulmonary hypertension (PH) may be an indication for monitoring with a PAC to guide the administration of nitric oxide or other pulmonary vasodilators.

The use of the arterial tracing for evaluation of systolic pressure or pulse pressure variation is predictive of fluid responsiveness[11] (see Chapters 13 and 47). A respiratory-related decrease less than 13% suggests that the patient would be fluid responsive. A change of 9–13% has been shown to reflect an intermediate range of predictability, a gray zone, in which the patient may be fluid responsive. If the systolic pressure or pulse pressure variation is less than 9%, it is unlikely that the patient would be fluid responsive.[12] There has been some question about the usefulness of central venous pressure to predict fluid responsiveness during anesthesia.[13] However, in the open-chest context of a thoracotomy, central venous pressure may be more useful than other monitors to predict fluid responsiveness.[14] A general goal of fluid management for thoracic surgery is to avoid excessive fluid administration and possible pulmonary edema that is more likely to occur following larger lung resections, particularly a right pneumonectomy.

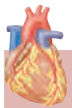
Cardiomyopathies

During OLV for thoracotomy or thoracoscopy, there is an obligate 20–30% shunt through the nonventilated lung. If the CO is decreased, the fall in mixed venous oxygen saturation will lead to a fall in arterial oxygen saturation. Thus, patients with cardiomyopathies may poorly tolerate OLV. They need monitoring of venous saturation and inotropes to support CO. This is particularly a concern in patients having video-assisted thoracoscopic cardiac sympathectomy procedures to treat refractory ventricular arrhythmias.[15] These procedures are being done with increasing frequency to treat ventricular tachyarrhythmias refractory to medical or ablative therapies and also for long QT syndrome.[16] The approach is by left or bilateral video-assisted thoracoscopic surgery (VATS). Intraoperative considerations include reprogramming of implanted electronic antitachycardia devices, percutaneous defibrillator pads, and provisions to optimize CO and oxygenation during OLV. These patients recover slowly from episodes of desaturation during OLV so it is best to avoid desaturation with prophylactic measures discussed later.

Pulmonary Hypertension

Patients with PH (mean PAP > 25 mm Hg by catheterization or systolic PAP > 50 on echocardiography)[17] may present for a variety of noncardiac thoracic surgical procedures, including pulmonary resections for malignant or benign lesions, esophageal surgery, or vascular surgery.[18] Compared to patients with normal PAPs, patients with PH are at increased risk of respiratory complications and the need for prolonged intubation after noncardiac surgery.[19] The classification of PH is discussed in Chapter 26, and it includes primary and secondary causes, including pulmonary arterial hypertension, pulmonary veno-occlusive disease, left-sided heart disease, lung disease and chronic hypoxemia, pulmonary thromboembolic disease, and a variety of autoimmune, metabolic, and systemic disorders.[20] Anesthesiologists often encounter two main types of PH: PH caused by left-sided heart disease and PH caused by lung disease (Box 49.2). Most of the anesthesia literature has focused on patients with underlying cardiac disease.[21] However, patients who present for noncardiac surgery are more likely to have PH secondary to lung disease and the anesthetic management is very different for these two types of PH. This section focuses on patients with PH due to lung disease. Much of what has been learned about anesthesia for patients with this type of PH has come from clinical experience with pulmonary endarterectomies[22] and lung transplantation (see Chapters 25 and 26).

Although estimates vary widely, depending on disease severity and the method of measurement, the prevalence of PH in patients with severe chronic lung disease ranges from 40–50%.[23] As PAPs rise, evidence of cor pulmonale develops as increased strain causes the right ventricle to become hypertrophic and dysfunctional. In the United States, cor pulmonale accounts for 10–30% of all hospital admissions of patients with heart failure, of which 84% are secondary to chronic obstructive pulmonary disease (COPD). The risk of right ventricular (RV) ischemia is also increased. The right ventricle is normally perfused throughout the cardiac cycle. However, the increased RV transmural and intracavitary pressures associated with PH may restrict perfusion of the right coronary artery during systole, especially as PAPs approach systemic levels. Avoiding hypotension is key to managing these patients.



BOX 49.2 MODIFIED CLASSIFICATION OF PULMONARY HYPERTENSION FOR THORACIC ANESTHESIA

Left Heart Disease
- Systolic dysfunction
- Diastolic dysfunction
- Mitral valvular disease: stenosis, regurgitation
- Congenital cardiac disease

Lung Disease
- Pulmonary vascular disease
- Chronic lung diseases, hypoxemia, sleep apnea
- Thromboembolic pulmonary hypertension
- Miscellaneous: autoimmune, metabolic, etc.

The impact of PH on RV dysfunction has several anesthetic implications. The hemodynamic goals are similar to other conditions in which CO is relatively fixed. Care should be taken to avoid physiologic states that will increase pulmonary vascular resistance (PVR), such as hypoxemia, hypercarbia, acidosis, and hypothermia. Conditions that impair RV filling, such as tachycardia and arrhythmias, are not well tolerated. Ideally, under anesthesia, RV contractility and SVR are maintained or increased, whereas PVR is decreased. This would ensure forward flow and minimize the risk of RV ischemia. In practice, these goals can be a challenge to achieve because anesthetics are commonly associated with a decrease in SVR and a variable effect on PVR. An animal study has suggested that desflurane may offer a better hemodynamic profile than sevoflurane or isoflurane with better maintenance of systemic arterial pressure and a more favorable pulmonary-to-systemic pressure ratio.[24]

Ketamine is a useful anesthetic agent in PH due to lung disease.[25] Ketamine is well known for its sympathomimetic effects, increasing cardiac contractility and SVR. However, its effect on PVR is controversial. Although concern is often raised over ketamine's potential to worsen PH, animal and human clinical studies have suggested that in some contexts it may decrease PVR.[26] Anecdotally, ketamine is commonly and safely used for anesthetic induction of patients with severe PH. Inodilators such as dobutamine and milrinone may improve hemodynamics in patients with PH secondary to left-sided heart disease. However, they tend to cause tachycardia and decreased SVR, potentially leading to hemodynamic deterioration of patients with PH due to lung disease. To maintain a systemic blood pressure (SBP) that is greater than the PAP, vasopressors such as phenylephrine or norepinephrine are commonly used. Of the two, norepinephrine is preferable because it maintains CO and decreases the PAP/SBP ratio. In contrast, phenylephrine causes the CO to drop while the PAP/SBP ratio remains unchanged.[27] Increasingly, vasopressin is also used to maintain systemic pressures. Vasopressin appears to significantly increase SBP without affecting PAP in patients with PH (Fig. 49.2).[28,29] In patients with severe PH, selective inhaled pulmonary vasodilators including nitric oxide (10–40 ppm)[30] or nebulized prostaglandins (prostacyclin, 50 ng/kg per min) (Fig. 49.3) [31] should be considered. A useful pharmacologic management strategy for the failing right ventricle in patients with PH secondary to lung disease is the combination of a potent intravenous vasoconstrictor and an inhaled pulmonary vasodilator (Box 49.3). Patients requiring inhaled nitric oxide can be weaned with oral sildenafil postoperatively.[32]

The extremes of tidal volumes (high and low) can cause compression of the extraalveolar or interalveolar blood vessels, both of which contribute to an increased PVR. As a result, a ventilation strategy that avoids atelectasis as well as lung hyperinflation should be employed.

Echocardiography is useful for diagnosis and management of patients with PH. However, it should be appreciated that transthoracic echocardiographic assessments of RV systolic pressure may be plus or minus 10 mm Hg compared to catheterization measurements in more than 40% of patients[33] with a tendency toward underestimation. Transesophageal echocardiography (TEE) is commonly recommended for intraoperative monitoring of RV function in patients with PH.[34] Although echocardiography is extremely useful for differentiating between a normally functioning right ventricle and a dilated hypokinetic right ventricle (and this correlates with outcome in cardiac surgery),[35] for minute-to-minute continuous objective monitoring of RV function, TEE is not yet the ideal monitor. This is because the right ventricle is a very complex nongeometric structure in three dimensions. At present, continuous monitoring of minor changes in regional RV function with standard two-dimensional TEE is, at best, difficult.

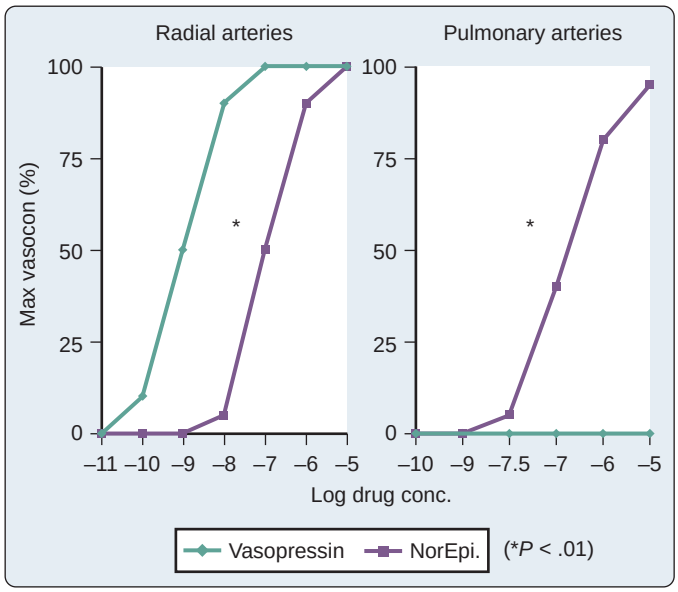


Fig. 49.2 In vitro maximal vasoconstriction *(max vasocon.)* dose-response curves of human radial *(left)* and pulmonary *(right)* arteries to vasopressin and norepinephrine. All vasoconstrictors studied (including phenylephrine and metaraminol) showed similar dose-response patterns in both types of arteries except vasopressin, which showed no constriction of pulmonary arteries. *(Based on data from Currigan DA, Hughes RJA, Wright CE, et al. Vasoconstrictor responses to vasopressor agents in human pulmonary and radial arteries.* Anesthesiology. *2014;121:930–936.)*

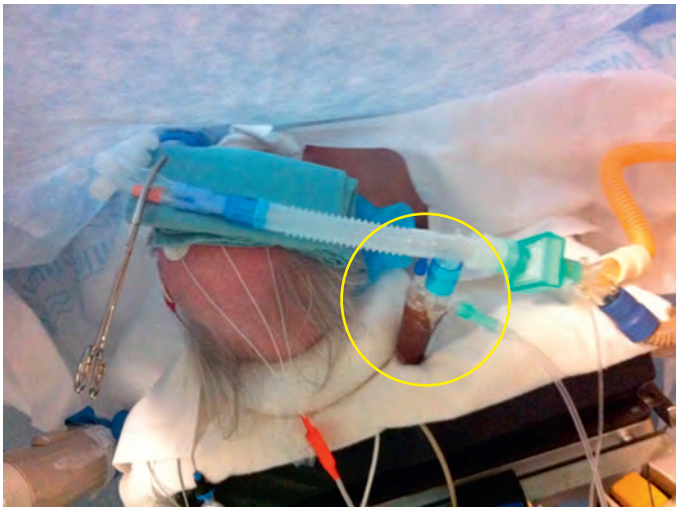

Fig. 49.3 Prostacyclin can be delivered continuously into a standard anesthetic circuit and the dose titrated as needed. In the photograph, prostacyclin is delivered by nebulization to the ventilated lung via a double-lumen tube during thoracic surgery and one-lung ventilation in a patient with pulmonary hypertension.

Advances in echocardiography technology may make continuous objective monitoring of RV function possible in the near future[36] (see Chapters 14–16 and 46).

At present, the basis of intraoperative monitoring for patients with PH who are undergoing noncardiac thoracic surgical procedures remains the PAC. However, it must be understood that PA data alone can be misleading in these patients. Rising PAPs are almost always a bad sign. Falling PAPs may be a good sign, indicating pulmonary vasodilation, or may be a very bad sign, indicating impending RV

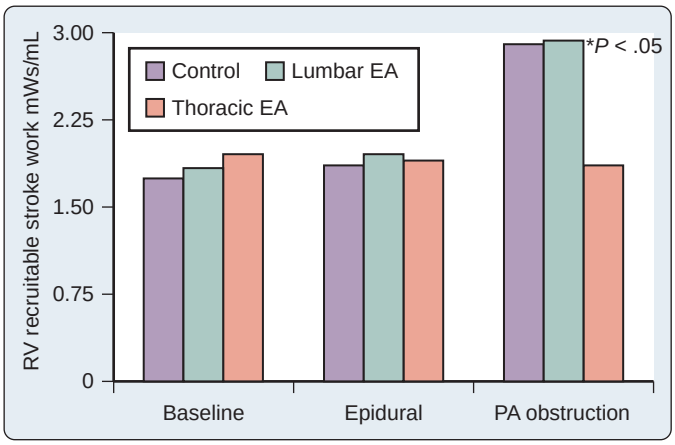

Fig. 49.4 Right ventricular *(RV)* recruitable stroke work, a measure of RV contractility, measured in three groups of anesthetized pigs: *Control* (no epidural) group, *Lumbar EA* (lumbar epidural anesthesia) group, and *Thoracic EA* (thoracic epidural anesthesia) group. Epidural bupivacaine injection had no effect on RV function in either of the study groups. Subsequent inflation of a balloon in the main pulmonary artery *(PA obstruction),* increasing RV afterload, resulted in a compensatory increase in RV contractility in the control and lumbar EA groups but not in the thoracic EA group. *(Based on data from Missant C, Claus P, Rex S, Wouters PF. Differential effects of lumbar and thoracic epidural anesthesia on the haemodynamic response to acute right ventricular pressure overload.* Br J Anaesth. *2009;104:143–149.)*

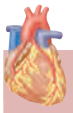

BOX 49.3 MANAGEMENT PRINCIPLES FOR PULMONARY HYPERTENSION SECONDARY TO LUNG DISEASE

- Avoid hypotensive and vasodilating anesthetic agents whenever possible.
- Ketamine does not exacerbate pulmonary hypertension.
- Support mean systolic pressure with vasopressors: norepinephrine, phenylephrine, vasopressin.
- Use inhaled pulmonary vasodilators (nitric oxide, prostacyclin) in preference to intravenous vasodilators.
- Use thoracic epidural local anesthetics cautiously and with inotropes.
- Monitor cardiac output.

decompensation. Thus, PAP data must be followed in concert with CO, mixed venous saturation, and/or central venous pressure data.

Although there have been multiple case reports of the successful use of lumbar epidural analgesia and anesthesia in obstetric patients with PH,[37] there are very few reports of the use of thoracic epidural analgesia (TEA) in patients with PH. Patients with PH secondary to lung disease seem to be extremely dependent on tonic cardiac sympathetic innervation for normal hemodynamic stability. Animal studies suggest that the hemodynamic response to an increase in RV afterload is very different with thoracic versus lumbar epidural anesthesia. In one study, RV contractility increased as afterload increased in animals with a lumbar epidural, similar to the response in animals without neuraxial block. The cardiac sympathectomy of TEA abolished this increase in contractility[38] (Fig. 49.4). Because of the increased risk of postoperative respiratory complications in these patients, the use of postoperative TEA is often desirable. However, it must be appreciated that these patients will often require a low-dose infusion of inotropes or vasopressors during TEA. This may necessitate continued central venous catheterization and intensive care unit admission. Paravertebral analgesia has been associated with better hemodynamic stability after thoracotomy compared with TEA in patients with normal cardiac

function,[39] but this has not been specifically studied in patients who have PH.

Lung Isolation for Cardiac Patients Having Thoracic Procedures

Procedures in the thoracic cavity are greatly facilitated by the use of OLV. Procedures on the lung, esophagus, or thoracic aorta, or resection of mediastinal masses, frequently require a collapsed lung for a motionless surgical field and optimal surgical exposure.

The Robertshaw-type DLTs have been used in clinical practice for over half a century and are considered the gold standard to achieve lung separation.[40] The Univent tube (Fuji Corp, Tokyo, Japan) and other independent endobronchial blockers were introduced to clinical practice as an alternative to the DLT. These 9-Fr blockers have a steering mechanism to direct them into the selected bronchus. The EZ-Blocker (Teleflex Medical Inc, Research Triangle Park, NC), recently introduced into clinical practice, is a 7-Fr catheter designed with a Y shape and two distal extensions that ride over the carina, and each lung can be selectively deflated. Whether a DLT or blocker is used to provide lung separation, proper position should be confirmed by fiberoptic bronchoscopy (FOB).

Double-Lumen Tubes

Advantages of Double-Lumen Tubes

1. In cases in which the nondiseased lung is exposed to contamination by blood or pus from the diseased lung, the lungs must be isolated. When lung isolation is required, DLTs are preferable to endobronchial blockers because they provide a superior protective seal to prevent contamination of the unaffected lung.
2. DLTs are preferred for bilateral procedures such as bilateral lung transplantation, bilateral sympathectomy, and bilateral lung wedge resection. Once in place, they minimize the manipulation and resulting hemodynamic response.
3. DLTs are more stable once positioned and have less tendency to dislocate during surgical manipulation and patient positioning. This is important in patients with cardiac disease in whom any irritation of the tracheobronchial tree can induce tachycardia, hypertension, and ischemia.
4. It is easier to suction thick secretions or blood clots through the lumen of the DLT. Aggressive pulmonary toilet is particularly crucial in cardiac patients.

Disadvantages of Double-Lumen Tubes

1. DLTs are somewhat bulky and may be more difficult to insert and position compared with SLTs. It may be challenging to switch from a DLT to an SLT if the patient requires postoperative ventilatory support. The use of tube exchange catheters may trigger a cardiovascular response that can be detrimental to the patient with cardiac disease. Tracheal intubation causes a stress response, resulting in increased sympathetic activity that may result in hypertension, tachycardia, and arrhythmias. These changes in hemodynamics can be harmful to patients with hypertension and myocardial ischemia due to inadequate perfusion of the coronary arteries.
2. Previous studies have found a higher incidence of sore throat, hoarseness, and pharyngeal or bronchial tree laceration (Fig. 49.5) associated with DLT use. Knoll and colleagues evaluated the incidence of airway injury after lung surgery and compared techniques.[41] They concluded that the incidence of postoperative hoarseness and number of days with hoarseness and sore throat were significantly decreased in the blocker group compared with the DLT group. Moreover, the blocker technique was associated with a decreased incidence of vocal cord injuries (44% vs 17%, respectively). Any added injury to patients with cardiac disease, who are often on anticoagulant therapy for cardiac stents or arrhythmia, can add a significant increased risk of complications and prolong recovery.

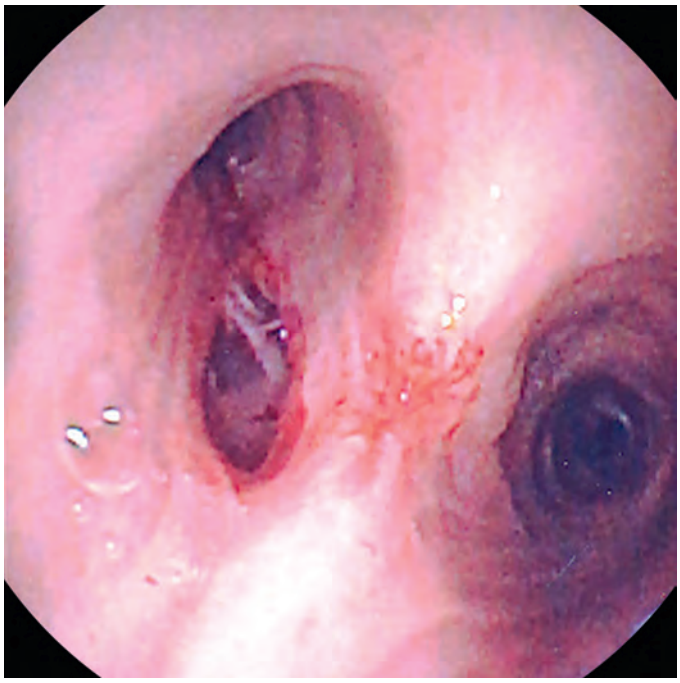

Fig. 49.5 Photograph taken through a fiberoptic bronchoscope of a laceration of the posterior membranous portion of the left mainstem bronchus just dustal to the carina caused by a left-sided double-lumen tube.

Endobronchial Blockers for Lung Separation

Endobronchial blockers can be placed to achieve lung separation and may offer several advantages to patients with cardiac disease.[42] The most significant advantage is the decrease in hemodynamic stress. Because the blocker is inserted through an SLT, it is less stimulating than the insertion and manipulation of a DLT. Some patients arrive from the intensive care unit to the operating room with endotracheal tubes in place; insertion of a blocker would be the best option to avoid changing the existing SLT.

Lung Separation in Thoracic Aortic Aneurysm Surgery

Because of the close anatomic relationship, a thoracic aortic aneurysm can potentially compress the airway at the level of the trachea or, more often, left mainstem bronchus. Patients with a descending thoracic aortic aneurysm and left mainstem bronchus compression who require lung isolation should be managed with a right-sided DLT (Fig. 49.6). Placement of a left-sided DLT is both difficult and dangerous in these patients, presenting the risk of airway trauma and rupture of the aneurysm. A DLT in a descending thoracic aortic aneurysm repair improves surgical exposure and makes it easier to remove blood and secretions. The use of blockers for thoracic aneurysm repair should be limited to situations in which intubation is difficult.

Management of One-Lung Ventilation

During OLV the anesthesiologist has the unique and often conflicting goals of trying to maximize atelectasis in the nonventilated lung to improve surgical access while trying to avoid atelectasis in the ventilated lung (usually the dependent lung) to optimize gas exchange.[43] This can be particularly challenging in the patient with underlying cardiac disease. The gas mixture in the nonventilated lung immediately before OLV has a significant effect on the speed of collapse of this lung. Because of its low blood-gas solubility, nitrogen (or an air-oxygen mixture) will

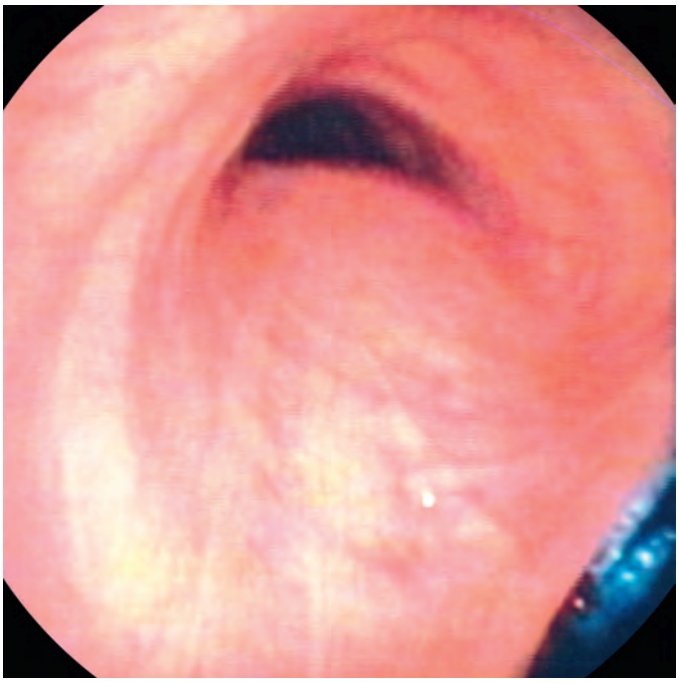

Fig. 49.6 Photograph taken through a fiberoptic bronchoscope of a posterior compression of the left mainstem bronchus caused by an aneurysm of the descending thoracic aorta.

delay collapse of this lung.[44] This is a problem at the start of minimally invasive surgery when surgical visualization in the operative hemithorax is limited. It is important to thoroughly denitrogenate the operative lung, by ventilating with oxygen, immediately before it is allowed to collapse.

During the period of two-lung anesthesia before the start of OLV, atelectasis will develop in the dependent lung. It is useful to perform a recruitment maneuver of the dependent lung immediately after the start of OLV to decrease this atelectasis. Recruitment is important to maintain Pa_{O_2} levels during subsequent OLV.[45]

Hypoxemia

A major concern that influences anesthetic management of patients undergoing thoracic surgical procedures is the occurrence of hypoxemia during OLV. There is no universally acceptable value for the safest lower limit of oxygen saturation during OLV. An arterial oxygen saturation of 90% ($Pa_{O_2} \approx 60$ mm Hg) is commonly seen as the lowest acceptable limit. However, the lowest acceptable saturation will be higher in patients with organs at risk of hypoxia due to limited regional blood flow (eg, coronary or cerebrovascular disease) and in patients with limited oxygen transport (eg, anemia or decreased cardiopulmonary reserve). It has been shown that during OLV, patients with COPD desaturate more quickly during isovolemic hemodilution than do patients without COPD.[46]

Previously, hypoxemia occurred frequently during OLV. Reports for the period 1950–1980 describe an incidence of hypoxemia (arterial saturation <90%) of 20% to 25%.[47] Current reports describe an incidence of less than 5%.[48] This improvement is most likely due to several factors: improved lung isolation techniques, such as routine FOB to prevent lobar obstruction from DLTs; improved anesthetic agents, which cause less inhibition of HPV; and better understanding of the pathophysiology of OLV. The pathophysiology of OLV involves the body's ability to redistribute pulmonary blood flow to the ventilated lung. The anesthesiologist's goal during OLV is to maximize PVR in the nonventilated lung while minimizing PVR in the ventilated lung. Key to understanding this physiologic goal is the appreciation that PVR is correlated with lung volume in a hyperbolic fashion. PVR is lowest at functional residual capacity (FRC) and increases as lung volume rises or falls above or below FRC.[49] The anesthesiologist's aim, to optimize pulmonary blood flow redistribution during OLV, is to maintain the ventilated lung as close as possible to its FRC while facilitating collapse of the nonventilated lung to increase its PVR.

Most thoracic surgery is performed while the patient is in the lateral position. Patients having OLV in the lateral position have significantly better Pa_{O_2} levels than patients during OLV in the supine position because of gravitational enhancement of blood flow to the dependent, ventilated lung.[50] This applies both to patients with normal lung function and to those with COPD.[51]

Hypoxic Pulmonary Vasoconstriction

HPV can decrease the blood flow to the nonventilated lung by as much as 50%.[52] The stimulus for HPV is primarily the alveolar oxygen tension ($P_{A_{O_2}}$), which stimulates precapillary vasoconstriction redistributing pulmonary blood flow away from hypoxemic lung regions via a pathway involving nitric oxide and/or cyclooxygenase synthesis inhibition.[53] The mixed venous P_{O_2} is also a stimulus although considerably weaker than $P_{A_{O_2}}$. HPV has a biphasic temporal response to alveolar hypoxia. The rapid-onset phase begins immediately and reaches a plateau by 20 to 30 minutes. The second (delayed) phase begins after 40 minutes and plateaus after several hours.[54] The offset of HPV is also biphasic, and PVR may not return to baseline for several hours after a prolonged period of OLV. This may contribute to increased desaturation during the collapse of the second lung during bilateral thoracic procedures. HPV also has a preconditioning effect, and the response to a second hypoxic challenge will be greater than to the first challenge.[55]

The surgical trauma to the lung can affect pulmonary blood flow redistribution. Surgery may oppose HPV by release of vasoactive metabolites locally in the lung. Conversely, surgery can dramatically decrease blood flow to the nonventilated lung by deliberately or accidentally mechanically interfering with the unilateral pulmonary arterial or venous blood flow.[56] HPV is decreased by vasodilators such as nitroglycerin and nitroprusside. In general, vasodilators can be expected to cause a deterioration in Pa_{O_2} during OLV. Thoracic epidural sympathetic blockade probably has little or no direct effect on HPV, which is a localized chemical response in the lung.[57] However, thoracic epidural anesthesia can have an indirect effect on oxygenation during OLV if it is allowed to cause hypotension and a fall in CO.

Choice of Anesthetic

All the volatile anesthetics inhibit HPV in a dose-dependent fashion. Animal studies suggest that this inhibition is dependent on the agent: halothane > enflurane > isoflurane.[58] In doses of 1 MAC or less, the modern volatile anesthetics (isoflurane, sevoflurane,[59] and desflurane[60]) are weak and equipotent inhibitors of HPV. The inhibition of the HPV response by 1 MAC of a volatile agent such as isoflurane is approximately 20% of the total HPV response, and this could account for only a net 4% increase in total arteriovenous shunt during OLV.[61] In addition, volatile anesthetics cause less inhibition of HPV when delivered to the active site of vasoconstriction via the pulmonary arterial blood than via the alveolus. During established OLV, the volatile agent only reaches the hypoxic lung pulmonary capillaries via the mixed venous blood. No clinical benefit in oxygenation during OLV has been shown for total intravenous anesthesia above that seen with 1 MAC of the modern volatile anesthetics.[62]

The use of nitrous oxide/oxygen (N_2O/O_2) mixtures is associated with a higher incidence of postthoracotomy radiographic atelectasis (51%) in the dependent lung than when air/oxygen mixtures are used (24%). Nitrous oxide also tends to increase pulmonary artery pressures in patients who have PH, and N_2O inhibits HPV. For these reasons N_2O is usually avoided during thoracic anesthesia.

Cardiac Output

The effects of alterations of CO during OLV are complex. Increasing CO tends to cause increased PAPs and passive dilation of the pulmonary vascular bed, which in turn opposes HPV and has been shown to be associated with increased arteriovenous shunt (Qs/Qt) during OLV.[63] However, in patients with a relatively fixed oxygen consumption, as is seen during stable anesthesia, the effect of an increase in CO is to increase the mixed venous oxygen saturation ($S\bar{v}o_2$). Thus, increasing CO during OLV tends to increase both shunt and $S\bar{v}o_2$, which have opposing effects on PaO_2. There is a ceiling effect to the amount that $S\bar{v}o_2$ can be increased. Increasing the CO to supranormal levels by administering inotropes such as dopamine tends to have an overall negative effect on PaO_2.[64] Conversely, allowing the CO to fall will lead to falls in both shunt and $S\bar{v}o_2$ with a net effect of decreasing PaO_2. It is very important to maintain CO in patients with limited cardiac reserve.

Ventilation Strategies During One-Lung Ventilation

The strategy used to manage the ventilated lung during OLV plays an important part in the distribution of pulmonary blood flow between the lungs. It has been the practice of many anesthesiologists to use the same large tidal volume (eg, 10 mL/kg ideal body weight) during OLV as during TLV. This strategy decreases hypoxemia probably by recurrently recruiting atelectatic regions in the dependent lung and may result in higher PaO_2 values during OLV than compared with smaller tidal volumes.[65] However, there is a trend to use smaller tidal volumes with positive end-expiratory pressure (PEEP) during OLV for several reasons. First, the incidence of hypoxemia during OLV is much lower than it was 20 to 30 years ago. Second, there is a risk of causing acute injury to the ventilated lung with prolonged use of large tidal volumes. Third, a ventilation pattern that allows cyclic atelectasis and recruitment of lung parenchyma seems to be injurious.[66]

Respiratory Acid-Base Status

The efficacy of HPV in a hypoxic lung region is increased in the presence of respiratory acidosis and is inhibited by respiratory alkalosis. However, there is no net benefit to gas exchange during OLV from hypoventilation because the respiratory acidosis preferentially increases the PVR of the well-oxygenated lung and this opposes any clinically useful pulmonary blood flow redistribution.[67] Overall, the effects of hyperventilation usually tend to decrease PAPs.

Positive End-Expiratory Pressure

Resistance to blood flow through the lung is related to lung volume in a biphasic pattern and is lowest when the lung is at its FRC. Keeping the ventilated lung as close as possible to its normal FRC using modest amounts of PEEP favorably encourages pulmonary blood flow to this lung. Several intraoperative factors that are known to alter FRC tend to cause the FRC of the ventilated lung to fall below its normal level; these factors include lateral position of the patient, paralysis, and opening the nondependent hemithorax, which allows the weight of the mediastinum to compress the dependent lung. Attempts to measure FRC in human patients during OLV have been complicated by the presence of a persistent end-expiratory airflow in patients who have COPD.[68] Many patients do not reach their end-expiratory equilibrium FRC lung volume as they try to exhale a relatively large tidal volume through one lumen of a DLT. These patients develop dynamic hyperinflation and an occult PEEP (auto-PEEP).[41]

Auto-PEEP

Auto-PEEP (also called *intrinsic PEEP*) is most prone to occur in patients with decreased lung elastic recoil, such as older adult patients or patients with emphysema.[69] Auto-PEEP increases as the inspiratory-to-expiratory (I:E) ratio increases (ie, as the time of expiration decreases). This auto-PEEP, which averages 4 to 6 cm H_2O in most series of lung cancer patients studied, opposes the previously mentioned factors, which tend to diminish dependent-lung FRC during OLV. The effects of applying external PEEP through the ventilator circuit to the lung in the presence of auto-PEEP are complex. Patients with a very low auto-PEEP (<2 cm H_2O) will experience a greater increase in total PEEP from a moderate (5 cm H_2O) external PEEP than those with a high level of auto-PEEP (>10 cm H_2O). Whether the application of PEEP during OLV improves a patient's gas exchange depends on the individual's lung mechanics. If the application of PEEP tends to shift the expiratory equilibration position on the compliance curve toward the lower inflection point of the curve (ie, toward the FRC) then external PEEP is of benefit (Fig. 49.7). However, if the application of PEEP raises the equilibration point such that it is further from the lower inflection point of the curve, then gas exchange deteriorates.

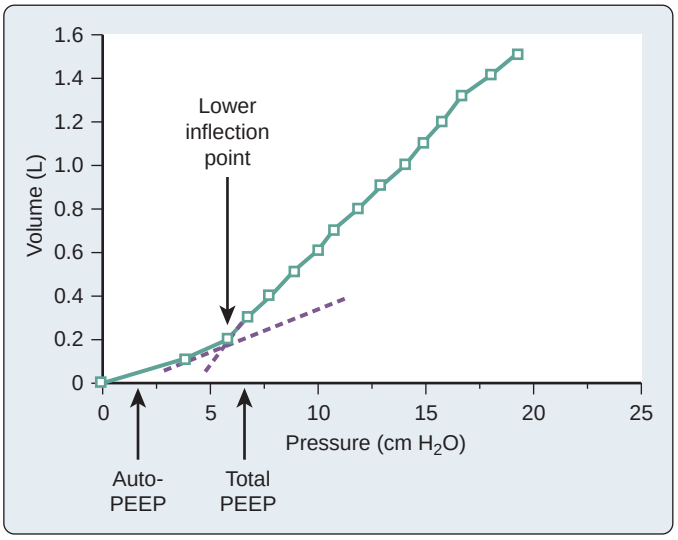

Fig. 49.7 Inspiratory static compliance curve of a young patient with normal pulmonary function during one-lung ventilation (OLV), in this case for removal of a mediastinal tumor. The lower inflection point of the curve (functional residual capacity) was at 6 cm H_2O. The patient had 2 cm H_2O auto–positive end-expiratory pressure (PEEP) during OLV. Adding 5 cm H_2O PEEP to the ventilator raised the total PEEP to 7 cm H_2O and improved arterial partial pressure of oxygen (PaO_2). Young patients and patients with increased lung elastic recoil (eg, as caused by restrictive lung diseases) have an increase in PaO_2 from PEEP during OLV. *(Based on data from Slinger P, Kruger M, McRae K, Winton T. Relation of the static compliance curve and positive end-expiratory pressure to oxygenation during one-lung ventilation.* Anesthesiology. *2001;95:1096–1102.)*

Auto-PEEP is difficult to detect and measure using currently available anesthetic ventilators. To detect auto-PEEP, the respiratory circuit must be held closed at the end of a normal expiration until an equilibrium appears in the airway pressure.[70] Most current intensive care ventilators can be used to accurately measure auto-PEEP, but most anesthesia ventilators cannot.

Tidal Volume

There is an optimal combination of tidal volume, respiratory rate, I:E ratio, pressure- or volume-control ventilation for each patient undergoing OLV. However, to try to assess each of these parameters while still providing anesthesia with the available anesthetic ventilators is not practical and the clinician must initially rely on a simplified strategy (Table 49.1). The results of alterations in tidal volume are unpredictable, in part, because of the interaction of tidal volume with auto-PEEP. The use of 5 to 6 mL/kg tidal volume plus 5 cm H_2O PEEP initially for most patients (except those with COPD) seems a logical starting point during OLV. Tidal volume should be managed so that peak airway pressures do not exceed 35 cm H_2O. This will correspond to a plateau airway pressure of approximately 25 cm H_2O.[71] Peak airway pressures exceeding 40 cm H_2O may contribute to hyperinflation injury of the

TABLE 49.1 Suggested Ventilation Parameters for One-Lung Ventilation

Parameter	*Suggested*	*Guidelines/Exceptions*
Tidal volume	5–6 mL/kg	Maintain: Peak airway pressure <35 cm H_2O Plateau airway pressure <25 cm H_2O
Positive end-expiratory pressure	5 cm H_2O	Patients with COPD: no added PEEP
Respiratory rate	12/min	Tolerate mild hypercapnia $PaCO_2$ (<60 mm Hg), Pa-$ETCO_2$ will usually increase 1–3 mm Hg during OLV
Mode	Volume or pressure controlled	Pressure control for patients at risk of lung injury (bullae, pneumonectomy, post lung transplantation, etc)
FIO_2	Initially 1.0	Decrease as tolerated with air to maintain acceptable SpO_2

COPD, Chronic obstructive pulmonary disease; *FIO_2,* fraction of inspired oxygen; *OLV,* one-lung ventilation; *$PaCO_2$,* arterial pressure of carbon dioxide; *Pa-$ETCO_2$,* arterial-to-end-tidal CO_2 tension gradient; *PEEP,* positive end-expiratory pressure; *SpO_2,* pulse oximetric oxygen saturation.

ventilated lung during OLV.[72] Turning the patient to the lateral position will increase respiratory dead space and the arterial-to-end-tidal CO_2 tension gradient (Pa-$ETCO_2$). This will usually require a 20% increase in minute ventilation to maintain the same $PaCO_2$. Individual variations in Pa-$ETCO_2$ gradient become much larger and $PETCO_2$ is less reliable as a monitor of $PaCO_2$ during OLV. This effect is possibly due to the fact that there are differences in the excretion of CO_2 between the dependent and nondependent lungs.

Volume-Controlled Versus Pressure-Controlled Ventilation

Traditionally, volume-controlled ventilation has been used in the operating room for all types of surgery. The recent availability of anesthesia ventilators with pressure-control modes has made it possible to study and use this form of ventilation during thoracic surgery. Pressure-controlled ventilation has not been shown to improve oxygenation compared with volume-controlled ventilation for most patients, although the peak airway pressures are lower.[73] The decrease in peak pressure with pressure control ventilation may be largely in the anesthetic circuit and not at the distal airway.[74] Pressure control ventilation diminishes the possibility of sudden increases in peak airway pressures that may result from surgical manipulation in the chest. This is of benefit to patients at increased risk for lung injury from high volumes or pressures such as after lung transplantation or during a pneumonectomy.[75] Because of the rapid changes of lung compliance that occur during pulmonary surgery, when pressure-control ventilation is used the delivered tidal volume needs to be closely monitored as this may change suddenly.

Prediction of Hypoxemia During One-Lung Ventilation

The problem of hypoxemia during OLV has prompted much research in thoracic anesthesia. Hypoxemia during OLV is predictable (Box 49.4), preventable, and treatable in most cases.[76]

Preoperative Ventilation-Perfusion Scan

The shunt and PaO_2 during intraoperative OLV are highly correlated with the fractional perfusion of the ventilated lung as determined by a preoperative ventilation/perfusion scan.[77] Patients with long-standing unilateral disease on the operative side develop a unilateral decrease of ventilation and perfusion and tolerate OLV very well. Similarly, patients who intraoperatively have a higher proportion of gas exchange in the dependent lung during OLV tend to have better oxygenation during OLV.

Side of Operation

Patients having right-sided thoracotomies tend to have a larger shunt and lower PaO_2 during OLV because the right lung is larger and normally receives10% more blood flow than the left. The overall mean PaO_2 difference between left and right thoracotomies during stable OLV is approximately 100 mm Hg.[78]

BOX 49.4 FACTORS THAT CORRELATE WITH AN INCREASED RISK OF DESATURATION DURING ONE-LUNG VENTILATION

- High percentage of ventilation or perfusion to the operative lung on preoperative ventilation/perfusion scanning
- Poor PaO_2 during two-lung ventilation, particularly in the lateral position intraoperatively
- Right-sided thoracotomy
- Normal preoperative spirometry (FEV_1 or FVC) or restrictive lung disease
- Supine position during one-lung ventilation

FEV_1, Forced expiratory volume in 1 second; FVC, forced vital capacity; PaO_2, arterial partial pressure of oxygen.

Two-Lung Oxygenation

Patients who have better PaO_2 levels during TLV in the lateral position tend to have better oxygenation during OLV. These patients may have better abilities to match ventilation and perfusion (individual variability of HPV response) and/or they may have less atelectasis in the dependent lung.

Preoperative Spirometry

Studies consistently show that when the previous mentioned factors are controlled, patients with better spirometric lung function preoperatively are more likely to desaturate and have lower PaO_2 values during OLV. Clinically this is evident because emphysematous lung volume reduction patients generally tolerate OLV very well. The explanation is not clear, but it may be related to maintenance of a more favorable FRC in patients with obstructive airway disease during OLV with an open hemithorax due to the development of auto-PEEP.[53]

Treatment of Hypoxemia During One-Lung Ventilation

During OLV there is a fall in arterial oxygenation that usually reaches its nadir 20 to 30 minutes after the initiation of OLV. The oxygen saturation will then stabilize or rise slightly as HPV increases over the next 2 hours. Most patients who desaturate do so quickly and within the first 10 minutes of OLV. Hypoxemia during OLV responds to treatment in the majority of cases. Potential therapies are outlined in Box 49.5.

1. Resume TLV. Reinflate the nonventilated lung and deflate the bronchial cuff of the DLT or the bronchial blocker. This necessitates interruption of surgery, but it is necessary in case of severe or precipitate desaturation, especially in the cardiac patient. After an adequate level of oxygenation is obtained, the diagnosis of the cause of desaturation can be made and prophylactic measures instituted before another trial of OLV is attempted.
2. Increase fraction of inspired oxygen (FIO_2). Ensure that the delivered FIO_2 is 1.0. This is an option in essentially all patients except those who have received bleomycin or similar therapies that potentiate pulmonary oxygen toxicity.
3. Recheck the position of the DLT or bronchial blocker with FOB. Ensure that there is no lobar obstruction in the ventilated lung.
4. Check the patient's hemodynamics to ensure that there has been no decrease in CO. It is very common for the surgeon to accidentally compress the inferior vena cava during pulmonary resections, and the fall in blood pressure and CO that this causes leads to rapid desaturation during OLV. Treat the fall in CO as indicated (eg, inotropes or vasopressors if due to thoracic epidural sympathetic blockade). Stop administration of vasodilators and decrease MAC of volatile anesthetics to less than 1 MAC.
5. Perform a recruitment maneuver of the ventilated lung. To eliminate any atelectasis, inflate the lung to 20 cm H_2O or more for 15

BOX 49.5 THERAPIES FOR DESATURATION DURING ONE-LUNG VENTILATION

Severe or precipitous desaturation: resume two-lung ventilation (if possible).

Gradual desaturation:

- Ensure that delivered F_{IO_2} is 1.0.
- Check position of double-lumen tube or blocker with fiberoptic bronchoscopy.
- Ensure that cardiac output is optimal; decrease volatile anesthetics to <1 MAC.
- Apply a recruitment maneuver to the ventilated lung (this will transiently make the hypoxemia worse).
- Apply PEEP 5 cm H_2O to the ventilated lung (except in patients with emphysematous disease).
- Apply CPAP 1–2 cm H_2O to the nonventilated lung (apply a recruitment maneuver to this lung immediately before CPAP).
- Apply intermittent reinflation of the nonventilated lung.
- Partial ventilation techniques of the nonventilated lung include:
  - Lung oxygen insufflation
  - Lobar insufflation
  - Lobar collapse (using a bronchial blocker)
- Apply mechanical restriction of the blood flow to the nonventilated lung.

CPAP, Continuous positive airway pressure; F_{IO_2}, fraction of expired oxygen; MAC, minimum alveolar concentration; PEEP, positive end-expiratory pressure.

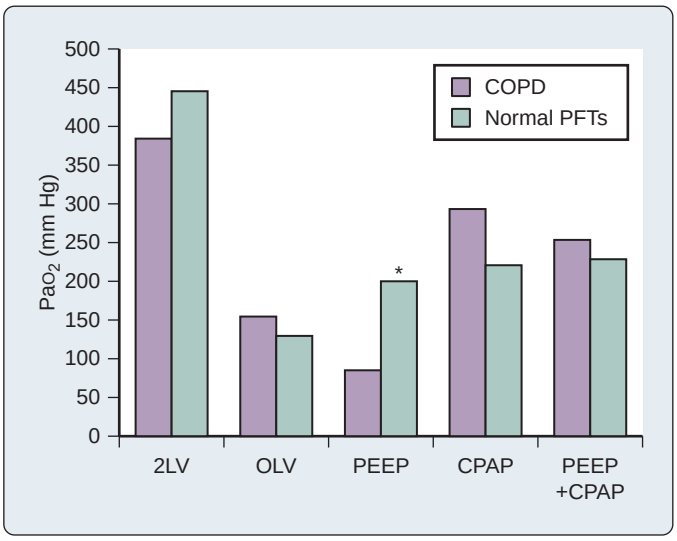

Fig. 49.8 A comparison of the effects of positive end-expiratory pressure *(PEEP)* to the ventilated lung and continuous positive airway pressure *(CPAP)* to the nonventilated lung on mean arterial partial pressure of oxygen *(PaO_2)* levels during one-lung ventilation *(OLV). 2LV,* Two-lung ventilation; *COPD,* group of lung cancer surgery patients; *Normal PFTs,* group of esophageal surgery patients with normal preoperative pulmonary function tests. (*, signif. $P < .05$ vs OLV.) *(Based on data from Fujiwara M, Abe K, Mashimo T. The effect of positive end-expiratory pressure and continuous positive airway pressure on the oxygenation and shunt fraction during one-lung ventilation with propofol anesthesia.* J Clin Anesth. *2001;13:473–477. to 20 seconds. This may cause transient hypotension and will also cause a transient further fall in the PaO_2 as the blood flow is temporarily redistributed to the nonventilated lung.

6. Apply PEEP to the ventilated lung. It is necessary to perform a recruitment maneuver before applying PEEP to get the maximal benefit. PEEP will raise the end-expiratory volume of the ventilated lung toward the FRC in patients with normal lung mechanics and in those with increased elastic recoil due to restrictive disease. It is not possible to predict the optimal PEEP for individual patients; a level of 5 cm H_2O is a useful starting point. PEEP will increase the end-expiratory lung volume of patients with significant levels of auto-PEEP (eg, patients with emphysema). Unlike CPAP, application of PEEP does not require reinflation of the nonventilated lung and interruption of surgery. PEEP has been shown to be as effective for increasing PaO_2 levels during OLV in patients with normal lung function as CPAP to the nonventilated lung (Fig. 49.8).[79] For patients with normal pulmonary function, it is logical to routinely apply a recruitment maneuver and PEEP from the start of OLV.
7. CPAP with oxygen to the nonventilated lung is the next line of therapy after application of PEEP.[80] An important caveat to be observed when CPAP is applied to the nonventilated lung is that CPAP must be applied to an inflated (recruited) lung to be completely effective. The opening pressure of atelectatic lung regions is greater than 20 cm H_2O,[81] and these units will not be recruited by simple application of CPAP levels of 5 to 10 cm H_2O. Even a period as short as 5 minutes of collapse prior to CPAP application can have deleterious effects on oxygenation during OLV.[82] When CPAP is applied to a fully inflated lung, levels of CPAP as low as 1 to 2 cm H_2O can be used.[83] Because the normal transpulmonary pressure of the lung at FRC is approximately 5 cm H_2O, levels of 5 to 10 cm H_2O CPAP applied to a fully recruited lung result in a large-volume lung that impedes surgery, particularly during minimally invasive procedures.

CPAP levels less than 10 cm H_2O do not interfere with hemodynamics. The beneficial effects of low levels of CPAP are due primarily to oxygen uptake from the nonventilated lung and not to blood flow diversion to the ventilated lung. CPAP is most effective when oxygen (F_{IO_2} 1.0) is applied to the nonventilated lung. Lower F_{IO_2} levels of CPAP are of clinical benefit and can be used along with decreased F_{IO_2} to the ventilated lung in patients at risk of oxygen toxicity.

CPAP, even when properly administered, is not completely reliable to improve oxygenation during OLV. When the bronchus of the operative lung is obstructed, or open to atmosphere (as in a bronchopleural fistula or during endobronchial surgery) CPAP will not improve oxygenation. Also in certain situations, particularly during thoracoscopic surgery where access to the operative hemithorax is limited, CPAP can interfere significantly with surgery.[84]

Pharmacologic Manipulations

Eliminating known potent vasodilators such as nitroglycerin, halothane, and large doses of other volatile anesthetics improves oxygenation during OLV.[85] The selective administration of the vasodilator prostaglandin E_1 to the ventilated lung[86] or a nitric oxide synthase inhibitor (L-NAME)[87] to a hypoxic lobe results in improved redistribution of pulmonary blood flow in animal models. This is not applicable to humans at present. Selective administration of nitric oxide alone to the ventilated lung was not shown to be of benefit in humans.[88] The combination of inhaled nitric oxide (20 ppm) and an intravenous infusion of almitrine, which enhances HPV, has been shown to restore PaO_2 values during OLV in humans to essentially the same levels as during TLV.[89] However, this may have been due primarily to the augmentation of HPV by almitrene.[90] It is unlikely that almitrine, which was previously available in North America as a respiratory stimulant, will be reintroduced to this market because of side effects such as hepatic enzyme changes and lactic acidosis. However, the combination of nitric oxide and other pulmonary vasoconstrictors such as phenylephrine has been shown to improve oxygenation in ventilated intensive care unit patients with adult respiratory distress syndrome,[91] and this may have applications in OLV.

Intermittent Reinflation of the Nonventilated Lung

HPV becomes more effective during repeated hypoxic exposure. Often after reinflation, the oxygen saturation will be more acceptable during a second period of lung collapse. Reexpansion can be performed by regular reexpansion of the operative lung via an attached CPAP circuit.

Partial Ventilation Methods

Several alternative methods of OLV, all involving partial ventilation of the nonventilated lung, have been described and improve oxygenation during OLV. These techniques are useful in patients who are particularly at risk of desaturation, such as those who have had previous pulmonary resections of the contralateral lung or low CO states. These alternatives include the following:

1. Intermittent positive airway pressure to the nonventilated lung. This can be performed by a variety of methods. Russell described attaching a standard bacteriostatic filter to the nonventilated lumen of the DLT with a 2-L oxygen inflow attached to the CO_2 port of the filter.[92] Manual occlusion of the filter for 2 seconds gives an insufflation of approximately 66 mL of oxygen to the nonventilated lung. This could be repeated at 10-second intervals with minimal interference with surgical exposure.
2. Selective insufflation of oxygen to recruit lung segments on the side of surgery but remote from the site of surgery (Fig. 49.9).[93] A useful technique in minimally invasive surgery is intermittent insufflation of oxygen using a fiberoptic bronchoscope. A 5-L oxygen flow is attached to the suction port of a fiberoptic bronchoscope, which is passed under direct vision into a segment of the lung remote from the site of surgery which is then reinflated by triggering the suction on the fiberoptic bronchoscope. The surgeon aids this technique by observing the lung inflation with the thoracoscope to avoid overdistention of the recruited segment(s).
3. Selective lobar collapse of only the operative lobe in the open hemithorax.[94] This is accomplished by placement of a blocker in the appropriate lobar bronchus of the ipsilateral operative lung.

Mechanical Restriction of Pulmonary Blood Flow

It is possible for the surgeon to directly compress or clamp the blood flow to the nonventilated lung.[95] This can be done temporarily in emergency desaturation situations or definitively in cases of pneumonectomy or lung transplantation. Another technique of mechanical limitation of blood flow to the nonventilated lung is the inflation of a pulmonary artery catheter balloon in the main pulmonary artery of the operative lung. The pulmonary artery catheter can be positioned at induction with fluoroscopic or TEE guidance and inflated as needed intraoperatively. This has been shown to be a useful technique for resection of large pulmonary arteriovenous fistulas.[96]

Hypoxemia Prophylaxis

Most treatments outlined as therapies for hypoxemia can be used prophylactically to prevent hypoxemia in patients who are at high risk of desaturation during OLV. The advantage of prophylactic therapy of hypoxemia, in addition to the obvious patient safety benefit, is that maneuvers involving CPAP or alternative ventilation patterns of the operative lung can be instituted at the onset of OLV in a controlled fashion and will not require interruption of surgery and emergent reinflation of the nonventilated lung at a time that may be extremely disadvantageous.

Bilateral Pulmonary Surgery

Because of mechanical trauma to the operative lung, the gas exchange in this lung will always be temporarily impaired after OLV. Also HPV offset may be delayed after reinflation of the first lung collapsed.

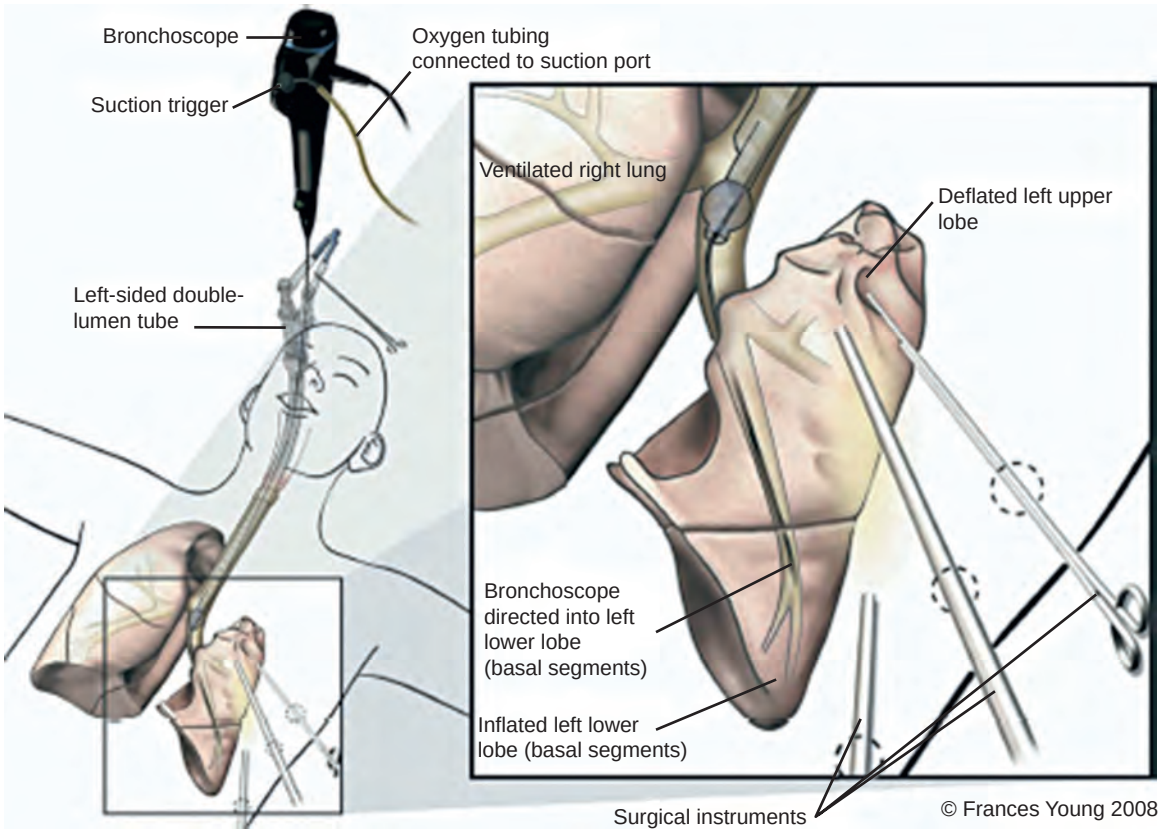

Fig. 49.9 Intermittent oxygen insufflation during thoracoscopic surgery to segments of the nonventilated lung on the side of surgery using a fiberoptic bronchoscope; see text for details. *(Reproduced with permission from Slinger P.* Principles and Practice of Anesthesia for Thoracic Surgery. *New York: Springer; 2011.)*

Desaturation during bilateral lung procedures is particularly a problem during the second period of OLV.[97] Thus, for bilateral procedures it is advisable to operate first on the lung that has better gas exchange and less propensity to desaturate during OLV. For most patients this means operating on the right lung first.

Transesophageal Echocardiography for Noncardiac Thoracic Surgery

TEE is recommended as a category I indication for noncardiac surgery in the circumstances of life-threatening unexplained hypoxemia and/or hypotension[98] (see Chapters 14–16 and 46). It is also recommended when patients have known or suspected cardiovascular disease that may impact outcomes.[99] In clinical practice, TEE is used in a wide variety of circumstances in noncardiac thoracic surgery, including to assess cardiac or great vessel compression from intrathoracic masses, hemodynamic instability, and RV and left ventricular preload and contractility. TEE can be useful in assessing the existence or extent of cardiac involvement from benign or malignant tumors of the lung or mediastinum (Figs. 49.10–49.12). It is often difficult for the surgeon to assess this during thoracotomy or sternotomy. TEE can also be useful in assessing the extent of compression of the superior vena cava, which can occur with lung tumors of the right upper lobe. In addition, TEE can be useful for evaluating hemodynamic instability in patients having noncardiac thoracic surgery. Pericardial tamponade, pulmonary embolism, hypovolemia, and left- or right-sided heart failure may be diagnosed by TEE when other clinical signs or monitors are misleading (Fig. 49.13).

Airway Surgery

Anesthetic Management for Diagnostic or Therapeutic Airway Procedures

Patients with underlying cardiac disease may present for a variety of surgical procedures involving the airways. Flexible FOB is a diagnostic and therapeutic procedure of great value. In many centers, it is common practice to perform flexible FOB before airway or other thoracic surgeries, to reconfirm the diagnosis (if a tumor compresses the airway), or to determine the invasion and obstruction of the distal airway. There are multiple techniques for flexible FOB. Options include awake versus general anesthesia and oral versus nasal approaches. Options for local anesthesia include topical anesthesia via a nebulizer, handheld aerosol, or soaked pledgets; nerve blocks (laryngeal and/or glossopharyngeal nerves); direct administration of local anesthetic through the bronchoscope (spray-as-you-go technique),[100] with or without sedation or opioid or antisialagogues. Options during general anesthesia include spontaneous versus positive pressure ventilation with or without muscle relaxation. Airway management during general anesthesia can be done with an endotracheal tube (ETT) or a laryngeal mask airway (LMA). A swivel bronchoscopy connector with a self-sealing valve is used to facilitate the ventilation and manipulation of the bronchoscope at the same time inhalation and/or intravenous agents can be used for anesthesia. Patients who have copious secretions in the preoperative period should receive anticholinergic medication to ensure a dry field, which provides optimal visualization.

The advantages of an LMA technique include that it allows visualization of the vocal cords and subglottic structures and there is a lower airway resistance, compared with an ETT, when the bronchoscope is inserted (Fig. 49.14). This is particularly useful in the patient with a difficult airway when maintaining spontaneous respiration may be the safest method of anesthetic management.[101] Self-expanding

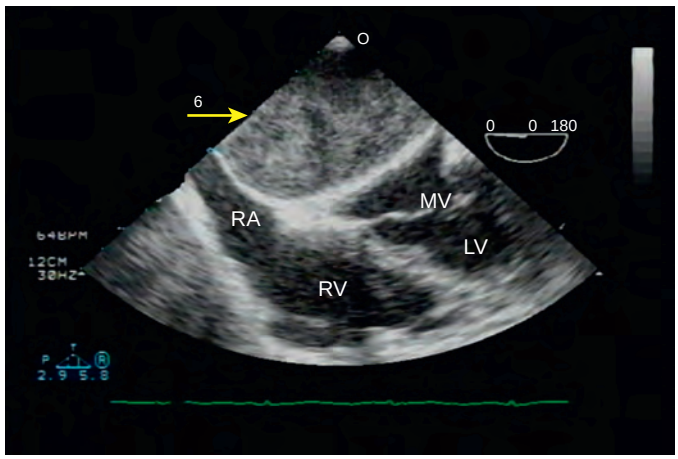

Fig. 49.10 Initial intraoperative midesophageal four-chamber transesophageal echocardiographic view at 0 degrees of the heart. Patient with a posterior mediastinal tumor that was compressing the left atrium, showing near complete compression of left atrium by the tumor *(yellow arrow)* posteriorly and also compression of the right atrium *(RA)*. Although the left atrium was severely compressed by the tumor (a mediastinal Schwannoma), there is no clear evidence that the tumor extends through the wall of the atrium. *MV,* mitral valve; *LV,* left ventricle; *RV,* right ventricle.

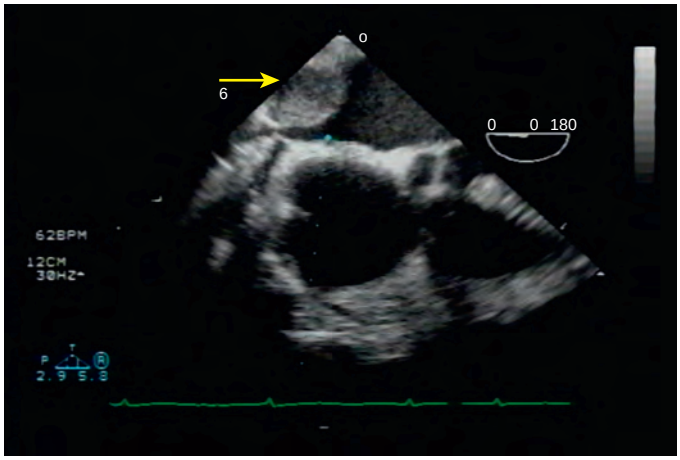

Fig. 49.11 Modified four-chamber transesophageal echocardiographic (TEE) view at 0 degrees after surgical resection of the posterior mediastinal tumor. TEE shows that one lobe of the tumor *(yellow arrow)* remains adherent to the posterior left atrial wall. This was not initially evident to the surgeon.

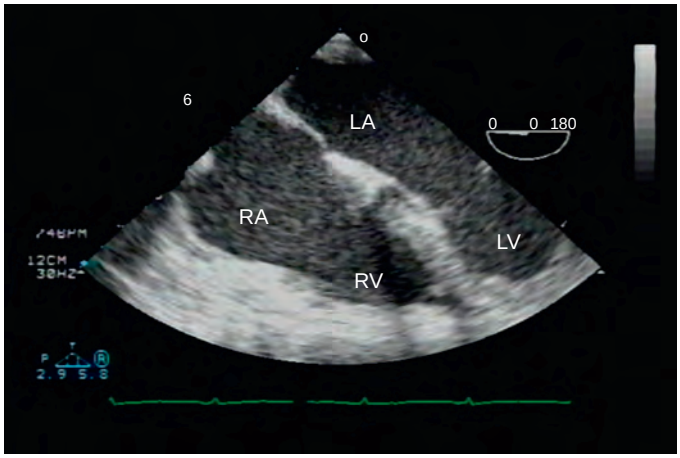

Fig. 49.12 Midesophageal four-chamber transesophageal echocardiographic view after excision of the remaining portion of the mediastinal tumor. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

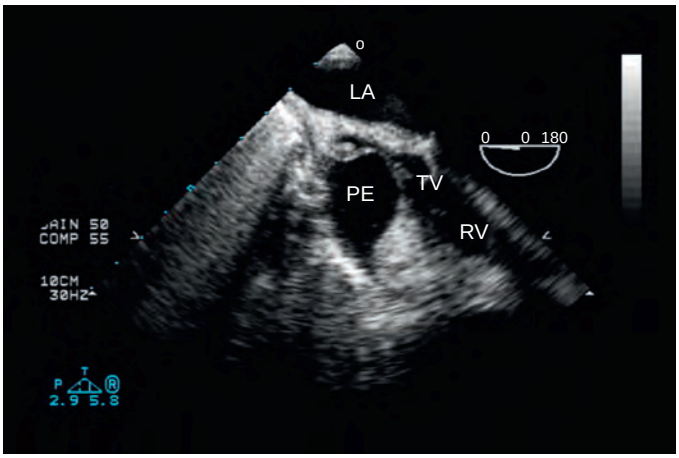

Fig. 49.13 Intraoperative midesophageal four-chamber transesophageal echocardiographic (TEE) view of a patient with bilateral pleural effusions, thought to be secondary to metastatic breast cancer, performed for the diagnosis of severe refractory hypotension after induction of anesthesia. A loculated pericardial effusion *(PE)* is nearly completely obliterating the right atrium and causing a cardiac tamponade. Based on the TEE diagnosis it was possible to add a video-assisted thoracoscopic surgery pericardial window to the originally planned surgery. *LA,* Left atrium, *RV,* right ventricle; *TV,* tricuspid valve.

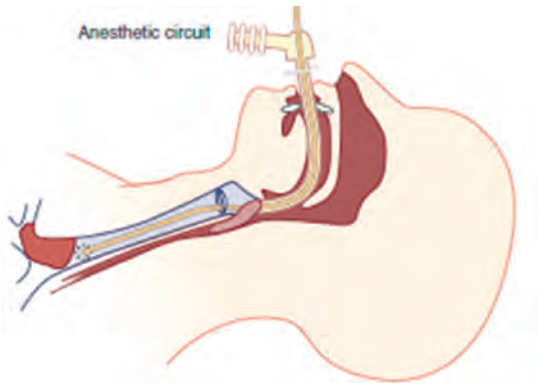

Fig. 49.14 Diagram of fiberoptic bronchoscopy performed via a laryngeal mask airway (LMA) during general anesthesia in a spontaneously breathing patient with a carinal tumor, in this case for diagnosis and Nd:YAG laser tumor excision. The LMA permits visualization of the vocal cords and subglottic structures with the bronchoscope, which is not possible when fiberoptic bronchoscopy is performed via an endotracheal tube. *(Reproduced with permission from Slinger PD, Campos JH. Anesthesia for thoracic surgery. In: Miller RD, ed.* Miller's Anesthesia. *8th Ed. Philadelphia: Saunders; 2015:1942–2006.)*

flexometallic tracheal and bronchial stents can be placed with fiberoptic or rigid bronchoscopy. However, Silastic airway stents require rigid bronchoscopy for placement.

Rigid bronchoscopy has traditionally been considered the technique of choice for the preoperative diagnostic assessment of an airway obstruction involving the trachea and in the therapy of massive hemoptysis and foreign bodies in the airway. The role of interventional bronchoscopy with laser, bronchial dilation, or stent insertion is well established for the treatment of malignant and benign central airway and endobronchial lesions.[102] Rigid bronchoscopy is the procedure of choice for operative procedures such as dilation of tracheal stenosis.

Patients undergoing rigid bronchoscopy should have a complete preoperative evaluation, including radiologic studies. Chest radiographs and chest computed tomographic (CT) scans should be reviewed in the preoperative evaluation. If time permits, it is recommended that patients with severe stridor receive pharmacologic interventions for temporary stabilization of the condition. Treatments may include inspired cool saline mist, nebulized racemic epinephrine, and the use of systemic steroids.[103]

There are four basic methods of ventilation management for rigid bronchoscopy.

1. Spontaneous ventilation. The addition of topical anesthesia or nerve blocks to the airway decreases the tendency to breath-hold and cough when volatile anesthetics are used.
2. Apneic oxygenation (with or without insufflation of oxygen). This requires thorough preoxygenation, and the anesthesiologist will have to interrupt surgery to ventilate the patient before desaturation occurs. This should allow the surgeon working intervals of 3 minutes or longer, depending on the underlying condition of the patient.
3. Positive pressure ventilation via a ventilating bronchoscope. This allows the use of a standard anesthetic circuit but may cause significant air leaks if there is a discrepancy between the size of a smaller bronchoscope and a larger airway.
4. Jet ventilation. This can be performed with a handheld injector such as the Sanders injector[104] or with a high-frequency ventilator. These techniques are most useful with intravenous anesthesia because they entrain gas from either the room air or an attached anesthetic circuit, and the dose of any volatile agent delivered will not be known.

The use of anticholinergic agents before manipulation of the airway will decrease secretions during the bronchoscopic examination. For a patient undergoing rigid bronchoscopy, the surgeon must be at the bedside for the induction of anesthesia and be prepared to establish airway control with the rigid bronchoscope. In adults, intravenous anesthesia and the use of muscle relaxants is more common with ventilation by a combination of methods 3 and 4.

For cases in which the use of muscle relaxants is not contraindicated, a short-acting agent (succinylcholine) can be used initially to facilitate intubation with either a small SLT or the rigid bronchoscope. Non-depolarizing relaxants may be needed for prolonged procedures such as stent placement or tumor resection. Remifentanil and propofol infusions can be administered if an intravenous regimen is the planned anesthetic.[105] This is a useful technique if the surgeon needs repeated access (for suction or instrumentation) to the open airway, because it maintains the level of anesthesia and avoids contaminating the operating room with anesthetic vapors.

In cases where a neodymium-doped yttrium aluminium garnet (Nd:YAG) laser is used, the F_{IO_2} should be maintained in the lowest acceptable range (ie, <30% if possible) according to patient oxygen saturation, to avoid the potential for fire in the airway. Because any common material (including porcelain and metal) can be perforated by the Nd:YAG laser, it is best to avoid any potentially combustible substance in the airway when the Nd:YAG laser is used.[106] Because of its high energy and short wavelength, the Nd:YAG laser has several advantages for distal airway surgery over the CO_2 laser, which is used in upper airway surgery. The Nd:YAG laser penetrates tissue more deeply so it causes more coagulation in vascular tumors, and it can be refracted and passed in fibers through a flexible or rigid bronchoscope. However, there is a higher potential for accidental reflected laser strikes and there is more delayed airway edema.

Rigid bronchoscopes have different sizes, commonly from 3.5 to 9 mm in diameter, with a ventilating side-port to facilitate ventilation when the bronchoscope is placed into the airway. If excessive leak of tidal volume occurs around the bronchoscope with positive pressure ventilation, it may be necessary to place throat packs to facilitate ventilation. Continuous communication with the surgeon or pulmonologist is necessary in case desaturation occurs. If desaturation does occur, it must be corrected by stopping surgery and allowing the anesthesiologist to ventilate and oxygenate the patient, either via the rigid bronchoscope or by removing the bronchoscope and ventilating with a mask, LMA, or ETT.

Pulse oximetry is vital during rigid bronchoscopy because there is a high risk of desaturation. There is no simple way to monitor end-tidal CO_2 or volatile anesthetics because the airway remains essentially open to atmosphere. For patients with underlying cardiac disease, an arterial catheter is usually placed for rigid bronchoscopy to facilitate rapid hemodynamic control. For prolonged procedures, it is useful to perform repeated arterial blood gas analysis to confirm the adequacy of ventilation. An alternative is to interrupt surgery and ventilate the patient with a standard circuit and a mask or ETT to assess the end-tidal CO_2.

Unlike during FOB via an ETT, with rigid bronchoscopy the airway is never completely secure and there is always the potential for aspiration in patients at increased risk, such as those with a full stomach, hiatus hernia, or morbid obesity. It is always best to defer rigid bronchoscopy to decrease the aspiration risk, if possible, in these patients. When there is no benefit to be gained by deferring and/or the airway risk is acute (eg, aspiration of an obstructing foreign body), each case must be managed on an individual basis depending on the context and competing risks.

Other rigid bronchoscopic procedures that require anesthesia include dilation for benign airway stenosis, core-out of malignant lesions in the trachea, laser ablation of endobronchial and carinal tumors, and therapeutic bronchoscopic interventions before surgical resection of lung cancer. In addition, interventional bronchoscopy is often used for the management of airway complications following lung transplantation. Rigid bronchoscopy can be performed in combination with extracorporeal membranous oxygenation or cardiopulmonary bypass (CPB) in high-risk patients.[107]

Complications of rigid bronchoscopy include airway perforation, mucosal damage, hemorrhage, postmanipulation airway edema, and potential airway loss at the end of the procedure. In some situations, it may be necessary to keep the patient intubated with a small (ie, 6.0 mm internal diameter) SLT after a rigid bronchoscopy if an edematous airway is suspected or the patient is not able to be extubated. These patients may require the use of steroids, nebulized racemic epinephrine, or helium/oxygen mixtures to treat stridor in the postoperative period.

Anesthesia for Tracheal Resection

Tracheal resection and reconstruction is indicated in patients who have a tracheal obstruction as a result of a tracheal tumor, previous tracheal trauma (most commonly, postintubation stenosis), congenital anomalies, vascular lesions, and tracheomalacia. For patients who have operable tumors, approximately 80% undergo segmental resection with primary anastomosis, 10% undergo segmental resection with prosthetic reconstruction, and the remaining 10% undergo placement of a Montgomery T-tube stent.

Diagnostic studies are reviewed as part of the preoperative evaluation. The CT scan is a useful diagnostic tool to evaluate the degree, level, and length of the lesion. Bronchoscopy is one of the definitive diagnostic tests for tracheal obstruction. Bronchoscopy for a patient with tracheal stenosis should be carried out in the operating room where the surgical and anesthesia teams are present and ready to intervene should loss of airway occur. An advantage of rigid bronchoscopy over flexible bronchoscopy is that it can bypass the obstruction and provide a ventilation pathway if complete obstruction occurs. During surgery, all patients should have an invasive arterial catheter placed to facilitate measurement of arterial blood gases, as well as measure arterial blood pressure. Central venous pressure catheters are only used if the patient requires CPB.

Various methods for providing adequate oxygenation and elimination of CO_2 have been used during tracheal resection. The alternatives include (1) standard orotracheal intubation, (2) insertion of a sterile SLT into the opened trachea or bronchus distal to the area of resection, (3) high-frequency jet ventilation through the stenotic area, (4) high-frequency positive pressure ventilation, and (5) the use of CPB or extracorporeal membranous oxygenation.

Induction of anesthesia in patients with a compromised airway requires good communication between the surgical team and the anesthesiologist. The surgeon should always be in the operating room during induction and available to manage a surgical airway if this becomes necessary.[108] A rigid bronchoscope must be immediately available. The patient should be thoroughly preoxygenated with 100% oxygen before induction. The airways of patients with congenital or acquired tracheal stenosis are unlikely to collapse during induction of anesthesia. However, intratracheal masses may lead to airway obstruction with induction of anesthesia and should be managed similarly to anterior mediastinal masses (see "Mediastinal Masses"). One airway management technique is to begin the case with rigid bronchoscopy and tracheal dilation and then to pass an SLT through the stenosis. This tube is withdrawn into the proximal trachea once the distal trachea is opened and a second sterile SLT is placed into the distal trachea by the surgeon. Ventilation is via a sterile anesthetic circuit passed across the drapes into the surgical field. With a low tracheal lesion, a right thoracotomy provides the optimal surgical exposure. A sterile SLT is used to provide ventilation to the lung distal to the resection. After the posterior anastomosis is completed, the endobronchial tube is removed and the original SLT is advanced past the site of resection. This technique can also be used for carinal resections.

A third technique for airway management during tracheal resection includes high-frequency jet ventilation through a small-bore ETT or catheter.[109] With this technique, a small-bore uncuffed catheter is placed through the stenotic area, and ventilation is accomplished by intermittently exposing the lung to a high flow of fresh gas through the catheter. Other techniques that have been used for oxygenation during distal airway resections include high-frequency positive pressure ventilation, helium-oxygen mixtures, and CPB.

After the tracheal resection is completed, most patients are kept in a position of neck flexion to reduce tension on the suture line. Replacement of the SLT by an LMA for emergence facilitates bronchoscopy if required. A thick chin-sternum suture may be placed for several days to maintain neck flexion, or a cervical splint may be used.[110] A T-tube with upper limb 0.5 to 1 cm above the vocal cords may be inserted at the end of surgery in cases when glottic edema is a concern, or for patients requiring ventilatory support. If a tracheostomy is performed, it will be done distal to the anastomosis. Early extubation is highly desirable. If a patient requires reintubation, it should be performed with a flexible fiberoptic bronchoscope by advancing an SLT under direct vision over the bronchoscope and then placing it in the patient's trachea. The patient is kept in a head-up position to diminish swelling. Steroids may be useful in these cases to decrease airway edema.

One of the complications in the postoperative period is tetraplegia, with hyperflexion of the neck having been implicated as a potential cause. In these cases, it is necessary to cut the chin stitch. An infusion of propofol and remifentanil, with FOB guidance and full patient cooperation, can aid extubation.[111]

Pulmonary Hemorrhage

Massive hemoptysis can be caused by carcinoma, bronchiectasis, pulmonary vascular disease, and trauma (blunt, penetrating, or secondary to a PAC). Death can occur quickly due to asphyxia. Management requires four sequential steps: lung isolation, resuscitation, diagnosis, and definitive treatment (see Chapters 24 and 26 for detailed discussions) (Fig. 49.15, Box 49.6).

Posttracheostomy Hemorrhage

Hemorrhage in the immediate postoperative period following a tracheostomy is usually from local vessels in the incision such as the anterior jugular or inferior thyroid veins. Massive hemorrhage 1 to 6 weeks postoperatively is most commonly due to trachea-innominate artery fistula.[112] A small sentinel bleed occurs in most patients before

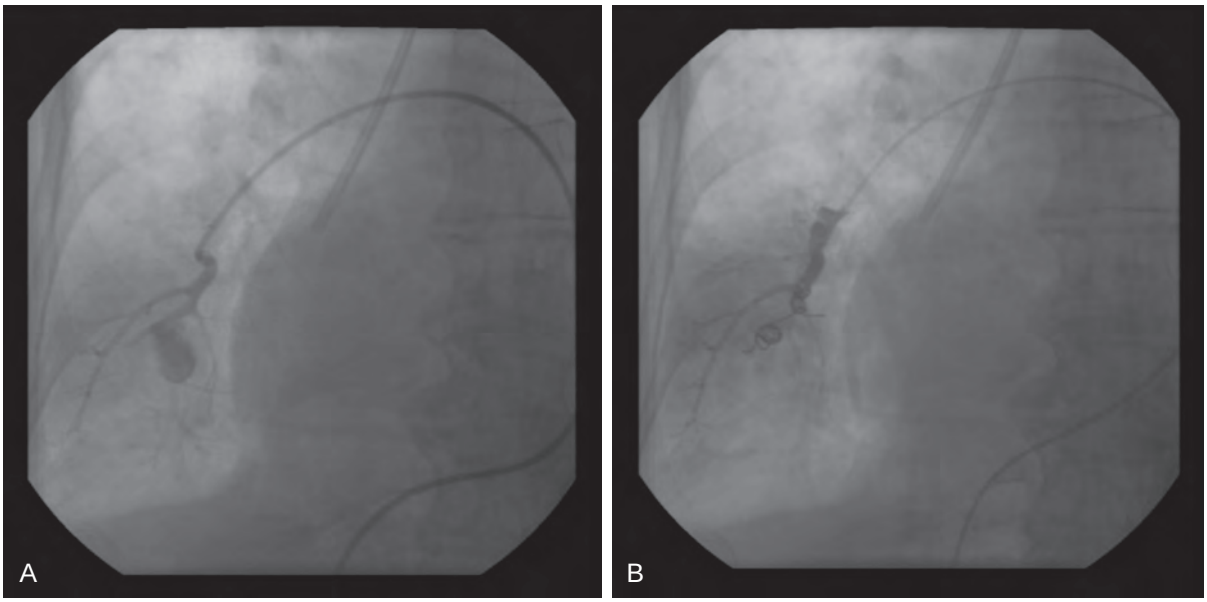

Fig. 49.15 (A) Radiographic dye injection showing a false aneurysm of the pulmonary artery of the right lower lobe following massive hemoptysis induced by a pulmonary artery catheter rupture. (B) A coil has been placed by interventional radiology in the false aneurysm of the right lower pulmonary artery in the same patient. Dye injection shows that the aneurysm has embolized with no further leakage.

BOX 49.6 MANAGEMENT OF THE PATIENT WITH PULMONARY ARTERY CATHETER–INDUCED PULMONARY HEMORRHAGE

- Initially position the patient with the bleeding lung dependent.
- Perform endotracheal intubation, oxygenation, and airway toilet.
- Isolate the lung with an endobronchial double- or single-lumen tube or bronchial blocker.
- Withdraw the pulmonary artery catheter several centimeters, leaving it in the main pulmonary artery. Do not inflate the balloon (except with fluoroscopic guidance).
- Position the patient with the isolated bleeding lung nondependent. Apply positive end-expiratory pressure (PEEP) to the bleeding lung if possible.
- Transport to medical imaging for diagnosis and embolization if feasible.

BOX 49.7 MANAGEMENT OF TRACHEOINNOMINATE ARTERY FISTULA HEMORRHAGE

- Overinflate the tracheostomy cuff to tamponade the hemorrhage. If this fails,
  - Replace the tracheostomy tube with an oral endotracheal tube. Position the cuff with fiberoptic bronchoscopic guidance just above the carina.
- Apply digital compression of the innominate artery against the posterior sternum using a finger passed through the tracheostomy stoma. If this fails,
  - Slowly withdraw the endotracheal tube and overinflate the cuff to tamponade.
  - Then proceed with definitive therapy: sternotomy and ligation of the innominate artery.

a massive bleed. The management protocol for trachea-innominate artery fistula is outlined in Box 49.7.

Mediastinal Masses

Patients with mediastinal masses, particularly masses in the anterior and/or superior mediastinum, present unique problems for the anesthesiologist. Patients may require anesthesia for biopsy of these masses by mediastinoscopy or VATS, or they may require definitive resection via sternotomy or thoracotomy. Tumors of the mediastinum include thymoma, teratoma, lymphoma, cystic hygroma, bronchogenic cyst, and thyroid tumors. Mediastinal masses may cause obstruction of major airways, pulmonary arteries, atria, and/or the superior vena cava. During induction of general anesthesia in patients with an anterior or superior mediastinal mass, airway obstruction is the most common and feared complication. It is important to note that the point of tracheobronchial compression usually occurs distal to an ETT and it is not possible to forcibly pass an ETT through the airway once it has collapsed. A history of supine dyspnea or cough should alert the clinician to the possibility of airway obstruction upon induction of anesthesia. The other major complication is cardiovascular collapse secondary to compression of the heart or major vessels. Symptoms of supine presyncope suggest vascular compression.

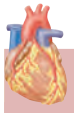
Anesthetic deaths reported have been mainly in children. These deaths may be the result of the more compressible cartilaginous structure of the airway in children or because of the difficulty in obtaining a history of positional symptoms. The most important diagnostic test in the patient with a mediastinal mass is the CT scan of the trachea and chest. Children with tracheobronchial compression greater than 50% on CT scan cannot be safely given general anesthesia.[112] Flow-volume loops, specifically the exacerbation of a variable intrathoracic obstructive pattern (expiratory plateau) when supine, are unreliable[113] for predicting which patients will have intraoperative airway collapse.[114] Preoperative transthoracic echocardiography is indicated for patients with vascular compression symptoms.

General anesthesia will exacerbate extrinsic intrathoracic airway compression in three ways. First, reduced lung volume occurs during general anesthesia, and tracheobronchial diameters decrease according to lung volume. Second, bronchial smooth muscle relaxes during general anesthesia, allowing greater compressibility of large airways. Third, paralysis eliminates the caudal movement of the diaphragm seen during spontaneous ventilation. This eliminates the normal transpleural pressure gradient that dilates the airways during inspiration and minimizes the effects of extrinsic intrathoracic airway compression.

Management of patients with mediastinal masses is guided by their symptoms and the CT scan. Patients with uncertain distal airways should have diagnostic procedures performed under local or regional anesthesia whenever possible. Patients with uncertain airways requiring general anesthesia need a step-by-step induction of anesthesia with continuous monitoring of gas exchange and hemodynamics. This NPIC (*noli pontes ignii consumere*; ie, "don't burn your bridges") anesthetic induction can be an inhalation induction with a volatile anesthetic such as sevoflurane or intravenous titration of propofol with or without ketamine, maintaining spontaneous ventilation until either the airway is definitively secured or the procedure is completed.[115] Awake intubation of the trachea before induction is a possibility in some adult patients if the CT scan shows an area of noncompressed distal trachea to which the ETT can be advanced before induction. If muscle relaxants are required, ventilation should first be gradually taken over manually to ensure that positive-pressure ventilation is possible and only then can a short-acting muscle relaxant be administered (Box 49.8).

Development of airway or vascular compression upon anesthetic induction requires that the patient be awakened as rapidly as possible and then other options for the procedure be explored. Intraoperative life-threatening airway compression usually has responded to one of two therapies: either repositioning of the patient (it must be determined before induction if there is a position that causes less compression and fewer symptoms) or rigid bronchoscopy and ventilation distal to the obstruction (this means that an experienced bronchoscopist and equipment must be immediately available in the operating room). The rigid bronchoscope, even if passed into only one mainstem bronchus, can be used for oxygenation during resuscitation.[115] Once adequate oxygenation has been restored, the rigid bronchoscope can be used to position an airway exchange catheter over which an ETT is passed after the bronchoscope is withdrawn. An alternative technique to secure the airway with rigid bronchoscopy is to first mount an ETT over a small rigid bronchoscope (eg, 6 mm) and then perform rigid bronchoscopy using the bronchoscope to deliver the ETT distal to the obstruction.[116]

Institution of femoral-femoral CPB before induction of anesthesia is a possibility for some adult patients who are unsafe for NPIC general anesthesia (Fig. 49.16). However, the concept of CPB "standby" during attempted induction of anesthesia is fraught with danger[117] because there is not enough time after a sudden airway collapse to establish CPB before hypoxic cerebral injury occurs.[118] The salient points in



BOX 49.8 MANAGEMENT FOR ALL PATIENTS WITH A MEDIASTINAL MASS AND AN UNCERTAIN AIRWAY FOR GENERAL ANESTHESIA

- Determine optimal positioning of patient preoperatively.
- Secure airway beyond stenosis with the patient awake if feasible.
- Have a rigid bronchoscope and surgeon available at induction.
- Maintain spontaneous ventilation if possible (NPIC; see "Mediastinal Masses").
- Monitor for airway compromise postoperatively.

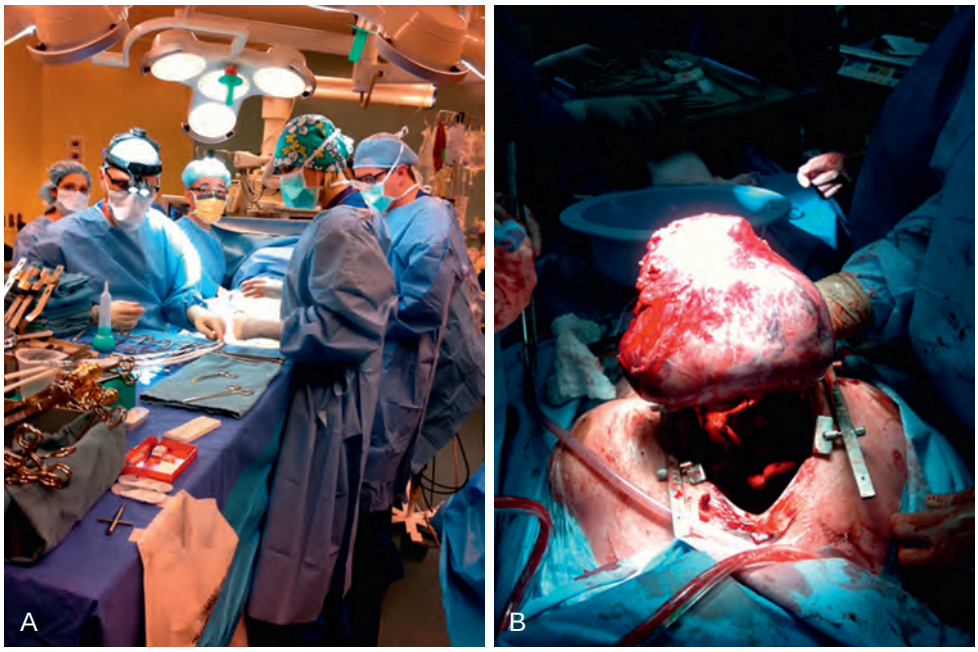


Fig. 49.16 (A) A patient with a large anterior mediastinal mass is placed on femoral-femoral arterial-venous cardiopulmonary bypass before induction of anesthesia. The perspective is from the foot of the operating room table. The patient was reclined to 45O for cannulation. The patient's head and upper body is concealed behind the surgical drapes. (B) A large anterior mediastinal sarcoma is removed from the same patient by sternotomy after induction of anesthesia with spontaneous ventilation while on cardiopulmonary bypass. The perspective is from the head of the operating room table over the surgical drapes.

managing a patient with an anterior or superior mediastinal mass include the following:[119]

1. In virtually all adults with a mediastinal mass, diagnostic procedures and imaging can be performed, if necessary, without subjecting the patient to the risks of general anesthesia.[120]
2. An extrathoracic source of tissue for diagnostic biopsy (pleural effusion or extrathoracic lymph node) should be sought as an initial measure in every patient.
3. Regardless of the proposed diagnostic or therapeutic procedure, the flat (supine) position is never mandatory.

With improved awareness of the risk of acute intraoperative airway obstruction in these patients, life-threatening events are now less likely to occur in the operating room. In adults, acute airway obstruction is now more likely to occur postoperatively, in the recovery room.[121] Vigilance must be maintained throughout the entire perioperative period.

Vascular Anomalies With Airway Compression

A spectrum of congenital vascular abnormalities can cause tracheal, bronchial, and/or esophageal compression. These abnormalities include double aortic arch, right aortic arch with anomalous origin of the left subclavian artery, left aortic arch with anomalous right subclavian, and Kommerell diverticulum.[122] Kommerell diverticulum is an aneurysm at the origin of an anomalous subclavian artery that represents an embryologic remnant of the interrupted fourth aortic arch between the carotid and subclavian arteries. In combination with the ligamentum arteriosum or a patent ductus, it may cause a complete vascular ring compressing the trachea. Symptoms involve varying degrees of esophageal or airway obstruction and may present at any age. There is a tendency for airway symptoms to predominate in children and esophageal symptoms to predominate in adults. Respiratory symptoms and simple bronchoscopy can lead to a misdiagnosis of congenital tracheal stenosis. Diagnosis is confirmed by CT scan (Figs. 49.17–49.19), magnetic resonance imaging, and barium swallow. Surgical correction should follow diagnosis because of the tendency for rupture or dissection of these abnormal vessels.[123] Depending on the anatomy, surgical correction may range from thoracoscopic ligation of the ligamentum arteriosum, to sternotomy with vascular and airway reconstruction potentially requiring hypothermic cardiac arrest.

As with all other lower airway abnormalities, airway management requires a flexible plan and full understanding of the anatomy by the

Fig. 49.18 Left lateral computed tomographic reconstruction of the trachea in the same patient showing the posterior compression of the mid-distal trachea.

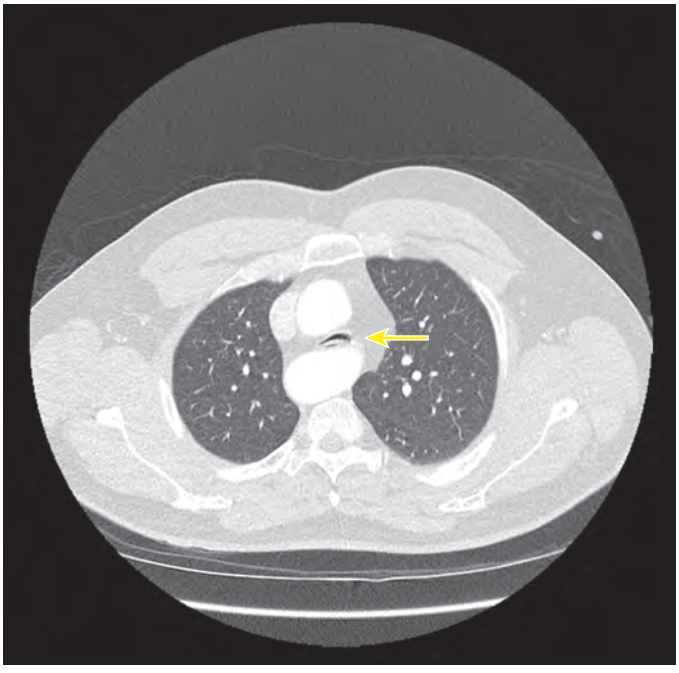

Fig. 49.17 Chest computed tomographic scan of an adult with a Kommerell diverticulum showing mid-distal tracheal compression *(yellow arrow)*. The anterior-posterior tracheal diameter was 3 mm at its narrowest point.

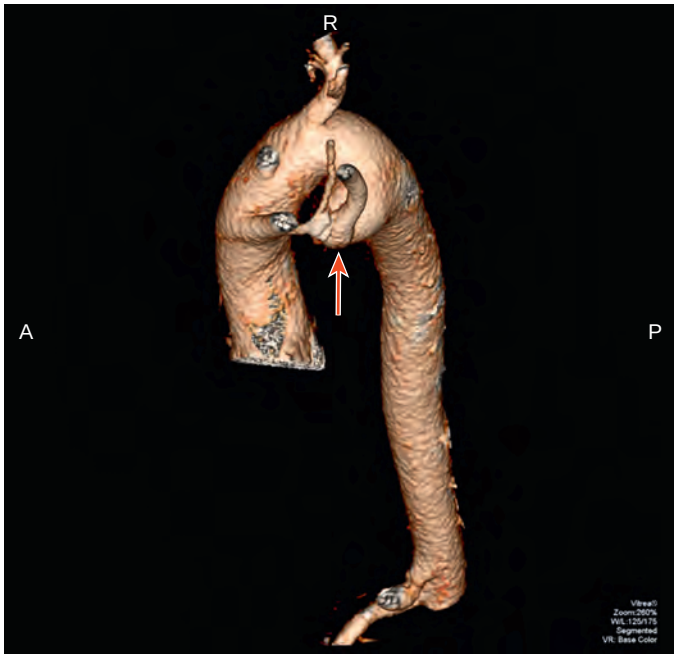

Fig. 49.19 Three-dimensional computed tomographic angiogram from the left lateral perspective of the same patient. The patient has a right-sided aortic arch. The trachea is compressed by the ring formed by the aberrant take-off of the left subclavian artery and the Kommerell diverticulum, which forms the origin of the left common carotid *(arrow)*.

anesthesiologist, based on the preoperative imaging. After induction of anesthesia, a complete FOB via an LMA is usually performed to guide further airway management. Lung isolation when needed may then require placement of a DLT or SLT with bronchial blocker. A rigid bronchoscope should be available in the operating room during induction and emergence from anesthesia in case of distal airway collapse. Consideration should be given to the use of corticosteroids to potentially decrease airway edema postoperatively.

There is the potential for postoperative tracheomalacia in patients who have had severe airway compression. Extubation should be approached in a cautious controlled fashion with the patient alert, sitting, and after a leak test of the ETT. It must be understood that the ETT cuff leak test is not infallible.[124] Another option to consider is extubation during general anesthesia with spontaneous ventilation and observation of the airway via a FOB through an LMA during emergence.

The Pregnant Patient With Cardiac Disease

MENACHEM M. WEINER, MD | JOSHUA HAMBURGER, MD | YAAKOV BEILIN, MD

KEY POINTS

1. Maternal heart disease is increasing and complicates up to 4% of pregnancies. It is a leading cause of maternal, fetal, and neonatal morbidity and death.
2. The diagnosis of new cardiovascular disease during pregnancy may be challenging because symptoms and physical signs often overlap with those of a normal, healthy pregnancy.
3. The preferred test during pregnancy to screen for structural cardiac abnormalities and to monitor ventricular and valvular functions and pulmonary pressures is transthoracic echocardiography.
4. A woman with known preexisting cardiac disease should receive preconception assessment and counseling with a rigorous, standardized risk assessment to make informed decisions regarding pregnancy. Several risk assessment tools have been developed.
5. The normal physiologic hemodynamic changes of pregnancy increase myocardial oxygen demand as a result of an increase in heart rate and preload and decrease myocardial oxygen supply secondary to reduced coronary perfusion pressure, dilutional anemia, and shortening of diastole.
6. The severity of valvular heart disease and the prepregnancy New York Heart Association functional class have been found to be the main predictors of adverse maternal and fetal outcomes.
7. Because of the enormous risk of maternal morbidity and mortality, women with pulmonary hypertension should be advised against pregnancy.
8. During labor, uterine contractions, pain, anxiety, and exertion from pushing during the second stage further increase heart rate, arterial blood pressure, and left atrial pressure. This increase adds further stress to a cardiovascular system already strained by the hemodynamic changes of pregnancy and can lead to heart failure.
9. When a pregnant woman with significant cardiac disease requires a nonobstetric operation, both mother and fetus are at a greater risk. The extent of the risk depends on the specific cardiac disease, its interaction with the hemodynamic changes of pregnancy, and its interaction with the hemodynamic changes caused by the surgical procedure and anesthesia.
10. The primary anesthetic goals in peripartum cardiomyopathy are avoidance of drug-induced myocardial depression, maintenance of normovolemia, prevention of increased or rapidly decreased ventricular afterload, and blunting of the sympathetic stimulation induced by pain and anxiety.
11. Resuscitation of the pregnant patient is a rare event that contributes to a lack of knowledge about the unique modifications to the advanced cardiac life support (ACLS) guidelines that are applicable in pregnancy.
12. Modifications to ACLS in pregnancy include performing chest compressions higher on the sternum and with left-sided uterine displacement. Intravenous access sites should be placed above the diaphragm.
13. Voltage for defibrillation and doses of medications during ACLS should not be altered.

Maternal heart disease complicates up to 4% of pregnancies and is a leading cause of maternal, fetal, and neonatal morbidity and death.[1] The prevalence of cardiovascular (CV) diseases (CVDs) in women of childbearing age is increasing for several reasons.[2] As the management and treatment of congenital heart disease (CHD) has improved, growing numbers of women with palliated or corrected CHD who survive into adulthood may become pregnant.[3] Advanced maternal age along with other risk factors, such as obesity, has led to an increase in women presenting with ischemic heart disease.[4] Furthermore, although the incidence of rheumatic heart disease has decreased in developed countries, it remains significant in developing countries and in immigrants from these countries.[5] Cardiomyopathy, manifesting during pregnancy or in the first few months after delivery, is uncommon but accounts for approximately 10% of maternal deaths.[6]

The anesthesiologist involved in the perioperative care of these patients must be well versed in the physiology of pregnancy, the pathophysiology of CVD, and their interactions, to optimize anesthetic management and improve patient outcome. Successful management requires early diagnosis and advanced planning by a multidisciplinary team of obstetricians, cardiologists, anesthesiologists, intensivists, and nurses to optimize outcome. Cardiac surgical procedures during pregnancy carry additional significant maternal and fetal risk and require modification of cardiopulmonary bypass.[7] This topic is covered in Chapters 24 and 31.

This chapter provides a review of the expected hemodynamic changes of pregnancy and the etiologic factors, underlying pathophysiologic features, and peripartum risk of obstetric patients with CVD. It also discusses the management issues faced by the anesthesiologist caring for these patients who present for noncardiac operations during pregnancy and for labor and delivery.

Diagnosis of Heart Disease During Pregnancy

Diagnosis Including Cardiovascular Imaging

The diagnosis of CVD during pregnancy may be challenging because symptoms and physical signs often overlap with the physiologic changes of pregnancy. Pregnant women frequently complain of dyspnea and fatigue, and exercise tolerance is often decreased. Tachypnea, peripheral edema, and lower extremity venous stasis also may occur during pregnancy in women without cardiac disease. Even in women with known preexisting CVD, it is important to differentiate expected pregnancy changes from pathologic exacerbations of underlying disease. The distinction is extremely important because it may trigger either unnecessary modifications in management or a failure to change management.[8]

A pregnant woman who presents with symptoms consistent with possible CVD or exacerbation of known CVD requires a careful medical history, family history, and physical examination (Box 50.1), all interpreted in the context of the physiologic changes of pregnancy. Many disorders, such as cardiomyopathy, Marfan syndrome, CHD, or Brugada syndrome, can be identified by taking a careful personal and family history.[9] In women who are already in the second trimester of pregnancy, blood pressure should be measured with the patient either upright or in the left lateral position to prevent compression of the inferior vena cava and aorta.[10] The pulse often has a rapid upstroke and collapse (a "bounding" character) secondary to the reduced systemic vascular resistance (SVR) and increased cardiac output (CO).[11] Resting heart rate (HR) is generally increased in pregnancy, but rates greater than 100 beats/minute (bpm) or bradycardia require further evaluation for an underlying cause.[8] Jugular venous pressure should be normal, so elevated jugular venous pressure and pulmonary rales are the most reliable signs of heart failure (HF). A loud and widely split S_1 heart sound, caused by the early closure of the mitral valve, and the presence of a third heart sound (S_3) are normal in pregnancy. Soft ejection systolic murmurs are heard in more than 90% of pregnant women, usually over the upper sternal border and the right side of the heart, as a result of increased CO and increased flow through cardiac valves.[12] These murmurs generally disappear at approximately 6 weeks post partum. Very loud systolic murmurs or a palpable thrill, however, suggest underlying disease. Diastolic murmurs are almost always caused by a pathologic process.[10] The murmurs of aortic and mitral regurgitation commonly decrease during pregnancy in response to the decrease in SVR, but the murmurs of mitral or aortic stenosis increase as a result of increased flow through the valves. Auscultation of new or changed murmurs is a reason for further investigation.

BOX 50.1 ABNORMAL PHYSICAL EXAMINATION FINDINGS DURING PREGNANCY

- Heart rate >100 bpm or <50 bpm at rest
- Pulmonary rales
- Systolic murmur louder than 3/6, especially with palpable thrill
- Any diastolic murmur
- Murmur that persists >6 weeks post partum
- Asymmetric lower extremity edema

Oximetry is an important diagnostic tool in patients with cyanotic CHD or shunt lesions.[9] Many pregnant women show some degree of peripheral edema and lower extremity venous stasis secondary to uterine compression of the inferior vena cava impeding venous return. The edema or stasis, however, should be symmetric and decrease with leg elevation and the left lateral decubitus position.

A woman with suggestive findings in the history and physical examination often requires CV testing during pregnancy. Additionally, pregnant women with known CVD may need testing to judge how CV function has been affected by the added stress imposed by pregnancy. Pregnancy may affect the safety, application, and interpretation of several diagnostic cardiac procedures. Additionally, choosing the optimal diagnostic procedure requires consideration of safety for the mother and the fetus.[10] Imaging modalities that do not require ionizing radiation are preferred so long as the required diagnostic information can be obtained. If the necessary information requires a study that uses ionizing radiation, the radiation dose to the fetus should be kept as low as possible.[9]

The electrocardiogram (ECG) often changes during pregnancy. These changes may include a 15- to 20-degree left-axis deviation resulting from diaphragmatic elevation, nonspecific ST-segment and T-wave changes (eg, T-wave inversion in leads III and aVF and ST-segment depression), supraventricular and ventricular ectopic beats, and the presence of small Q waves in lead AVF.[9,11] Ambulatory (Holter) monitoring is noninvasive and safe to use in pregnant patients with suspected arrhythmias that are not captured on an ECG or in patients with previous documented symptomatic arrhythmias and with palpitations. It is important, however, to correlate symptoms with any arrhythmias, so as not to expose the mother and fetus to potentially detrimental treatments.[9,11] Exercise testing may be useful in early pregnancy to establish functional capacity and assess HR, blood pressure, and ischemic changes to exercise. Exercise testing should be used with caution in women with an incompetent cervix, bulging membranes, recent vaginal bleeding, placenta previa or abruption, or preeclampsia. Women with symphyseal-pubic dysfunction, common during pregnancy, may be unable to perform the test because of limited movement. The procedure must be stopped if hypotension develops because this can lead to fetal distress. The European Society of Cardiology recommends performing submaximal exercise tests to reach 80% of predicted maximal HR in asymptomatic pregnant patients with suspected CVD because no evidence indicates that performing exercise testing up to that level increases the risk of spontaneous abortion.[9] Dobutamine stress tests should be avoided in pregnant women because of limited data on dobutamine safety in pregnancy.[9]

The preferred test during pregnancy to screen for structural cardiac abnormalities and to monitor ventricular and valvular function and pulmonary artery pressures (PAP) is transthoracic echocardiography.[9] Many echocardiographic measurements require adjustment for pregnancy, including measurement of chamber dimensions and left ventricular (LV) mass and quantifying velocities across valves, because these values all are increased in pregnancy.[9,12] The use of transesophageal echocardiography (TEE) allows for more detailed examination but is more invasive than transthoracic echocardiography and may be associated with pulmonary aspiration, which is a greater risk during pregnancy as compared with the nonpregnant state. TEE may still be indicated in the diagnosis of endocarditis, mechanical valve thrombosis, and complex CHD. The use of general anesthesia with tracheal intubation, however, may be necessary to protect the airway.[9]

Although it is preferable not to perform chest radiography during pregnancy because of the ionizing radiation exposure, if other tests fail to diagnose the cause of dyspnea or cough, it may be necessary. The chest radiographic findings in pregnancy may show several seemingly pathologic changes, including prominent vascular markings, a horizontal position of the heart, a flattened left heart border, and a raised diaphragm as a result of the gravid uterus. Pulmonary edema, however, should not be seen.[9]

In the setting of suspected acute pulmonary embolus, a computed tomography pulmonary angiogram should be performed because the

risk to the fetus is outweighed by the danger of missed pulmonary emboli and can be minimized by lead shielding. Although echocardiography may aid in the diagnosis by identifying elevated PAPs and impairment and dilatation of the right ventricle, it is less specific.[9]

Cardiac magnetic resonance imaging can provide information on cardiac anatomy and function without the use of ionizing radiation. It is generally used only if other investigations, such as echocardiography, cannot provide the relevant information because the safety of magnetic resonance imaging in the early stages of pregnancy has not been determined. The safety of gadolinium use during pregnancy has not been demonstrated, and this agent should be avoided if possible.[9]

Cardiac catheterization for visualization of coronary arteries and measurement of intracardiac pressures gives high radiation exposure to the fetus and should only be used if absolutely clinically required. It is the diagnostic tool of choice, however, in the management and treatment for ST-segment elevation myocardial infarction (MI) in pregnancy. To reduce fetal radiation exposure, catheterization through the radial artery is preferred to the femoral artery approach, and lead shielding of the uterus should be used. Although heparin is required for the procedure, an activated coagulation time not exceeding 300 seconds is preferable to minimize risk of placental bleeding.[9]

Ionizing Radiation Risk to the Fetus

Pregnant women with suspected or known CVD may require medical procedures for either diagnostic or therapeutic purposes that involve the use of ionizing radiation, such as fluoroscopy for right-sided heart catheterization or mitral balloon valvuloplasty. The effects of ionizing radiation on an embryo and fetus can include pregnancy loss, congenital malformations (eg, microcephaly and microphthalmia), neurobehavioral or intellectual abnormalities, fetal growth retardation, and cancer.[13] The type and magnitude of the potential effects of the radiation on the fetus vary depending on the gestational age at which exposure occurs and the dose of radiation.[9,14] If possible, procedures should be delayed until at least the completion of the period of major organogenesis (>8 weeks of gestational age) because this is when the risks are most significant. The risk is somewhat less in the second trimester, and least in the third trimester, although the central nervous system continues to develop after delivery.[14] The risks and benefits of performing or not performing the examination should be communicated to the patient.[9] Common sense dictates that ionizing radiation should only be used when no alternative exists and at the lowest possible dose and the shortest possible duration.[15] Whenever exposure must occur, it is vital to protect the fetus with lead shielding.[14]

It is unclear what dose of radiation constitutes a danger to the fetus because only limited knowledge of the effects of radiation on the fetus has been obtained from animal studies, human exposures to diagnostic and therapeutic radiation, and atomic bomb exposure.[14] No evidence indicates an increased risk of congenital malformations, neurobehavioral or intellectual abnormalities, fetal growth restriction, or pregnancy loss at doses of radiation lower than 50 mGy (milligray) (10 mGy = 1 rad).[9] Although the effect on these outcomes at radiation doses between 50 and 100 mGy (5–10 rad) is unclear, evidence suggests that doses higher than 100 mGy are associated with increased risk, particularly to the central nervous system tissues.[9,14] Cancer risk to the child is a well-known feature of intrauterine radiation exposure, and some evidence indicates that even very small doses (10–20 mGy) increase the risk by a factor of 1.5 to 2 (1:2000 vs 1:3000).[15] Based on the available information, the International Commission on Radiological Protection stated that radiation exposure of less than 100 mGy (10 rad) during pregnancy should not constitute medical grounds for termination of a pregnancy.[13] However, the American College of Obstetricians and Gynecologists designated that the threshold for medical concern, particularly regarding congenital malformations, should be lowered to 50 mGy (5 rad).[13]

Fortunately, most medical procedures do not expose the fetus to such high levels of radiation. For example, the fetal exposure from a chest radiograph is less than 0.01 mGy, and although the maternal exposure from a percutaneous coronary intervention or radiofrequency catheter ablation is 15 mGy, the fetal exposure is only approximately 3 mGy.[9,14]

Cardiac Risk Stratification During Pregnancy

Ideally, a woman with known preexisting CVD should undergo a preconception evaluation and counseling with a rigorous, standardized risk assessment (see later) to make informed decisions regarding pregnancy, to adjust to the possibility of not having a pregnancy, and to address any correctable lesions before pregnancy.[6,16,17] Evaluation should include assessment of New York Heart Association (NYHA) functional class, a 12-lead ECG, and transthoracic echocardiography. Right-sided heart catheterization may be necessary for women with CHD or pulmonary hypertension (PH).[6] Medications that are contraindicated during pregnancy should be discontinued or changed to acceptable alternatives when possible.[10] Many women present once they are already pregnant and should undergo immediate cardiac evaluation as described earlier.[18] This approach allows for the implementation of safe, guidelines-based care according to the risk assessment.[8] Although women found to be at low risk can often be managed by their primary cardiologist and obstetrician, women who are considered to be at medium or high pregnancy risk should be referred to a tertiary care referral center with expertise in pregnancy and cardiac disease for highly specialized management by a multidisciplinary team.[16]

Several risk assessment tools have been proposed to stratify cardiac risk during pregnancy. By using these risk scores it may be possible to predict whether the woman will tolerate the pregnancy.[16] Three risk assessment tools commonly used to predict maternal CV events during pregnancy are the CARPREG (Cardiac Disease in Pregnancy), the ZAHARA (Zwangerschap bij Vrouwen met een Aangeboren Hartafwijking-II, translated as Pregnancy in Women With CHD II), and one developed by the World Health Organization (WHO).[16] The CARPREG score is based on a prospective study of 562 consecutive pregnant women with known cardiac disease (74% had CHD) in which 13% of the pregnancies had maternal cardiac complications including pulmonary edema, arrhythmia, stroke, and cardiac death. This study identified several independent predictors for the occurrence of an adverse maternal cardiac event during pregnancy and incorporated them to formulate a risk index (Table 50.1).[19] The CARPREG score was modified for patients with CHD with the addition to the risk index of subpulmonary ventricular systolic dysfunction and severe

TABLE 50.1 CARPREG (Cardiac Disease in Pregnancy) System for Predicting Maternal Cardiovascular Events[a]

1. Previous cardiac event (1 point)
   a. Heart failure
   b. Transient ischemic attack
   c. Cerebrovascular accident
   d. Arrhythmia
2. NYHA >functional class II or cyanosis (1 point)
3. Mitral valve area <2 cm^2 (1 point)
4. Aortic valve area <1.5 cm^2 (1 point)
5. Left ventricular outflow tract gradient >30 mm Hg (1 point)
6. Ejection fraction <40% (1 point)

CARPREG Points	*Cardiac Complication Rate*
0	5%
1	27%
2	75%

pulmonic regurgitation.[20] This study, however, was limited by an overrepresentation of complex CHD that explained its very high rate of complications. The ZAHARA investigators constructed a weighted scoring system for women with CHD based on a study of 1802 women in which cardiac complications occurred in 7.6% of completed pregnancies incorporating several additional variables (Table 50.2).[21]

High-risk lesions were underrepresented in the study populations used to generate both the CARPREG and ZAHARA assessment tools, and this underrepresentation led to inaccurate pregnancy risk prediction for the sicker patients.[8] Measurement of serum levels of the biomarker brain natriuretic peptide (BNP) early in pregnancy has also been used to stratify risk. In a study of 87 pregnant women with structural heart disease, BNP levels up to 100 pg/mL had a 33% positive predictive value and a negative predictive value of 100% for identifying adverse maternal cardiac events including HF and arrhythmias during pregnancy, thus making it particularly useful to rule out a cardiac problem.[22]

It is important to stratify risk based on specific lesions because the risks of pregnancy depend on the specific cardiac condition. Predicted risks range from as high as a 50% mortality rate for women with severe PH to a risk that is indistinguishable from that in the general population for some minor lesions.[17]

The Task Force on the Management of Cardiovascular Diseases during Pregnancy of the European Society of Cardiology recommends that maternal risk assessment be carried out according to the WHO risk classification.[9] The WHO classification of cardiac risk during pregnancy depend on the specific underlying heart disease and on the presence and severity of ventricular and valvular dysfunction (Table 50.3).[10,17] In addition, in this system pregnancy-related risks are additive, meaning that a patient with a cardiac condition that is considered low risk (WHO 1 or 2) may move up a risk category if other cardiac or noncardiac risk factors (eg, poor ventricular function or diabetes) are present.[17]

Because maternal cardiac disease is associated with an increased incidence of neonatal complications (eg, prematurity, intrauterine growth retardation, and fetal death), it is necessary also to determine the fetal risk of the pregnancy (Box 50.2). Neonatal complications occur in 20% to 28% of pregnant women with heart disease. Neonatal risks increase with NYHA functional class greater than II, the presence of a mechanical valve prosthesis, cyanosis, anticoagulation use during pregnancy, multiple gestations, smoking during pregnancy, aortic stenosis (AS) or mitral stenosis (MS), and the use of cardiac medications before pregnancy.[19,21]

TABLE 50.3 Modified World Health Organization Cardiac Risk Assessment

Class I (No Increase or a Mild Increase in Morbidity From the General Population)

Follow-up during pregnancy may usually be limited to 1 or 2 visits.

- Mild pulmonic valve stenosis
- PDA
- Mitral valve prolapse with minimal mitral regurgitation
- Repaired ASD, VSD, PDA, anomalous pulmonary venous return
- Atrial or ventricular ectopic beats, isolated

Class II (Small Increase in Maternal Mortality, Moderate Increase in Maternal Morbidity)

Follow-up every trimester is indicated.

- Unrepaired ASD or VSD
- Repaired tetralogy of Fallot
- Most arrhythmias
- Mild left ventricular dysfunction
- Hypertrophic cardiomyopathy
- Marfan syndrome without aortic dilation
- Bicuspid aortic valve with aortic diameter <45 mm
- Repaired coarctation
- Heart transplantation

Class III (Significant Increase in Maternal Mortality and Severe Increase in Maternal Morbidity)

Expert cardiac and obstetric care is required before pregnancy, antenatally, and postnatally. Women need frequent (monthly or bimonthly) follow-up during pregnancy, both by a cardiologist and an obstetrician.

- Mechanical valve(s)
- Systemic right ventricle
- Fontan circulation
- Unrepaired cyanotic heart disease
- Complex congenital heart disease
- Marfan syndrome with aortic dilation 40–45 mm
- Bicuspid aortic valve with aortic dilation 45–50 mm

Class IV (Pregnancy Is Not Recommended or Is Contraindicated Because of an Extremely High Risk of Maternal Morbidity and Mortality)

Pregnancy termination should be discussed if women are already pregnant, but when they choose to carry on with the pregnancy, their follow-up is similar to that in women with WHO class III.

- Pulmonary artery hypertension of any cause
- Severe left ventricular dysfunction
- Previous peripartum cardiomyopathy with residual left ventricular dysfunction
- Severe mitral stenosis
- Severe aortic stenosis
- Marfan syndrome with aortic dilation >45 mm
- Bicuspid aortic valve with aortic dilation >50 mm
- Severe unrepaired aortic coarctation
- Severe systemic ventricular dysfunction (LVEF <30%)

Pregnancy and Cardiac Disease

Cardiovascular Physiologic Changes of Pregnancy, Labor, and Delivery

Cardiovascular physiologic changes of pregnancy are summarized in Table 50.4.

Coronary Artery Disease

The management and treatment goals of coronary artery disease (CAD) in the nonpregnant woman are discussed in Chapter 20. Although the incidence of significant CAD in pregnancy is not known, James and

TABLE 50.4 Cardiovascular Changes in Pregnancy

Variable	*Change-Peaks in the Early Third Trimester (at ≈32 Weeks)*
Blood volume	+35–50%
Plasma volume	+40–45%
Heart rate	+15–20%
Stroke volume	+30%
Cardiac output	+30–50%

BOX 50.2 FACTORS ASSOCIATED WITH SIGNIFICANTLY INCREASED FETAL MORBIDITY IN WOMEN WITH CARDIAC DISEASE

- NYHA functional class greater than II
- Presence of a mechanical valve prosthesis
- Cyanosis (oxygen saturation < 85%)
- Anticoagulation use during pregnancy
- Multiple gestation
- Smoking during pregnancy
- Aortic or mitral stenosis
- Use of cardiac medications before pregnancy

NYHA, New York Heart Association.

colleagues[23] reported that the incidence of acute MI (AMI) during pregnancy or the postpartum period is 6.2 in 100,000 deliveries, with a 5.1% mortality rate. In that study, the most common time frame for development of AMI was in the third trimester or the immediate postpartum period. Other investigators have reported an incidence of AMI ranging from 3 to 6 in 100,000 deliveries, with a mortality rate of 5% to 37 %.[4,10,24] The rate of fetal death following maternal AMI is approximately 12% to 34%.[24,25]

Myocardial oxygen demand is increased during pregnancy as a result of an increase in HR and preload, whereas myocardial oxygen supply is decreased secondary to a decrease in coronary perfusion pressure, dilutional anemia, and shortening of diastole.[26] This situation presents a challenge to women with known or previously undiagnosed CAD. This challenge becomes greater during labor and delivery and especially immediately after delivery because of further increases in CO. Although CAD in pregnancy is relatively uncommon, the incidence has risen with increasing maternal age and increased risk factors, such as hypertension, diabetes, obesity, and smoking among women of reproductive age.[23,25]

Factors unique to pregnancy may also increase the possibility of MI in women without previous CAD.[27] Investigators have hypothesized that a postpartum degeneration of coronary arterial intima and media leads to an increase in the incidence of coronary artery dissection.[28] Pregnancy-related hypertensive diseases are also associated with an increased incidence of AMI.[27] Additionally, the hypercoagulable state of pregnancy may lead to coronary thrombosis or embolism in women without underlying CAD. Severe postpartum hemorrhage may result in myocardial ischemia,[10] and the use of methylergonovine for postpartum bleeding can cause coronary vasospasm.[9]

The diagnostic principles for myocardial ischemia during pregnancy are the same as for the nonpregnant patient and are based on angina symptoms, changes on the ECG, and increases in cardiac biomarkers (eg, troponin).[9] Creatinine phosphokinase and its MB isoenzyme may not be helpful in the diagnosis of myocardial ischemia during pregnancy because levels of these enzymes are often elevated during pregnancy, especially during labor.[29] The differential diagnosis of chest pain includes common pregnancy symptoms (eg, gastroesophageal reflux disease, nausea and vomiting) musculoskeletal pain, aortic dissection, and preeclampsia.[30]

The hemodynamic goal during an acute coronary syndrome in a gravid patient is to prevent further ischemia by avoiding increases in myocardial oxygen demand or decreases in supply. Medical management is similar to that in nonpregnant patients, with medical therapy consisting of β-blockers for tight HR control and low-dose aspirin, both of which have been found safe and effective in pregnancy.[4] However angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), and statins are known teratogens and should be avoided in pregnancy. The preferred approach for women with either acute ST-segment elevation MI (class 1 recommendation) or non–ST-segment elevation MI with risk factors (class IIa recommendation) is percutaneous coronary angiography with intervention and reperfusion through stenting if needed.[9] The radiation exposure to the fetus when shielding is used is minimal, and the benefits outweigh the risks. Clopidogrel should be used only for the shortest duration as possible because of the risk of placental bleeding during pregnancy and the peripartum period, and the use of bare-metal stents is thus preferred over drug-eluting stents.[31]

Coronary artery bypass grafting is rarely needed during pregnancy and is associated with a high fetal mortality rate. In women with non–ST-elevation myocardial ischemia without risk factors, conservative management with medical therapy and watchful waiting can be applied (class IIa recommendation).[9] Women with CAD should have the early institution of neuraxial anesthesia during labor to prevent pain and the increased myocardial oxygen demand that accompanies it.[26] In the case of AMI, labor and delivery should be delayed for at least 2 weeks if possible because the risk of maternal death is significantly increased during this time.[24]

Valvular Heart Disease

A complete discussion of valvular heart disease (VHD), along with its management and treatment, can be found in Chapter 21. The most common causes of VHD in women of childbearing age are rheumatic heart disease and CHD (eg, bicuspid aortic valve), with MS the most common lesion encountered.[32] VHD is a significant cause of maternal cardiac disease because rheumatic heart disease accounts for more than 90% of maternal cardiac disease worldwide. Pregnant women with VHD have an increased incidence of adverse maternal and fetal outcomes,[33] and patients with severe MS form a particularly high-risk group with a reported maternal mortality rate of more than 10% and a cardiac event rate of 67% in some series.[34,35] The most commonly encountered maternal cardiac complications are HF and arrhythmias[36] and the most common fetal complications are prematurity and intrauterine growth retardation.[35]

Women with known VHD before pregnancy should undergo preconception counseling. Guidelines advise against pregnancy for women with moderate or severe MS unless the lesion is corrected before pregnancy. The same is true for women with moderate or severe AS who are symptomatic or have LV dysfunction (class I recommendation).[9] Women at high risk who desire to pursue pregnancy should be managed by a multidisciplinary team in centers with expertise in the management of these patients. The hemodynamic changes of pregnancy can exacerbate mild symptoms. Symptoms tend to worsen with increasing gestational age.[37] The severity of VHD and the prepregnancy NYHA functional class have been found to be the main predictors of

adverse maternal and fetal outcomes.[35,38] In many women with VHD, the disease is first diagnosed during pregnancy when the hemodynamic changes of pregnancy precipitate symptoms.

In general, regurgitant lesions are much better tolerated in pregnancy than are stenotic lesions because the decrease in SVR favors forward flow.[5] In the absence of LV dysfunction, these lesions pose only a minor threat. Symptomatic patients may be treated with diuretic agents and afterload reduction with close monitoring for uteroplacental insufficiency (class I recommendation).[9] Afterload reduction should be provided with nitrates and hydralazine because ACE inhibitors and ARBs are contraindicated in pregnancy.[39] The increase in preload, CO, and HR during pregnancy causes a significant increase in the transvalvular gradient across stenotic lesions.[40] MS also compromises LV filling and increases left atrial pressure (LAP), an increase that is then transmitted to the pulmonary veins.[37] Calculation of mitral valve area by using the pressure half-time technique has been found to be less accurate than the continuity equation during pregnancy (see Chapter 21 for calculations).[41] The decrease in LV filling and the increase in pressure in the pulmonary veins lead to deterioration in functional class, with increased dyspnea, decreased exercise tolerance, and possibly pulmonary edema. Atrial arrhythmias (eg, atrial fibrillation) that result in ventricular rate acceleration are a common cause of worsening symptoms and must be treated aggressively with rate control and possibly cardioversion.[16]

In general, MS is more of a management challenge than AS. In AS, the increase in pressure is reflected initially to the hypertrophied left ventricle, whereas in MS, it affects the pulmonary veins.[40] Women with mild or moderate AS generally tolerate pregnancy well.[39] Medical therapy for stenotic lesions in symptomatic women consists of HR control with β-blockers and restriction of physical activity and preload reduction with diuretic agents (class I recommendation).[9,39] Metoprolol is the preferred β-blocker because atenolol has been linked to adverse fetal outcomes, including intrauterine growth retardation and preterm delivery. HR control leads to improved LV filling and lower LAP. Diuretic use, in particular, must be accompanied by monitoring for signs of uteroplacental insufficiency. Patients with MS or AS whose conditions are refractory to medical therapy may be candidates for percutaneous balloon valvuloplasty, which should be performed with abdominal shielding and delayed until after the first trimester if possible to minimize the radiation risks to the fetus (class IIa recommendation).[9,16] No definitive data are available on transcatheter aortic valve replacement in pregnant patients, but it is likely that this technique will emerge as a viable option in patients with severe AS and hemodynamic decompensation.

Women with valve replacements, particularly mechanical prostheses, are at an increased risk for pregnancy complications and pose a particular challenge because of the risk of valve thrombosis and anticoagulation management. Some investigators consider the presence of a mechanical prosthesis, particularly in the mitral position, a contraindication to pregnancy.[40] Anticoagulation guidelines[9] recommend the continuation of warfarin until 36 weeks of gestational age (class I recommendation), with the possible exception of weeks 6 to 12, because warfarin is teratogenic, when a changeover to either unfractionated heparin or low-molecular-weight heparin may be recommended, particularly if the dose of warfarin is greater than 5 mg/day (class IIa recommendation). After 36 weeks, a changeover to heparin is recommended (class I recommendation). Alternatively, these women can be switched from warfarin to low-molecular-weight heparin from the beginning of pregnancy. These women require weekly monitoring of a postdose anti–factor Xa level (class I recommendation).[9] Investigators had also been concerned that accelerated bioprosthetic valve deterioration occurred during pregnancy, but this has not been borne out in studies.[42]

Pulmonary Hypertension

The incidence of PH in pregnancy is approximately 1.1 in 100,000 pregnancies.[43] The hemodynamic changes of pregnancy are not well tolerated by women with PH.[44] A review of outcomes in pregnant women with PH that covered the years 1978 to 1996 and included 125 pregnancies found an overall mortality rate of 38%.[45] A more recent review covering the years 1997 to 2007 that included 73 pregnancies found a mortality rate of 25%.[46] The risk of maternal morbidity and death in women with PH from any cause makes pregnancy particularly dangerous, and these women should be advised against pregnancy (class III recommendation).[9,26] Those patients who present already pregnant should be offered termination of pregnancy.[10] Death generally occurs in late pregnancy or in the first month after delivery and results from right-sided HF, PH crisis, pulmonary thromboembolism, or arrhythmias.[45,46] Although some evidence indicates better outcomes in women with mild PH (systolic PAP <50 mm Hg), no specific cutoff defines safety.[46,47] Furthermore, PH generally is exacerbated by the physiologic and hemodynamic changes of pregnancy, including increased CO and circulating blood volume and decreased SVR. The vascular remodeling present in women with PH prevents them from compensating with the pulmonary vasodilatory mechanisms of pregnancy that occur in healthy patients.[44] This situation results in increased pulmonary vascular resistance (PVR), overload of the right ventricle, and right ventricular (RV) strain. Even mild forms of PH may become severe.[9,26,43]

When termination of pregnancy is refused and the patient chooses to continue pregnancy, care should be managed in a facility with expertise in high-risk pregnancies and PH management under the care of a multidisciplinary team.[48] Treatment advances and the use of a multidisciplinary team are associated with an improvement in survival.[43] Management during pregnancy involves finding a balance between systemic pressures and PAPs because decreased systemic pressures compromise RV perfusion.[26] Therapy for PH should generally be continued, other than the endothelin-1 receptor blocker bosentan, which is teratogenic in animal studies (class IIa recommendation).[9,43,44] Prostacyclin analogues (eg, epoprostenol), inhaled nitric oxide, and phosphodiesterase-5 inhibitors (eg, sildenafil) have not been found to be teratogenic. Initiating targeted therapies at the beginning of the third trimester is recommended.[44] It is also critically important to avoid conditions that will increase PAPs, including hypoxia, hypercarbia, acidosis, and sympathetic stimulation because they may lead to RV failure.[26] Inotropic support may be needed in the setting of RV failure. Maternal hemodynamic decompensation generally occurs in the second or third trimester and shortly after delivery of the fetus.[26] Early planned delivery, usually at 32 to 34 weeks of gestational age, may have helped contribute to improved outcomes in more recent studies.[44]

Congenital Heart Disease

CHD management in the adult patient is discussed in Chapter 22. CHD has become the most prevalent chronic maternal heart disease during pregnancy, and it accounts for 66% to 80% of cases.[3,36] This change has stemmed from an increased number of patients with CHD living into their childbearing years as a result of advances in surgical repair and palliation procedures.[3] Although many women with CHD tolerate the expected hemodynamic changes of pregnancy, maternal CV complications occur in approximately 5% to 25% of such pregnancies.[20,21,49] The most common complications are HF, thromboembolism, and arrhythmias.

Because CHD is known in most women before pregnancy, preconception counseling with a through risk assessment is indicated. CHD encompasses a wide array of diseases from mild to extremely complex, so the risk of pregnancy varies greatly and also depends on whether the congenital defect has been repaired and whether permanent damage occurred before the repair. Risk increases with higher modified WHO class. Pregnancy should not be discouraged in patients who have had successful surgical repair and who have good exercise tolerance and functional status because these women have only a very small increased risk, provided no mechanical valve has been implanted.[9] Patients who have moderate or complex disease and who choose to continue with pregnancy should be managed in a facility

with expertise in high-risk pregnancies and CHD under the care of a multidisciplinary team.[10]

In the absence of PH, women with repaired shunt lesions, including atrial septal defect, ventricular septal defect, atrioventricular canal defect, and patent ductus arteriosus, tolerate pregnancy well without a significant increase in CV risk.[9] They are, however, at increased risk for preeclampsia.[50,51] Patients with unrepaired shunt lesions have a risk of paradoxical embolism, particularly during labor, when a Valsalva maneuver is employed during the second stage of labor.[3] Patients with unrepaired atrioventricular canal defects are at greater CV risk than patients with either atrial septal defects or ventricular septal defects because severe atrioventricular valve regurgitation or ventricular dysfunction may cause HF during pregnancy. Additionally, if Eisenmenger syndrome develops in patients with unrepaired shunt lesions, the maternal mortality rate increases to 28% to 52%, with a fetal mortality rate of 28%.[46,52,53] The reduction in SVR exacerbates the right-to-left shunt and increases cyanosis, whereas the increase in CO leads to HF.[3] Severe cyanosis (oxygen saturation <85%) makes the chance of a live birth extremely unlikely.[9] Management goals include maintenance of SVR and PVR with strict avoidance of hypoxia, acidosis, hypercarbia, and sympathetic stimulation.[3]

Women who have unrepaired cyanotic heart disease, such as tetralogy of Fallot, should be counseled against pregnancy because these pregnancies have a maternal complication rate greater than 30%.[53] Complications include HF, thromboembolism, and arrhythmias. When maternal resting oxygen saturation is less than 85%, the maternal risk is extremely high, and the chance of a live birth is only 12%.[53] Such women should be advised against pregnancy (class III recommendation).[10] Women with corrected tetralogy of Fallot generally tolerate pregnancy fairly well, with cardiac complications (eg, arrhythmias and HF) reported in up to 12% of patients.[54] Risk factors for complications are preexisting RV dysfunction or dilation, PH, severe pulmonic valve regurgitation, and RV outflow tract obstruction.[10]

The presence of a systemic right ventricle is independently associated with adverse maternal and pregnancy outcomes. This phenomenon is present in patients with congenitally corrected transposition of the great arteries, following an atrial switch operation for complete transposition of the great arteries (ie, Mustard or Senning procedures), or in hypoplastic left heart syndrome with Fontan physiology.[3,55] These patients are at increased risk for HF and life-threatening arrhythmias. Women with severe RV dysfunction or severe atrioventricular valve regurgitation, or those who have NYHA functional class III or IV, should be counseled against pregnancy (class III recommendation).[3,10] Women with Fontan physiology may experience deterioration in functional status. Hemodynamic goals include the maintenance of pulmonary blood flow by minimizing PVR and maintaining intravascular volume, SVR, and sinus rhythm.[3]

Management of Labor and Delivery in Women With Cardiac Disease

Importance of Multidisciplinary Planning

The period of labor and delivery is a critical time for women with heart disease because abrupt hemodynamic changes make decompensation more likely.[39] Uterine contractions, pain, anxiety, and exertion from pushing further increase HR, blood pressure, and LAP, thus stressing an already compromised CV system.[40] CO increases steadily from 15% in early labor to 50% to 60% (approximately 11 L/min) during pushing efforts to an 80% increase in the immediate postpartum period because of the relief of inferior vena cava obstruction.[56–58] Furthermore, each uterine contraction increases CO by 20% by autotransfusing blood into the central blood volume.[59] This process can result in HF and acute pulmonary congestion. As a result, the management of labor and delivery requires a skilled collaborative effort that includes a multidisciplinary team of cardiologists, obstetricians, anesthesiologists, and, for the highest-risk patients, a cardiac surgical team with availability of cardiopulmonary bypass[9] (Box 50.3).

BOX 50.3 QUESTIONS FOR THE MULTIDISCIPLINARY TEAM TO ADDRESS

- What is the best timing for delivery?
- What should be the mode of delivery?
- What is the optimal location for delivery (labor and delivery suite, cardiac operating room)?
- Should a cardiac surgeon and cardiopulmonary bypass capabilities be on standby?
- When should the mother be admitted for predelivery optimization and possible antenatal corticosteroid administration?
- Is any further diagnostic testing necessary?
- What type of anesthesia or analgesia should be planned for the patient?
- What type of monitoring should be employed?
- Where will the patient be monitored after delivery? For how long?
- Which oxytocic drugs will be given?
- What is the contingency plan if the mother presents urgently in labor or in acute decompensation?
- Should any other specific needs, precautions, or concerns be addressed?

Delivery should generally be planned so the team can be present, rather than allowing spontaneous labor. The timing of delivery should be individualized because prospective data are lacking and individual patients' characteristics influence the decision.[9] Women with complex cardiac lesions, severe HF, or severe PH often require an early, planned delivery before maternal and fetal decompensation.[11]

Mode of Delivery

The mode of delivery depends on both the obstetric indications and the maternal hemodynamic status.[11] If a decision is made that the delivery must take place significantly before term as a result of deteriorating maternal cardiac status, then a cesarean delivery will be necessary because induction of labor will likely be unsuccessful. For women who are able to continue the pregnancy to term, the guidelines of the European Society of Cardiology[9] favor vaginal delivery because it poses less cardiac risk, given that it is associated with less blood loss and fluid shifts and also has a decreased risk of venous thrombosis.[60] Studies have shown that vaginal delivery is well tolerated by most women with cardiac disease.[11,33,61–63] Vaginal delivery can be assisted by vacuum or forceps to shorten the second stage of labor and minimize maternal pushing efforts and Valsalva maneuvers, thus avoiding further increases in CO in women who will not be able to tolerate the hemodynamic challenge.[61] Cesarean delivery is generally reserved for obstetric indications.[9,63] In certain situations, however, vaginal delivery should be strongly considered (Box 50.4). These include women in severe HF, those taking oral anticoagulants (because of the risk of neonatal intracranial bleeding), and patients in whom the stress of labor and delivery puts them at greater risk for aortic dissection (eg, Marfan syndrome with an aortic diameter >40–45 mm).[9] Furthermore, some clinicians favor cesarean delivery for women with severe stenotic valvular lesions, severe PH, poor functional class, and acute HF.[9] The trend has tilted in favor of cesarean delivery because it is believed to allow greater control of both timing of delivery and hemodynamic status.

The choice of uterotonic agents is also important in these patients. Most women are able to tolerate a slow intravenous infusion of oxytocin post partum to prevent maternal hemorrhage.[11] Studies suggest that small doses of oxytocin are as effective as larger doses.[64] However, oxytocin causes an increase in PVR and tachycardia.[65] Methylergonovine should be avoided in most women with significant cardiac disease

BOX 50.4 CONDITIONS IN WHICH CESAREAN DELIVERY SHOULD BE STRONGLY CONSIDERED

- Planned early delivery in which induction is unlikely to succeed
- Acute or severe heart failure, poor functional class
- Severe mitral or aortic stenosis
- Severe pulmonary hypertension
- Aortic dilation >40–45 mm in Marfan syndrome
- Women receiving anticoagulation secondary to risk of fetal intracranial hemorrhage

because of the risk of coronary vasoconstriction and both systemic hypertension and PH.[66–68] Carboprost can also cause both systemic hypertension and PH and should be avoided.[69] Furthermore, although misoprostol (administered either sublingually or rectally) has no known cardiac side effects, its efficacy as a uterotonic agent is not clear.[70,71] Conversely, the avoidance of these medications is also not without risk because maternal hemorrhage and the concomitant need for rapid infusion of fluid and blood products are also poorly tolerated in these women.

Anesthetic Options and Monitoring

Anesthetic options differ, depending on mode of delivery, the specific cardiac disease, and the patient's functional status. Controlled studies or standards to guide the practitioner regarding the optimal anesthetic techniques for women with heart disease are lacking.[72] An understanding of the specific cardiac disease and its severity, along with knowledge of the hemodynamic goals, guides the optimal choice of individualized anesthetic techniques.[72,73] The use of neuraxial anesthesia techniques for women receiving anticoagulation must conform to guidelines of the American Society of Regional Anesthesia.[74]

For women who will be undergoing labor, the early institution of analgesia is recommended to decrease sympathetic stimulation secondary to pain that would in turn increase HR and CO. Continuous lumbar epidural analgesia with a low dose of local anesthetic along with an opioid (eg, bupivacaine 0.0625% with fentanyl 2 μg/mL) provides excellent analgesia, with attenuation of the increases in HR and CO with minimal changes in SVR. The addition of an opioid to the local anesthetic solutions enhances the quality of the analgesia without increasing the sympathetic blockade.[73] This regimen can be supplemented with the use of a short-acting β-blocker (eg, esmolol), if needed.[37] Careful titration providing a slow onset of sympathetic blockade enables tighter control over hemodynamic changes.[73] Epidural blockade, however, even with the use of low concentrations of local anesthetic, still reduces SVR. The resultant hypotension, decreased cardiac preload, and reflex tachycardia may be poorly tolerated in women with MS or AS, CAD, PH, or severe HF. A decrease in SVR in women with an intracardiac shunt also has the potential to reverse the direction of flow, thus leading to decreased pulmonary blood flow and hypoxemia. Careful titration and close monitoring are necessary to avoid these complications.[72] Hypotension should be aggressively treated with vasopressor, and HF should be aggressively treated with inotropic support.[26] Patients who are particularly at risk for decompensation and HF may benefit from the prophylactic institution of an inotropic infusion (eg, dobutamine 2–3 μg/kg per min) to prevent HF in the presence of autotransfusion and other changes associated with delivery.

Although women who are critically ill generally undergo cesarean delivery, if labor is chosen, the use of neuraxial opioids without local anesthetics will provide analgesia without any decrease in SVR and thus avoid CV effects.[75] This technique can be accomplished with the use of a continuous spinal technique because epidural analgesia typically requires some local anesthetic agent to provide analgesia.[76] Women with uncorrected tetralogy of Fallot, severe PH, and severe hypertrophic cardiomyopathy may be unable to tolerate any decrease in SVR or cardiac preload, so neuraxial blockade should be used with extreme caution.[72] Invasive monitoring of arterial pressure, central venous pressure, and PAP are reserved for women who have poor functional status or who have severe valvular stenosis or other hemodynamically significant lesions.[73] If instituted, invasive hemodynamic monitoring should be continued into the postpartum period because the large intravascular volume shifts may precipitate pulmonary edema following an otherwise uneventful delivery.[40]

Anesthetic options for women undergoing cesarean delivery include neuraxial and general anesthesia. The advantages of regional anesthesia include an attenuation of sympathetic-mediated increases in HR and CO and minimal alteration in hemodynamics when the doses are carefully titrated. It also avoids the abrupt changes in hemodynamics associated with induction of general anesthesia, laryngoscopy, tracheal intubation, and extubation, although these changes can be blunted with suitable pharmacologic agents, such as intravenous opioids or β-blockers.[73]

General anesthesia has the advantage of airway control and the potential to use TEE monitoring for real-time assessment of cardiac function and volume status.[5,26] Care must be taken to avoid situations that will increase PVR, including hypercarbia, hypoxemia, hypothermia, and sympathetic stimulation.[26] Women who are in the highest risk category should be seen ante partum by a cardiac surgeon, and preparation for lifesaving cardiac support (eg, extracorporeal membrane oxygenation or ventricular assist device) should be available during the cesarean delivery in case maternal decompensation occurs.

If general anesthesia is chosen, it is particularly important that an adequate depth of anesthesia be maintained throughout the intraoperative period to avoid tachycardia and hypertension.[5] Large concentrations of volatile anesthetic agents should be avoided, to prevent uterine atony. A high-dose opioid technique is associated with stable hemodynamics, but it can cause fetal respiratory depression. This effect can be minimized with the use of a short-acting opioid, remifentanil, which does cross the placenta, but its effects are short-lived.[5,63] Although standard monitoring according to the American Society of Anesthesiologists (ASA), including noninvasive blood pressure, ECG, and pulse oximetry, is usually adequate for vaginal delivery, cesarean delivery often requires more invasive monitoring for tight hemodynamic control. Most patients require invasive arterial blood pressure monitoring. Central venous and pulmonary artery catheter monitoring is reserved for critically ill patients and for women who are likely to need vasoactive medications.[77] The hemodynamic perturbations of delivery continue into the postpartum period, so monitoring should continue for at least 48 hours in an intensive care unit.[11,63] Cardiac status takes 2 to 6 weeks post partum to gradually return to baseline.[37]An algorithm for the anesthetic care of these patients is presented in Fig. 50.1.

Noncardiac Surgical Procedures During Pregnancy in Women With Cardiac Disease

Nonobstetric operation during pregnancy is one of the few times that the anesthesiologist must care for two patients simultaneously, with sometimes conflicting goals. When the mother has significant cardiac disease, the risks are even greater. Preoperatively, the anesthesiology team should be in close communication with the patient's cardiologist and obstetrician as part of a multidisciplinary perioperative planning team. A multidisciplinary intraoperative team should include the anesthesiologist, primary proceduralist, obstetrician, neonatologists, and two teams of surgeons: one for the mother and another for the baby in case a cesarean delivery is required. It is self-evident that all nonurgent operations should be delayed until after delivery. Furthermore, any patient requiring a procedure should be managed in a specialized

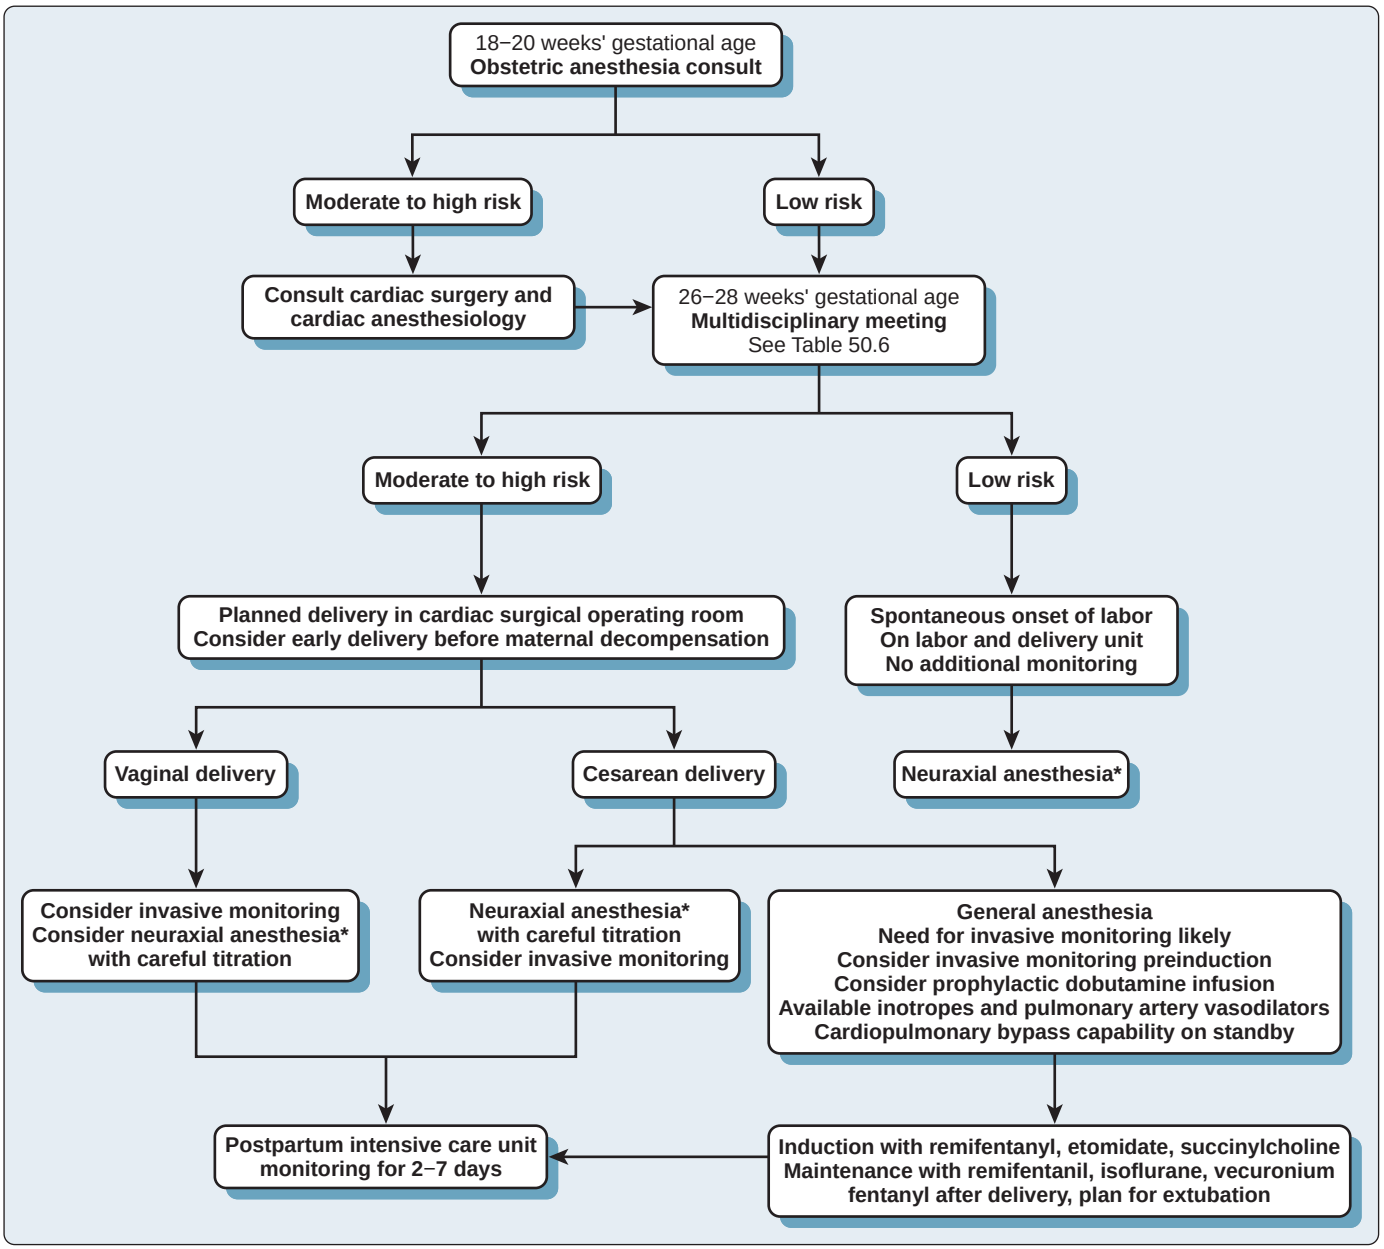

Fig. 50.1 Anesthetic algorithm for the parturient patient with cardiac disease. *Guidelines put forth by the American Society of Regional Anesthesia must be strictly followed.

center with the expertise and capability to care for the mother with cardiac disease and its possible consequences and also to be prepared for urgent delivery and subsequent care of the fetus.

Maternal and Fetal Risks

Between 0.75% and 2% of pregnant woman will require nonobstetric surgical procedures during their pregnancy.[78–80] Appendectomy is the most common operation, with a reported incidence of 1 in 1440 to 1 in 6600 deliveries.[81–83] As the number of pregnant women with heart disease increases, some of these women may also require nonobstetric surgical procedures. In a metaanalysis that included 44 studies of nonobstetric operations during pregnancy from 1966 to 2002, Cohen-Kerem and associates[84] found that perioperative maternal death in healthy women is extremely rare, at 0.006%. The miscarriage rate was 5.8% overall and 10.2% during the first trimester. Third trimester operations were associated with a high rate of preterm delivery.[79] Although it has not been specifically studied, when a pregnant woman with significant cardiac disease requires surgical treatment, both mother and fetus are likely even at a greater risk, the extent of which depends on the specific cardiac disease, its interaction with the hemodynamic changes of pregnancy, and its interaction with the hemodynamic changes caused by the surgical procedure and anesthesia.

Maternal and Fetal Monitoring

Patients with significant cardiac disease require increased monitoring during surgical procedures. This monitoring may include invasive arterial pressure, central venous pressure, or PAP monitoring and TEE, depending on the specific cardiac lesion, operation, and planned anesthetic technique. Patients with poor functional status and operations that involve large fluid shifts require the greatest amount of monitoring. Specific monitoring requirements for different cardiac diseases are found in earlier chapters.

The fetal HR (FHR) should be monitored, if at all possible.[85–87] It is the best way to ensure maintenance of a normal physiologic milieu

for the baby. This is even more important in women with significant cardiac disease because the fetus is at greater risk, given the decreased CO and hypotension leading to uterine hypoperfusion. Monitoring and interpretation should be performed by an obstetrician or someone other than the anesthesiologist, with expertise in FHR interpretation. Regardless of the decision to perform intraoperative FHR monitoring, the FHR and uterine contractions should be monitored before and after the surgical procedure.

Anesthetic Considerations

The anesthetic plan should focus on optimizing the mother's cardiac condition while protecting the developing fetus. A complete discussion of anesthetic considerations for the pregnant woman undergoing nonobstetric surgical procedures is beyond the scope of this chapter. Focused situations with specific considerations for the pregnant woman with cardiac disease are presented.

Organogenesis is complete by week 8, and it is therefore prudent to delay surgical procedures until after this critical period of development. None of the anesthetic agents are known teratogens, and the incidence of congenital defects is not greater following surgical procedures with either general or neuraxial anesthesia.[88] Although the risk of spontaneous abortions in the first and second trimester is increased when mothers undergo surgical procedures, it is not possible to determine which is the cause: the pathophysiologic condition requiring surgical treatment, the surgical procedure itself, or the anesthetic regimen.[80,88,89] The basic principles when anesthetizing the woman are to optimize uteroplacental blood flow by optimizing CO and avoiding hypoxia, hypercarbia, acidosis, and hypotension.

In the healthy parturient patient, uterine blood flow (UBF) is primarily determined by the perfusion pressure, which is directly related to maternal arterial pressure. Conditions that reduce maternal arterial pressure decrease uterine perfusion pressure. These conditions include the following: hypovolemia, which can be relative from sympathetic blockade or actual from hemorrhage; myocardial depressants, such as general anesthetic agents; and mechanical obstruction secondary to aortocaval compression by the gravid uterus. Decreases in UBF from aortocaval compression can be prevented by tilting the mother to the left.

In women with heart disease, uterine perfusion pressure is at risk of being compromised. In low-CO states such as systolic HF or critical AS, the UBF may be compromised by diversion of blood to critical organs. With right-sided HF or PH, the normally low-pressure venous system may become congested so that forward flow to the uterus can be compromised.

An increase in uterine vascular resistance can also decrease UBF. This can occur during anesthesia as a result of catecholamine release or initiation of vasopressors. The most common agents used in healthy parturient patients are phenylephrine and ephedrine. Although earlier studies recommended using a mixed agonist, such as ephedrine, to prevent increased uterine vascular resistance from unopposed α-blockade,[90] later studies indicated that not only is phenylephrine a safe choice, it may be a better choice because ephedrine causes fetal tachycardia that can lead to fetal acidosis.[91,92] The effects of epinephrine and norepinephrine on UBF and outcome have not been fully elucidated. However, the danger of not initiating vasopressor and/or inotropic support in a woman who needs it is great. Therefore, the use of these agents should be instituted as required.

Severe hypoxia and hypercarbia also decrease UBF,[93] whereas even mild hypoxia and hypercarbia directly affect the oxygen tensions and acid-base status of neonatal blood. Supplemental oxygen and end-tidal carbon dioxide monitoring should always be used when sedating this patient population.

The choice of regional or general anesthesia should depend on the type of cardiac disease and the extent of operation. In the patient without heart disease, no evidence indicates that one technique is superior to the other with regard to either maternal or neonatal outcomes.[80,94,95] However, neuraxial techniques may be relatively contraindicated or require very careful titration in some cardiac disease states.

Laparoscopic surgical procedures are safe during pregnancy,[96–98] but patients with cardiac disease may be less able to tolerate the reduced preload or the rise in carbon dioxide partial pressures from insufflation. For healthy patients, the Society of American Gastrointestinal and Endoscopic Surgeons recommends maximizing UBF with left uterine displacement, lowering insufflation pressures to no more than 10 to 15 mm Hg, and monitoring maternal end-tidal carbon dioxide to avoid acidosis.[99] These recommendations help in women with cardiac comorbidities as well.

Glycopyrrolate is commonly given in conjunction with neostigmine for reversal of nondepolarizing neuromuscular agents to prevent anticholinesterase-induced bradycardia or asystole. However, as a quaternary amine, glycopyrrolate does not readily cross the uteroplacental barrier, whereas neostigmine does, and this may lead to iatrogenic fetal bradycardia. Therefore some anesthesiologists prefer to use atropine, which does not cross the placenta. The tachycardic effects of atropine must be considered in women with cardiac disease.

Peripartum Cardiomyopathy

Definition

Although the occurrence of HF in pregnant and postpartum women has been described since the late 1800s, the unique disease entity, peripartum cardiomyopathy (PPCM) (Table 50.5), was first defined in the 1970s by Demakis and Rahimtoola[100] on the basis of three criteria. These criteria are (1) the development of idiopathic life-threatening cardiomyopathy that (2) begins in the last month of pregnancy or within the first 5 months post partum and (3) occurs in patients without recognizable preexisting heart disease.[101] The importance of the timeline provided in the definition was emphasized to exclude other acquired preexisting causes of cardiomyopathy, which may be unmasked earlier in pregnancy (second trimester) in response to CV changes of pregnancy. PPCM is a distinct form of cardiomyopathy resulting from pregnancy, not an exacerbation of underlying idiopathic dilated cardiomyopathy.[102–104]

The Demakis definition was updated, and strict echocardiographic criteria for recognition of LV dysfunction were added by the National Heart, Lung, and Blood Institute and the Office of Rare Diseases (National Institutes of Health) workshop.[105] An LV ejection fraction

TABLE 50.5 Peripartum Cardiomyopathy

Definition	*Echocardiographic Criteria*	*Possible Causes*	*Risk Factors*
Idiopathic	Left ventricular ejection fraction <45% or M-mode fractional shortening <30% or both	Oxidative stress	Multiparity Advanced maternal age Multifetal pregnancy Preeclampsia African American race Prolonged use of tocolysis Family history
No recognizable heart disease	Left ventricular end-diastolic dimension >2.7 cm/m^2	Autoimmunity	
Occurs in the last month of pregnancy or in the first 5 months post partum[a]		Inflammatory conditions	
		Myocarditis	

[a]The Working Group on Peripartum Cardiomyopathy from the Heart Failure Association of the European Society of Cardiology removed time frames from the definition because they believe that they are arbitrary and lead to underdiagnosis.

(LVEF) of less than 0.45 or M-mode fractional shortening of less than 30% (or both) and end-diastolic dimension greater than 2.7 cm/m^2 are required to meet the definition. The Working Group on PPCM from the Heart Failure Association of the European Society of Cardiology redefined PPCM because the investigators believed that the time frames provided in the original definition were arbitrary and led to underdiagnosis.[101] This Working Group defined PPCM as idiopathic cardiomyopathy, manifesting with HF secondary to LV systolic dysfunction toward the end of pregnancy or in the months following delivery, for which no other cause is found and in which LVEF is reduced to less than 45%, but the left ventricle is not always dilated. The Working Group further emphasized that PPCM is a diagnosis of exclusion.

Incidence

PPCM is a relatively rare disease, with an estimated incidence of less than 0.1% of pregnancies,[106] although the incidence varies according to race and geographic region. The actual incidence of PPCM is unknown because most studies have been single-center case series. Estimates of the incidence from case series range from 1 in 1485[107] to 1 in 15,000.[108] The National Hospital Discharge Survey was the first population-based study of PPCM. This survey assessed all births in the United States from 1990 to 2002 and found the incidence of PPCM to be approximately 1 in 3200 (2.5 in 10,000 live births).[109] Therefore, 1000 to 1300 cases occur annually in the United States.[110]

The incidence varies worldwide and is highest in developing countries; the highest incidence of PPCM is in Haiti, with 33 cases in 10,000 (1 in 300) live births, and in South Africa, where 1 case in 1000 live births is reported.[2,111,112] Investigators have speculated that the regional disparities may reflect environmental or genetic factors and different standards of perinatal care.[113] A higher incidence of disease is found among African American woman, even in the United States, who are 3- to 16-fold more likely to be diagnosed with PPCM.[6] No information is available regarding the incidence of PPCM in Europe.[114] A prospective, international, multicenter registry of patients who meet criteria for PPCM is ongoing.[115]

Risk Factors

Risk factors for PPCM include multiparity (parity of four or greater),[102,116,117] advanced maternal age (>30 years old),[117–119] multifetal pregnancy,[119,120] preeclampsia, gestational hypertension,[105,109] HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome,[2] and African American race.[117,121] The prolonged use of tocolysis has also been associated with development of PPCM.[122] Other risk factors include hypertension, diabetes, smoking,[123] and severe anemia.[117] A genetic susceptibility also appears to exist because some cases of PPCM have been found among patients with a family history of dilated cardiomyopathy.[124,125]

Etiology

The pathophysiology of PPCM is not well understood. Several causes have been proposed[126]:

1. Oxidative stress: The most recent hypothesis is that PPCM develops as a result of oxidative stress caused by an imbalance between the production of reactive oxygen species and the biologic system's ability to detoxify them. This oxidative stress enhances activity by the protease cathepsin-D, which leads to increased cleavage of the hormone prolactin, thus resulting in an N-terminal 16-kDa prolactin fragment (also called vasoinhibin), which is a potent antiangiogenic, proapoptotic, and proinflammatory factor. This process leads to massive endothelial damage, capillary dissociation, vasoconstriction, and myocardial dysfunction.[127,128] Consistent with these findings, a novel specific therapeutic approach through inhibition of prolactin secretion by bromocriptine, a dopamine D_2-receptor agonist, prevented the development of PPCM in an animal model of PPCM, and the first human clinical experience yielded promising data for survival and improvement of LV function.[129,130] Multicenter, randomized trials are necessary to confirm these findings and establish bromocriptine's safety profile in pregnancy before broader clinical adoption.[130]
2. Autoimmunity: In a phenomenon called fetal microchimerism, cells from the fetus take up residence in the mother and provoke a cardiotoxic autoimmune component.[131] High titers of autoantibodies against all types of cardiac tissue proteins have been found in most women with PPCM.[132–134] Treatment of PPCM with therapies proven successful in graft versus host disease and organ rejection may be useful.[131]
3. Inflammatory process: Proinflammatory serum markers, such as tumor necrosis factor-α, sFas/Apo1 (a plasma marker of apoptosis), C-reactive protein, interferon-γ, and interleukin-6, have been found to be significantly elevated in women with PPCM.[135,136] This mechanism is supported by the survival benefit observed in a small cohort study of the antiinflammatory agent pentoxifylline in a nonrandomized trial in 58 patients with PPCM.[137]
4. Myocarditis: Myocarditis has been found in the endomyocardial biopsy specimens of the right ventricle of women with PPCM, although the range has been 8.8% to 78% in different studies.[134,138–140] Immunosuppressive drug therapy should be considered when active myocarditis has been confirmed by endomyocardial biopsy.[141]

Clinical Presentation and Diagnosis

Fewer than 10% of cases of PPCM occur at the end of pregnancy,[107] whereas 78% of cases manifest in the first 4 months post partum.[106] The diagnosis of PPCM requires a high index of suspicion because symptoms of PPCM can be confused with the physiologic changes of pregnancy and the early postpartum period. Consequently, women with PPCM generally have a relatively late diagnosis, when they already have NYHA functional class III or IV, which is possibly associated with higher rates of morbidity and death.[2,6,142]

Most patients present with signs and symptoms similar to those of other forms of HF and reflect reduced CO resulting in tissue hypoperfusion and pulmonary edema from congestive HF.[143] These manifestations include dyspnea on exertion, cough, orthopnea, hemoptysis, and paroxysmal nocturnal dyspnea. Additional symptoms include nonspecific fatigue, malaise, palpitations, chest (pleuritic chest pain can be presenting symptoms of pulmonary embolism) and abdominal discomfort (secondary to hepatic congestion), and postural hypotension.[6,102]

On physical examination, signs of HF may be present, including tachycardia, displacement of the apical impulse, presence of an S_3 third heart sound, and evidence of mitral or tricuspid regurgitation. Elevated jugular venous pressure, pulmonary rales, hepatomegaly, and pedal edema may also be present.[2,6,103] Women may have difficulty lying flat.[6]

The differential diagnosis of suspected PPCM includes malignant hypertension, diastolic dysfunction, sepsis, pulmonary embolus, and obstetric complications (eg, preeclampsia, eclampsia, and amniotic fluid embolism).[103]

If PPCM is suspected, a complete blood count, electrolyte determinations, liver function tests, C-reactive protein, arterial blood gases, and troponin levels should be performed.[106] Disease-specific biomarkers include prolactin and factors involved in the prolactin cleavage pathway.[143] Levels of BNP and N-terminal pro-B-type natriuretic peptide can help in confirming the diagnosis.[106,136]

Findings on an ECG may be normal or may show sinus tachycardia and nonspecific ST-segment and T-wave abnormalities, conduction abnormalities such as prolonged PR and QRS intervals, and LV hypertrophy. A chest radiograph often shows cardiomegaly, pulmonary venous congestion, and sometimes pulmonary edema and pleural effusion. An echocardiogram is the key to diagnosis and shows moderate-to-severe LV systolic dysfunction. Doppler evaluation may show moderate-to-severe mitral and tricuspid valve regurgitation and PH.[106,114]

Outcomes and Predictors of Recovery

PPCM is a potentially life-threatening condition,[142] accounting for up to 11% of maternal deaths.[6] It has a highly variable clinical course because rapid progression to end-stage HF may occur within days, and spontaneous and complete recovery may also occur.[102,105] Recovery from PPCM is defined as recovery to an LVEF greater than 50% or improvement by 20%. End-stage HF is seen in 10% to 23% of patients, and recovery to an LVEF greater than 50% is seen in 35% to 50% of patients.[2,144,145]

Several factors have been associated with recovery or nonrecovery. Predictors of recovery include white race, LVEF greater than 30%, LV end-diastolic diameter less than 5.5 cm, and postpartum diagnosis.[146–148] Factors associated with lack of recovery are an LV end-diastolic dimension greater than5.6 cm, LVEF less than 30%, the presence of LV thrombus, and African American race.[126,143,145]

Recovery usually occurs between 2 and 6 months post partum, but it may occur as late as 48 months post partum. Delayed diagnosis, greater NYHA functional class, African American race, LV thrombus, multiparity, and coexisting medical illnesses are associated with delayed recovery.[145,149]

The mortality rate in women with PPCM seems to be decreasing as the treatment for HF has improved. The risk increases with older age, LVEF less than 25%, multiparity, African American ethnicity, and delayed diagnosis.[114] The estimated mortality rate of PPCM in the United States varies significantly in different series, ranging from 0% to 16.5%.[109,126,140,142,145,150]Worldwide, mortality rates range from 1.4% to 32%.[143,151,152] Race, ethnicity, and environmental differences, as well as access to medical care, may be responsible for the varying results in different studies.[153]

Although only a few studies have reported on subsequent pregnancies of women with a history of PPCM, the risk of PPCM in a subsequent pregnancy seems to be elevated, particularly if the LVEF has not recovered to baseline. Almost 50% of such women were reported to have had HF during or following the subsequent pregnancy.[154] In general, the severity of PPCM in a subsequent pregnancy increases.[154,155] Any woman with an LVEF of less than 25% at previous diagnosis or whose LVEF has not normalized should be advised against a subsequent pregnancy (class III recommendation).[9] All patients should be informed that pregnancy can have a negative effect on cardiac function, and development of HF and death may occur.[156]

Management During Pregnancy, Labor and Delivery, and Post Partum

Because of its setting in the peripartum period, PPCM requires a well-coordinated multidisciplinary approach that involves obstetricians, cardiologists, perinatologists, neonatologists, anesthesiologists, and cardiac surgeons to manage a pregnant woman with HF.[6,105,113] Both HF and its treatment in PPCM may result in placental insufficiency, leading to intrauterine fetal death or premature birth.[2] If the patient's condition can be stabilized with medical therapy, continuation of pregnancy to allow for fetal maturity may be possible with close monitoring.[114,143] If the mother's condition deteriorates, however, urgent premature delivery with timely use of corticosteroids for fetal lung maturation should be discussed to rescue both mother and child.[2] Termination of pregnancy often results in improvement of both symptoms and cardiac function and should be considered in patients with worsening symptoms or cardiac function.[114]

The medical management of PPCM is similar to that of other types of HF that focus on reducing preload and afterload and increasing cardiac inotropy (class I recommendation).[9] The treatment varies if the patient is still pregnant or is post partum because the medication safety profiles during pregnancy or lactation must be considered, and medication side effects must be closely monitored and managed.[106] The first aim is to improve symptoms, and the second is to attempt to manage the disease through the administration of targeted therapies.[106] Rapid treatment may be necessary when the patient has pulmonary edema or is hypoxemic. When women with PPCM have hypotension, worsening HF, altered mental status, and increased work of breathing, they should be treated in the hospital.[106] Medications should be continued until LV dysfunction is improved or resolved.[106]

Acute symptomatic management of PPCM should consist of with oxygen and HF medications, mainly β-blockers, afterload-reducing agents such as ACE inhibitors or ARBs, with the addition of loop diuretic agents if necessary.[2,106]

β-Blockers (eg, metoprolol and carvedilol) have been approved for use in PCCM, are considered safe for use during pregnancy, and have been shown to improve survival.[106] These drugs are also crucial for long-term management of systolic dysfunction, if present.[106] β_1-Selective blockers, such as metoprolol or carvedilol, are preferred over nonselective β-blockers, such as propranolol, to avoid the antitocolytic action induced by β_2-receptor blockade.[157] Carvedilol combined with an afterload-reducing agent has been shown effective in PPCM.[105] Newborns born to mothers taking β-blockers are at risk for bradycardia, hypoglycemia, and respiratory depression and these infants should to be monitored for 48 to 72 hours.[6]

ACE inhibitors and ARBs are considered first-line drugs for HF management and have been shown to improve survival.[158–160] These drugs are contraindicated in pregnancy, however, because of their teratogenicity; they may cause oligohydramnios, renal agenesis, and fetal death.[6] These medications are the mainstays of treatment of PPCM after delivery for afterload reduction.[106] They are secreted in breast milk, so breastfeeding must be stopped before commencing therapy.[105] Prenatally, the preferred afterload reduction agent is hydralazine. Patients with more severe cases require intravenous nitroglycerin. Nitroprusside is not recommended because of the potential for cyanide toxicity (see Chapter 11).[113]

Diuretic agents are used to treat symptomatic volume overload, including pulmonary congestion and peripheral edema. Both hydrochlorothiazide and furosemide are safe during pregnancy and lactation. However, the benefit of symptomatic relief must be weighed against the risk of diuretic-induced reduction in intravascular volume that can result in uteroplacental hypoperfusion.[106] For patients taking furosemide, fetal amniotic fluid volume should be measured regularly.[6] Although the potassium-sparing diuretic spironolactone has been used successfully to treat HF, data on its use during pregnancy are insufficient.[106,113]

The use of inotropic agents, such as epinephrine, dobutamine, or milrinone, should be confined to patients severely low CO and those with congestion that persists despite optimal medical therapy with vasodilators and diuretics. The patient should be weaned from these agents as soon as she is hemodynamically stable, adequate organ perfusion is restored, and congestion is reduced.[143]

When inotropes are insufficient to restore CO or in patients who present in cardiogenic shock, temporary circulatory support with an intraaortic balloon pump, extracorporeal membrane oxygenation, or implantation of an LV assist device as a bridge to recovery or even as a bridge to heart transplantation is necessary.[2,143] After clinical and echocardiographic evidence of recovery of cardiac function is observed, weaning from the device may be attempted.[143] Bridging to recovery with an LV assist device has helped to dramatically decrease the percentage of PPCM patients requiring cardiac transplantation (see Chapter 28).[2] However, if attempted weaning from the device is unsuccessful, transplantation should be considered.[143] A large study[161] showed that transplant rejection and graft failure were more likely in patients with PPCM compared with other transplant recipients.

HF[162] and pregnancy[163] are independent risk factors for thromboembolism. Therefore, although the incidence of thromboembolic complications in pregnant women with cardiomyopathy is not known, therapeutic anticoagulation is recommended in patients with PPCM, particularly if the LVEF is less than 35%.[2,6] The administration of heparin or low-molecular-weight heparin during pregnancy and post partum is recommended.[6,164] Warfarin is teratogenic and should

be avoided during pregnancy. Warfarin is considered safe during breastfeeding.[6]

Ventricular arrhythmias have been reported in up to 20% of patients with PPCM. At least one-fourth of deaths in PPCM are presumed to be sudden cardiac deaths caused by malignant ventricular arrhythmias.[135] However, no recommendations exist regarding the need for implantation of an implantable cardioverter-defibrillator for primary prevention. The decision on device implantation is particularly difficult in patients with PPCM because many patients experience an improvement in LV function within the first few months after delivery. Temporary use of a wearable defibrillator should be considered until a final decision is made.[165]

No randomized trials or large cohort studies have addressed the timing and mode of delivery in PPCM or its anesthetic management. It should be a multidisciplinary decision that depends on the clinical status of the mother and the unborn child.[114] A plan for the mode of delivery, type of anesthesia, and need for any invasive hemodynamic monitoring should be identified before the commencement of labor.[6] The use of invasive hemodynamic monitoring before labor and delivery allows for optimization of the hemodynamic status before delivery and for monitoring during and after the delivery.[114,143]

Labor is best accomplished in an institution with experience in managing pregnancies with cardiac disease, and labor should be induced at a time when all necessary medical and surgical teams are present in the hospital.[6] Labor and delivery produce hemodynamic challenges, including increased CO, and blood loss.[143] Women must be carefully monitored during labor, delivery, and the postpartum period. In addition to continuous ECG monitoring, continuous pulse oximetry, and noninvasive blood pressure monitoring, the use of an arterial catheter for continuous blood pressure monitoring and a central venous catheter in anticipation of the need for inotropes and vasopressors should be considered, particularly in women at high-risk for decompensation.[6] In general, medications such as β-blockers should be continued, whereas diuretics and vasodilators should be continued or discontinued on an individual basis. Vaginal delivery is preferred in patients in stable condition. Aggressive pain management is pivotal for controlling HR and SVR.[114,143] Nevertheless, an elective planned cesarean delivery is preferable to better control hemodynamic fluctuations for women who are critically ill and in need of inotropic therapy or mechanical support.[143] Furthermore, a cesarean delivery will be necessary if a preterm delivery is necessary because inducing labor will likely be unsuccessful.

Anesthetic technique must be individualized and depends on an understanding of the physiology of pregnancy and its interaction with the individual patient's pathophysiologic features. Anesthesia during labor and delivery can cause rapid hemodynamic changes, including hypotension from rapid lowering of the SVR, which can be deleterious for the woman with cardiomyopathy.[6] The primary anesthetic goals are avoidance of drug-induced myocardial depression, maintenance of normovolemia, prevention of increased or rapidly decreased ventricular afterload, and blunting of the sympathetic stimulation induced by pain and anxiety.[143] Careful use of general or regional anesthesia can effectively meet these goals.[6] Regional anesthesia may not be possible if the mother is receiving anticoagulation. Furthermore, the use of general anesthesia provides the additional benefit of allowing TEE monitoring. Because alterations in hemodynamic status continue to occur for the first 24 hours after delivery, adequate CV monitoring must be maintained into the postpartum period.[5]

A therapeutic algorithm for patients with acute severe PPCM has been published (Fig. 50.2).[143]

Management During Noncardiac Surgical Procedures

Patients with HF require continuous optimization of cardiac status before, during, and after all surgical procedures. These patients generally do not tolerate any sudden increases or decreases in sympathetic tone leading to increases or decreases in preload and afterload, hypoxia, or hypercarbia that will increase PVR. Patients with severe dysfunction can rapidly decompensate with even small changes in hemodynamic parameters. Anesthetic considerations for patients with HF are discussed in Chapter 28, and anesthetic considerations for pregnant women with other cardiac diseases who are undergoing noncardiac operations are discussed earlier in this chapter. Both require an individualized approach, keeping hemodynamic goals in mind. Pregnant women with HF require even more attention to detail because of the potential for even faster decompensation. Invasive monitoring with an arterial catheter and a CVP catheter for the ability to titrate inotropes and vasopressors rapidly is recommended, particularly in women with severe dysfunction and for procedures with rapid fluid shifts. The use of intraoperative TEE monitoring can be invaluable for early detection of decompensation.

Advanced Cardiac Life Support in the Pregnant Woman

Cardiac arrest in the pregnant woman is challenging to the health care team as they try to resuscitate two patients, the mother and the unborn baby. Maternal cardiac arrest is rare. The 2003 to 2005 Confidential Enquiries into Maternal and Child Health (CEMACH)[166] estimated that cardiac arrest occurs in the United Kingdom in approximately 1 in 20,000 pregnancies. Mhyre and associates[167] estimated that in the United States, between 1998 and 2011, in women hospitalized for delivery, cardiac arrest occurred in 1 in 12,000 admissions, and the most common causes were hemorrhage, HF, amniotic fluid embolism, or sepsis. Because the incidence is rare, most health care professionals will never need to provide advanced cardiac life support (ACLS) to the pregnant women. Furthermore, studies have demonstrated a lack of knowledge among health care providers regarding ACLS for the pregnant woman.[168–170] Cantwell and colleagues[171] identified substandard care in 70% of pregnant women undergoing ACLS for direct deaths (related to an obstetric cause such as preeclampsia) and 55% related to indirect deaths. This lack of knowledge and substandard care led to a worse survival rate in pregnant versus nonpregnant patients.[172]

In 2015, The American Heart Association (AHA) published the most recent ACLS guidelines for pregnant[172] and nonpregnant women.[173] The basic tenets of ACLS are similar between the two groups of patients, with some modifications primarily related to the physiologic and anatomic changes in the pregnant woman. These modifications, however, may mean the difference between a successful and an unsuccessful resuscitation.

In this section, the modifications to ACLS in the pregnant patient and the reasons for the changes are discussed (Table 50.6). These modifications, with practical advice on how to perform them, were published by a group from Toronto,[174] as well as in a consensus statement from the Society for Obstetric Anesthesia and Perinatology.[175]

Activation of Cardiac Arrest Alarm

Most hospitals have a system in place to activate a cardiac arrest alarm, such as "code blue." In addition to the typical resuscitation team, successful resuscitation of the pregnant woman and neonate requires multiple specialty teams that must arrive at the onset of the cardiac arrest. The team includes anesthesiologists, obstetricians, pediatricians or neonatologists, and nurses. Successful resuscitation may require expeditious delivery of the neonate that should be started within 4 minutes of the arrest and completed within 5 minutes (see the later section on perimortem resuscitation).[176] This requires advanced planning and a means of alerting the resuscitation team that a pregnant woman has had a cardiac arrest because the additional personnel (eg, obstetricians, pediatricians, and neonatologists) do not routinely participate in adult resuscitations. This protocol is

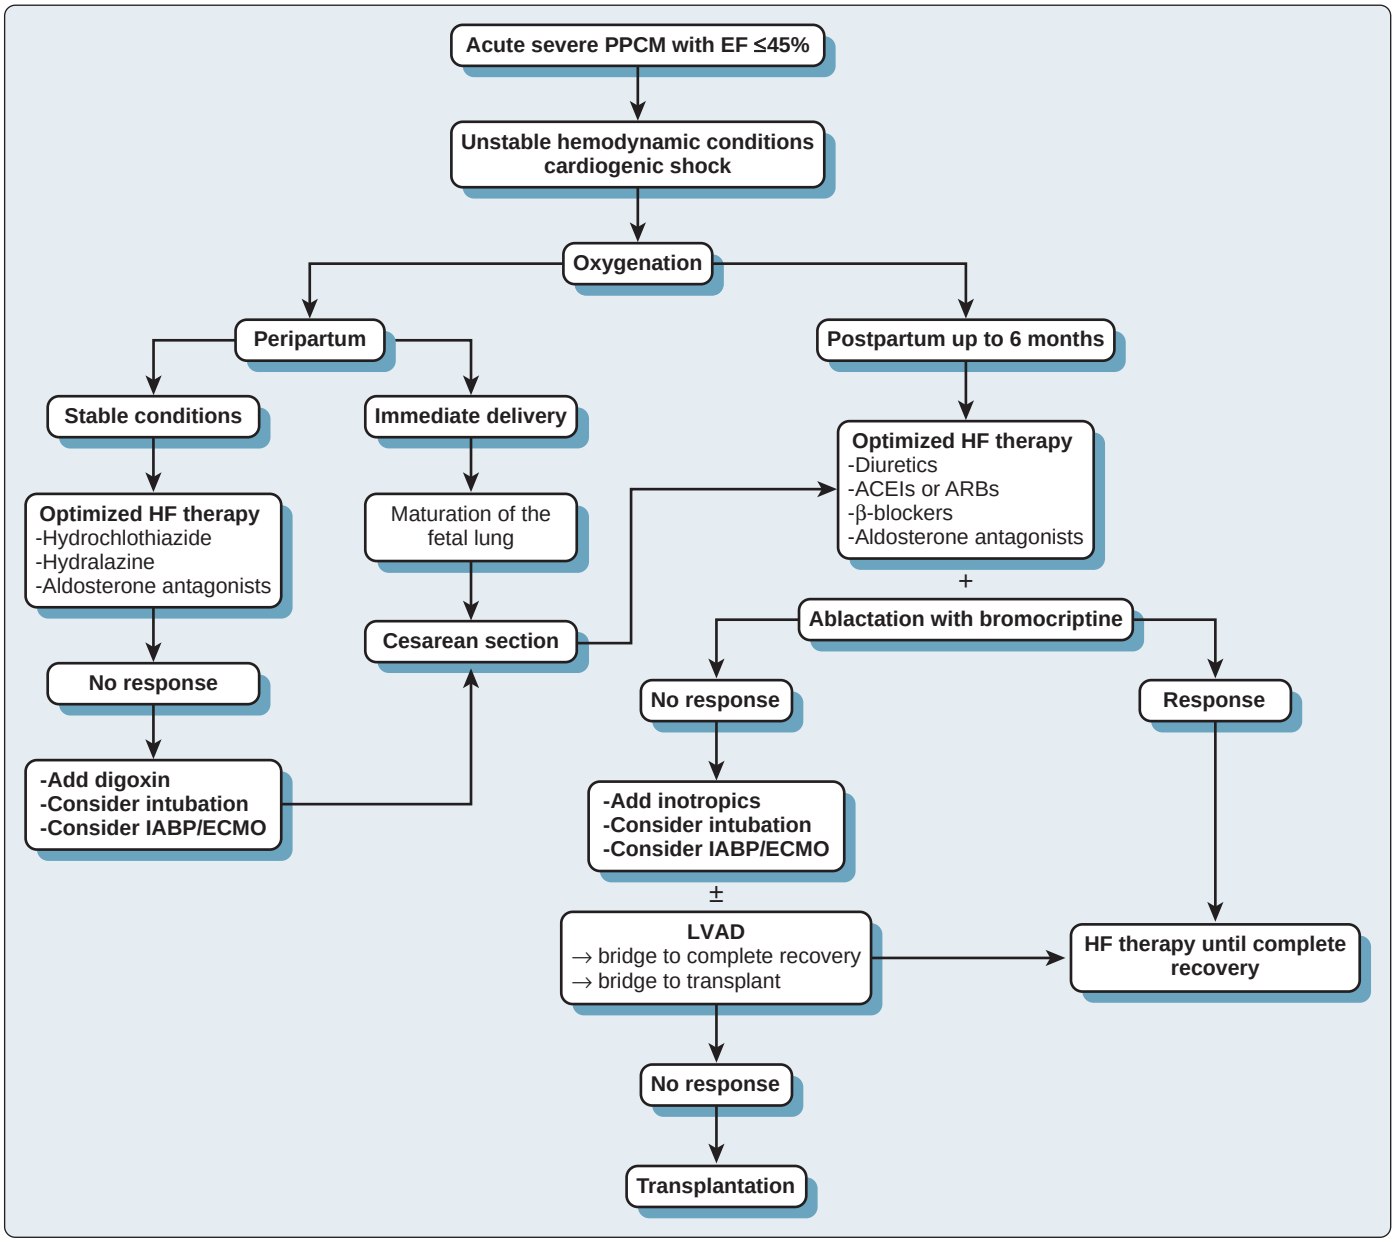

Fig. 50.2 Therapeutic algorithm for acute severe peripartum cardiomyopathy *(PPCM). TABLE 50.6 Modifications to Advanced Cardiac Life Support Protocol for the Pregnant Woman

ACLS Intervention	*Modifications*
Activation of cardiac arrest:	Notifying multiple specialty teams (eg, anesthesiologists, obstetricians, pediatricians or neonatologists, and nurses)
Patient position	Manual left uterine displacement
Chest compressions	Hand placement higher on the sternum than normal
Airway	Difficult intubation, so laryngoscopy by most experienced person.
	Application of cricoid pressure until airway is secured
Defibrillation	Removal of fetal monitor before defibrillation, if possible
Medications	Intravenous access placed above the diaphragm
Cause of cardiac arrest	BEAUCHOPS: bleeding/DIC, embolism, anesthetic complications, uterine atony, cardiac disease, hypertension/preeclampsia, other (differential diagnosis for standard ACLS guideline), placental issues, and sepsis
PMCD	Cesarean delivery begun within 4 minutes of cardiac arrest, and delivery complete by 5 minutes
Cesarean delivery equipment on crash cart	

ACLS, Advanced cardiac life support; *DIC,* disseminated intravascular coagulation; *PMCD,* perimortem cesarean delivery.

particularly important if the cardiac occurs in a location other than the labor floor.

Patient Position

Aortocaval compression in the supine position occurs by the 20th week of pregnancy and even earlier in some pregnant women.[177] In the supine position, inferior vena cava compression decreases venous return and results in reduced CO during chest compressions. In addition, placental blood flow is reduced in the supine position, thus leading to fetal acidosis. Tilting the patient on her left side improves CO and uteroplacental perfusion.[178] However, tilting the patient to the left may reduce the effectiveness of chest compressions, with greater degrees of tilt decreasing the maximum resuscitative force.[179] Left uterine displacement should be performed with either a human wedge[180] (knees of the resuscitator under the patient's right side) or manual displacement of the uterus, rather than full body tilt, to maximize chest compression force. This maneuver should be performed in anyone with an obvious gravid uterus regardless of gestational age.[167]

Chest Compressions

The 2005 AHA guidelines emphasized the requirement for high-quality chest compressions that included pushing hard and fast at a rate of 100/minute.[181] In the updated guidelines in 2010, high-quality chest compressions were reemphasized, and the sequence of cardiopulmonary resuscitation was changed from starting with rescue breaths in the traditional airway-breathing-circulation (ABC) sequence to starting with chest compressions followed by airway and breathing (CAB).[173] The same applies to the pregnant woman, except that hand placement for chest compressions should be slightly higher on the sternum than normal to account for cephalad movement of the diaphragm from the gravid uterus.[173]

Airway

Anatomic changes to the airway, including laryngeal and pharyngeal edema, can make ventilation and tracheal intubation more difficult. Decreases in functional residual capacity in conjunction with increases in CO, metabolic rate, and oxygen consumption lead to the development of arterial hypoxemia at a faster rate than in the nonpregnant woman.[182] In addition, a decrease in gastric emptying along with a decrease in lower esophageal sphincter tone places the pregnant woman at risk for pulmonary aspiration.[183] Therefore tracheal intubation to maximize oxygen delivery should occur as soon as possible following cardiac arrest and should be performed by the most experienced anesthesiologist. Moreover, a smaller than usual tracheal tube should be used. Although the efficacy of applying cricoid pressure to reduce pulmonary aspiration is controversial,[184,185] cricoid pressure should be applied until tracheal intubation is confirmed, to reduce the risk of pulmonary aspiration. If applying cricoid pressure makes ventilation or tracheal intubation more difficult, however, this pressure should be released.[175,186]

Defibrillation

Nanson and associates[187] measured transthoracic impedance in pregnant women at term and again 6 to 8 weeks after delivery. These investigators found that transthoracic impedance was unchanged. Therefore voltage administered for defibrillation in the pregnant woman should be the same as for the nonpregnant patient.[172] A theoretical concern is that electrical current could induce burns in the fetus or mother if FHR monitors are being used. This is highly unlikely because the electrical current is administered to the maternal thorax. However, it is prudent to remove any fetal monitors before defibrillation if possible.[172] Additionally, a theoretical risk of inducing fetal arrhythmias exists, but the risk is small, and defibrillation should not be delayed or avoided for this reason.[188]

Medications

Aortocaval compression could increase the time for medication to reach the heart or completely impede medications from reaching the heart. Therefore intravenous access should be placed above the diaphragm. Although intravascular volume and volume of distribution increase and protein binding decreases during pregnancy, the timing and doses of medications during ACLS should not be altered from those in the nonpregnant woman.[172]

Etiology of Cardiac Arrest

The maternal mortality rate has been increasing in the United States.[189] Cardiac arrest has direct (obstetric-related) and indirect (not obstetric-related) causes. The nonobstetric causes are not different from those in the nonpregnant woman. The CEMACH found that cardiac disease is the most common indirect cause of cardiac arrest (2.27 in 100,000 pregnancies).[166] This may not be surprising because maternal age is increasing. In addition, women with CHD are surviving into adulthood and becoming pregnant, and they, too, are at greater risk for cardiac arrest.[190]

The AHA has suggested the mnemonic BEAUCHOPS to help remember the possible causes of maternal cardiac arrest. The mnemonic stands for bleeding/disseminated intravascular coagulation, embolism, anesthetic complications, uterine atony, cardiac disease, hypertension/preeclampsia, other (differential diagnosis for standard ACLS guidelines), placental issues, and sepsis.[172] Reversible and treatable causes of cardiac arrest should be sought and include magnesium sulfate toxicity, amniotic fluid embolism, hemorrhage, and anesthetic complications, such as local anesthetic toxicity and total spinal. Magnesium sulfate toxicity should be treated by stopping the infusion and administering calcium.[191] Amniotic fluid embolism had a high fatality rate, but with aggressive treatment survival has increased.[192] Hemorrhage requires aggressive replacement of blood and blood products. Local anesthetic toxicity should be treated with intravenous fat emulsion (Intralipid, Baxter Healthcare, Deerfield, Ill), and total spinal anesthesia should be treated with tracheal intubation and management of hemodynamic instability.

Perimortem Cesarean Delivery

Perimortem cesarean delivery (PMCD) refers to cesarean delivery that is performed after the start of resuscitation and may increase survival for both mother and baby. In 1986, Katz and associates,[176] primarily based on their understanding of the physiology of pregnancy and partially based on existing case reports, recommended that if no return of spontaneous circulation occurs within 4 minutes, cesarean delivery should commence and delivery should occur within 5 minutes. Physiologically, these investigators believed that cardiac compressions are ineffective because of aortocaval compression leading to decreased CO. Katz and colleagues[193] performed a follow-up study in 2005 and reaffirmed the 4-minute rule based on a review of 38 cases in which most mothers and neonates survived when cesarean delivery occurred within this time frame. The AHA included this recommendation in their guidelines.[172] Einav and associates[194] reviewed the literature in 2012 regarding PMCD and found 94 cases of maternal cardiac arrest. These investigators found that most neonates survived if the cesarean delivery occurred within 10 or even 15 minutes of maternal cardiac arrest. Moreover, PMCD was beneficial to the mother in 32% of cases, and none were harmed by the procedure. Furthermore, Einav and colleagues[194] found that performing a cesarean delivery within 4 minutes is challenging. Lipman and colleagues[195] confirmed this finding in a simulation study in which they demonstrated that delivery within 4 minutes cannot be accomplished if the patient is taken from a delivery room to the operating room. Therefore, the recommendation is to perform a PMCD at the location of the cardiac arrest and not attempt to move the patient to the operating room.[175,195] However, even if the decision is made to perform the cesarean delivery in the

room, equipment to perform an emergency cesarean delivery must be present in the delivery room, and some clinicians recommend having equipment for an emergency cesarean delivery present on the labor and delivery resuscitation cart.[196]

51 Critical Care Medicine in the Operating Room

TORIN SHEAR, MD | JEFFREY KATZ, MD | STEVEN B. GREENBERG, MD | JEFFERY S. VENDER, MD

KEY POINTS

1. There exists a significant increase in morbidity associated with perioperative complications.
2. Identifying risk factors associated with intensive care unit (ICU) admission in noncardiac surgical patients may help modify these patients' overall perioperative risk.
3. Patients scheduled for ambulatory surgery who have significant risk factors associated with increased morbidity and mortality may require more in-depth perioperative planning.
4. Patients with coronary stents undergoing noncardiac surgery require coordination between perioperative team members.
5. The most common etiology of perioperative stroke is embolic in nature.
6. Identifying patient risk factors for perioperative stroke may aid in reducing the overall perioperative stroke risk.
7. The prompt recognition of acute coronary syndrome in the perioperative period is paramount because therapy should begin immediately to prevent myocardial injury.
8. The mainstays of therapy for perioperative heart failure are diuresis and afterload reduction.
9. In the setting of valvular disease, anesthetic agents should be chosen carefully with hemodynamic goals in mind.
10. Respiratory failure is a heterogeneous syndrome with two major types: hypoxemia and hypercarbia. Each is associated with unique pathophysiology and requires treatment of the underlying disease leading to respiratory failure.
11. A key concept of mechanical ventilation in acute respiratory distress syndrome (ARDS) is avoidance of ventilator-induced lung injury by volutrauma and barotrauma.
12. Noninvasive ventilation should be considered in patients with respiratory failure from COPD or heart failure.
13. The new oral anticoagulants include dabigatran, apixaban, rivaroxaban, and edoxaban. Dabigatran is a direct thrombin inhibitor that can be reversed with idarucizumab (Praxbind) for noncardiac surgery. The other three drugs are factor Xa inhibitors that do not have specific reversal agents at present.
14. Massive hemorrhage remains a common clinical challenge for anesthesiologists. Massive transfusion protocols help facilitate patient care between the bedside physicians and nurses with blood bank and laboratory services.
15. The cornerstone of sepsis therapy is aggressive resuscitation, administration of antibiotics in a timely fashion, and source control of anatomically based infections.

Approximately 230 million surgical procedures are performed worldwide each year.[1] Perioperative mortality is relatively low, but this may be a misleading statistic of surgical safety because postoperative complications continue to be significant.[2] In fact, elderly (>70 years old) high-risk patients may have a postoperative complication rate as high as 50%.[1,3] This subset of patients accounts for only 13% of all surgical procedures but more than 80% of postoperative deaths.[2,4] The management of these high-risk patients presents a unique challenge for the perioperative physician.

This chapter will discuss the perioperative management of critically ill cardiac patients for noncardiac surgery. Given the wide scope of the topic, the authors have addressed several key perioperative complications and issues in the setting of noncardiac surgery and highlight the management of such events. A broad discussion of patient triage is provided initially, followed by a discussion of key diseases presented by organ system.

Perioperative Triage

Although critical care admissions are routine for cardiac surgical patients, they are rare for the noncardiac surgical population. It is vital to determine which patients are appropriate for various perioperative care areas—outpatient surgery, routine inpatient care, or critical care services. Triage can be defined as the process of deciding which patients should be treated first based on degree of sickness or severity of injury.[5] In the present value-based health care system, placing the "right" patients in the "right" location is a difficult but crucial task.

Ambulatory Surgery

A challenging triage decision is identifying which surgical patients are best cared for in inpatient hospital-based versus ambulatory settings. Adequate preoperative patient assessment is important in

determining the appropriate surgical environment. Criteria associated with increased hospital admission after outpatient surgery include age 65 years or older, cardiac diagnoses, peripheral vascular disease (PVD), surgery lasting more than 2 hours, cerebrovascular disease, malignancy, human immunodeficiency virus (HIV), and general anesthesia.[6] However, patients with stable coronary artery disease (CAD) may not be at higher risk for perioperative complications following ambulatory surgery. Nevertheless, a recent National Surgical Quality Improvement Program (NSQIP) database evaluating 5 years of common day case–eligible surgical procedures (244,397 procedures) suggests the following risk factors are associated with an increase in morbidity and mortality: previous cardiac surgical intervention (percutaneous coronary intervention or cardiac surgery), overweight body mass index, obese body mass index, chronic obstructive pulmonary disease (COPD), history of transient ischemic attack/stroke, hypertension, and prolonged surgical time.[7] Patients with cardiac pacemakers or implantable cardioverter-defibrillators can be evaluated for ambulatory surgical cases. However, it is important to determine the type and function of these devices before proceeding with surgery. Similarly, it is appropriate to develop a definitive perioperative plan for the management of these devices in terms of electromagnetic interference and follow-up[8,9] (see Chapters 5 and 45).

Critical Care Services

Roughly 8% of patients undergoing inpatient noncardiac surgery require critical care services.[4] Among approximately 90,000 surgical patients admitted to intensive care units (ICUs) analyzed in an Austrian database, chronic heart failure (HF) and cardiac disease were significant risk factors that led to an increase in mortality.[2] General factors that may contribute to perioperative morbidity and subsequent ICU admissions can be divided into four major groups: (1) significant comorbidities (eg, cardiac disease), (2) increasing age, (3) type and urgency of surgery, and (4) physiologic disturbances that occur during the operation.

Triaging healthy or moribund patients away from critical care services (excluding palliative services and services to those who are brain dead) seems to be relatively straightforward. However, health care providers are challenged by a scarcity of ICU beds and an inherent cost in determining which patients will truly benefit from intensive care.[4,5,10] Improving preoperative evidence-based strategies to identify which patients are at highest risk for postoperative complications may aid in determining patient need. Similarly, reducing hospital variability in managing these patients once they develop postoperative complications is also paramount to reducing morbidity and mortality.[2]

The Society of Critical Care Medicine (SCCM) supports the notion that ICU beds should be given to those patients with a reasonable chance of significant recovery.[11] Before 2012, many studies were published regarding scoring systems for evaluating ICU mortality. However, no large trials addressed the need for an evaluative ICU triage scoring method. Sprung and colleagues performed the first large prospective study (Eldicus) in 11 ICUs among eight European countries developing a triage procedure for the use of critical care services.[12] Factors favoring ICU admission are listed in Table 51.1. Approximately 30% of patients accepted for ICU services had cardiac diseases.[12] The heart was the second most frequent organ involved (second to the lungs) in ICU admissions. The authors further suggested that mortality was reduced with ICU admission, especially in patients with more severe acute illness.[12]

The second question explored in an expansive observational study was the potential benefit of ICU admission for the elderly.[13] Elderly patients are more likely to be rejected for admission to the ICU. Yet analysis suggests a greater mortality reduction in elderly patients admitted to the ICU when compared with younger patients. Based on these findings, the authors recommended intensivists change triage decisions regarding the elderly and consider accepting even those elderly who appear "well."[13]

TABLE 51.1 Factors Associated With Triage Decisions

Factors Associated With ICU Admission	*Factors Associated With Increased Hospital Admission After Outpatient Surgery*	*Factor Associated With Increased Risk of Morbidity/Mortality After Day Case Eligible Procedures*
Surgical patients (vs medical patients)	Age > 65	Previous cardiac surgical intervention (percutaneous coronary intervention or cardiac surgery)
Absence of comorbidities	Cardiac diagnoses	Overweight/obese BMI
Presence of hematologic malignancy	Peripheral vascular disease	COPD
Acute clinical condition	Malignancy	History of TIA/CVA
Need for active intensive care therapies	HIV	Hypertension
Trauma	General anesthesia	Prolonged surgical time
Vascular involvement	Surgery > 2 hours	
Hepatic Involvement		
Acute severity of illness (APS II)		
Lowest surgical Apgar score		

Data from references 6, 7, 12, 14.

Another large retrospective study investigated the utility of the surgical Apgar score (SAS) in determining ICU admission after major abdominal surgery.[14] This scoring system assigns numbers to ranges of estimated blood loss, lowest mean arterial pressure (MAP), and lowest heart rate (HR). After multivariate adjustments, a strong correlation between lowest SAS and decision for ICU admission was noted (odds ratio [OR], 14.41; confidence interval [CI], 95%; 6.-88-30.19; $P < 0.001$). This study suggested that intraoperative hemodynamics and blood loss do indeed influence ICU triage.[14]

Triaging Patients With Coronary Stents and Noncardiac Surgery

Between 5% and 20% of patients with coronary stents may undergo surgical procedures within 2 years following PCI.[15] One of the largest observational studies to date reported an approximately 23% rate of noncardiac surgery 1 year following PCI.[16] Multiple guidelines report that elective surgery should be delayed for at least 4 to 6 weeks after bare metal stent (BMS) placement and 6 to 12 months after drug-eluting stent (DES) placement, depending on the type of stent.[15] The major challenge is determining the risk of perioperative surgical hemorrhage versus dual antiplatelet therapy (DAPT) interruption and its relation to subsequent coronary stent thrombosis (see Chapters 3, 43, and 44).

A safe time period for antiplatelet therapy interruption has yet to be clearly defined. One study suggested that the incidence of coronary stent thrombosis seems to stabilize at approximately 6 months after DES or BMS placement even in the presence of intraoperative cessation of DAPT.[16] However, the three strongest risk factors for a coronary event were recent MI, high cardiovascular (CV) risk and nonelective surgery.[16] Still, the continuation of aspirin is often recommended throughout the perioperative period. In the absence of guidelines supported by strong evidence, it may be important for the care team (primary care doctor, cardiologist, perioperative physicians) to collaborate and develop a definitive perioperative plan regarding continuation of DAPT, type and timing of stent placement, and disposition.[15] Risk factors such as those mentioned earlier may lead the perioperative team to suggest hospital-based surgery with the potential for an overnight stay. Noncardiac surgery that is required in the setting of recent stent placement may be best performed where a 24-hour interventional cardiologist is present and can institute emergent PCI as necessary.[17]

Neurologic System

Perioperative Cerebrovascular Accident

Cerebrovascular accident (CVA) is one of the most significant perioperative complications. The incidence of perioperative CVA in the general surgical population depends on the type of procedure and associated perioperative risk factors but remains low at approximately less than 0.7%.[18] However, CVA is responsible for a substantial increase in long-term disability, length of ICU and hospital stay, and mortality (18%–26%).[18] The etiology is primarily ischemic or embolic. Noncardiac surgery induces a hypercoagulable state. Trauma to tissues enhances formation of thrombus and promotes inflammation. Studies suggest that the perioperative period is marked by decreased levels of tissue plasminogen activator (tPA), increased fibrinogen degradation products, increased thrombin-antithrombin complex, and increased D-dimer. These prothrombotic changes coupled with dehydration, bed rest, general anesthesia, and cessation of anticoagulants increase the risk for postoperative CVA.[19,20]

Embolic perioperative strokes are far more common than those related to hypoperfusion.[21] The majority of embolic perioperative CVAs occur after the second postoperative day and are typically related to the development of atrial fibrillation (AF) or myocardial ischemia. New-onset AF occurs or is present approximately 30% of the time with perioperative stroke.[22]

Perioperative CVA risk factors can be classified as preoperative, intraoperative, and postoperative.[18–20] Common perioperative risk factors are listed in Table 51.2. Modifiable risk factors may be addressed in the preoperative period to reduce morbidity and mortality.[19]

Preventative strategies for perioperative CVA are not well defined. Decreasing surgical time may reduce risk for CVA, but this may be difficult to modify. Patients with symptomatic carotid artery stenosis may benefit from carotid revascularization before undergoing major surgery. However, at least one study of 2000 high-risk patients undergoing noncardiac surgery suggested no association between carotid artery stenosis and perioperative stroke.[23] Poor systolic ejection fraction (EF) may lead to an increased risk in perioperative stroke presumably caused by intracardiac thrombus and atherosclerotic disease. If indicated, transthoracic echocardiography (TTE) or transesophageal echocardiography (TEE) may be considered preoperatively to identify intracardiac clots and atherosclerosis, which may increase the risk of an embolic stroke. Preliminary studies suggest a small reduction in perioperative stroke risk with perioperative β-blockers, statins, and glycemic control.[19,20]

TABLE 51.2 Perioperative Risk Factors for Cerebrovascular Accident (CVA)

Preoperative	*Intraoperative*	*Postoperative*
Patient age > 70	Surgery type	Heart failure
Female sex	Type of anesthesia (general vs local)	Low ejection fraction
History of CVA/TIA	Duration of surgery	Myocardial infarction
History of symptomatic carotid artery stenosis	Manipulation of proximal Aortic lesions	Arrhythmias
Atherosclerosis of the ascending aorta	Arrhythmias	Dehydration
History of hypertension	Hyperglycemia	Blood Loss
DM	Hypotension	Hyperglycemia
Creatinine > 2 mg/dl	Hypertension	
History of cardiac disease		
Peripheral vascular disease		
Ejection fraction < 40%		
Smoking		

Data from Macellari F, Paciaroni M, Agnelli G, Caso V. Perioperative stroke risk in nonvascular surgery. *Cerebrovasc Dis.* 2012; 34:175–181; Selim M. Perioperative stroke. *N Engl J Med.* 2007; 356:706–713; and Szeder V, Torbey MT. Prevention and treatment of perioperative stroke. *Neurologist.* 2008; 14:30–36.

Identifying the appropriate timing of elective noncardiac surgery in patients with a prior stroke is important. A large database study (over 400,000 noncardiac surgeries) out of Denmark suggested that a prior stroke is associated with a 1.8-fold increased risk of mortality in patients undergoing noncardiac surgery.[24] More important, this study suggested a very high risk of adverse outcomes in those patients undergoing noncardiac surgery less than 3 months after a stroke. This risk stabilized at approximately 9 months.[24] The risk to patients with prior stroke was similar in those undergoing low- and intermediate-risk surgery when compared with high-risk surgery. Although this study has yet to be replicated in other countries, the perioperative care team should consider delaying elective noncardiac surgery in patients with recent stroke when feasible.[24]

Perioperative anticoagulation should be continued whenever the risk of bleeding is deemed low by the surgical team. Cessation of anticoagulation may result in an increased risk of perioperative CVA.[25] Discontinuing aspirin is likely to exacerbate the already hypercoagulable state of surgery.[25] Studies involving patients undergoing carotid endarterectomies (CEAs) suggested that perioperative continuation of aspirin resulted in a reduction in stroke risk.[26] The 2012 American College of Chest Physicians (ACCP) guidelines suggest continuing aspirin in all perioperative situations except for those with very low cardiac risk or in situations where even minor bleeding may be catastrophic.[27] However, this is a decision best made by the care team in consideration of patient and procedure specific risks and benefits.

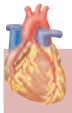
Other anticoagulants such as warfarin and clopidogrel are often stopped several days before surgery. However, cessation of these medications should be based on each unique clinical situation. For instance, one recent study suggested that patients with AF who discontinued warfarin before endoscopy procedures had an approximate threefold increased risk of stroke within 30 days of the procedure.[20] Bridging anticoagulation with heparin or low-molecular-weight heparin (LMWH) may be considered in those patients at high perioperative risk of stroke and where hemorrhage is also a concern.[19,20] If oral anticoagulants must be held prior to surgery, it is prudent for the managing service to restart these drugs as soon as appropriate in the postoperative period.

Currently available therapies for perioperative CVA are sparse. Recent guidelines suggest that early diagnosis and management in a stroke unit with general supportive care (eg, airway protection and mechanical ventilation, if necessary, and avoiding further cerebral damage) are paramount.[21] Administration of intravenous tPA is a proven therapy for ischemic CVA, but relatively contraindicated after major surgery because of the high risk of bleeding.[21,25] Still, the 2013 AHA guidelines recommend against excluding all surgical patients from consideration.[28] Instead, each case should be evaluated by the perioperative team and if possible an expert in the field of CVA. Other modalities such as intraarterial thrombolysis and endovascular mechanical clot disruption may be viable alternatives, with appropriate consultation, for those who have undergone recent major noncardiac surgery. However, two recent trials showed no benefit with these modalities when compared with systemic thrombolysis[29,30] (Box 51.1). Further research may help identify surgical patient populations in which these techniques may be most efficacious.

Cardiovascular System

Cardiac issues remain a significant contributor to perioperative morbidity and mortality.[2] The intraoperative and postoperative management of cardiac complications in noncardiac surgery with specific focus on CAD, HF, valvular disease, and arrhythmias is discussed in Chapters 43 to 51.

Cardiac complications may arise from structural disease of the heart involving coronary arteries, valves, myocardium, or the conduction system. Patients with underlying cardiac disease may require advanced monitoring throughout the perioperative period.[31–34] TEE may serve as an important monitor in the operating room to evaluate cardiac function and fluid status.[35] Smaller "mini-TEE" probes have been described for continuous perioperative monitoring both in the



BOX 51.1 PREVENTATIVE AND THERAPEUTIC STRATEGIES IN CEREBROVASCULAR ACCIDENT (CVA)

Preventative

- Decrease surgical time
- Carotid artery revascularization in symptomatic patient???
- Beta blockers
- Statins
- Glycemic control
- Continuation of anticoagulants when safe
- Consider delaying elective surgery for > 9 months after CVA

Therapeutic

- IV TPA: higher risk of bleeding
- Supportive care: intubation for airway protection and mechanical ventilation
- Intraarterial thrombolysis: questionable efficacy
- Endovascular mechanical clot disruption: questionable efficacy

Data from references 19, 20, 23, 24.

operating room and ICU[36,37] (see Chapters 15 and 46). An understanding of common cardiac diseases will help perioperative clinicians gauge the level of care (monitoring and otherwise) that is appropriate for each unique scenario. For all surgical patients, postoperative disposition may depend on the cardiopulmonary status of the patient, as well as the need for advanced monitoring or critical care.

Acute Coronary Syndrome

Patients with or at risk for CAD present significant challenges to anesthesiologists in the perioperative period. As many as 5% of patients undergoing noncardiac surgery may suffer cardiac complications.[38] Risk factors include a history of ischemic heart disease, HF, stroke, diabetes mellitus, or renal insufficiency.[38] Preoperative risk stratification is discussed in Chapters 1, 43, 44, and 51). Perioperative acute coronary events may range from myocardial ischemia or myocardial injury with and without electrocardiogram (ECG) changes. Myocardial infarction (MI) can be universally defined as an elevation of cardiac biomarkers such as troponin, ECG changes, new regional wall motion abnormalities (RWMAs) seen on echocardiography, or coronary catheterization findings consistent with acute blockages.[39]

The perioperative management of acute coronary syndrome (ACS) or unstable angina presents a unique challenge as patients under anesthesia or those sedated postoperatively may not present with the same signs and symptoms often seen in nonoperative patients. In fact, one large study found that 65% of patients with perioperative MI did not reveal symptoms.[40] In addition, those patients who are diabetic, elderly, or female may present with atypical symptoms or even "silent" MI.[41,42]

The diagnosis is thus often confirmed only when clinical suspicion leads to further laboratory testing or investigation. When patients do complain of symptoms or clinical suspicion exists, clinicians should obtain a 12-lead ECG and serial cardiac biomarkers (troponin, creatine kinase–MB). Cardiology consultation for risk stratification and further testing may be warranted.

The management of ACS in nonoperative patients is well defined, and clinical care pathways are in place to improve patient outcome.[43] Care pathways for the perioperative patient are not well studied. Unique concerns such as bleeding risk, surgical stressors, and perioperative physiologic changes make therapy protocols challenging. Management must be considered in context for each patient and the relative risk/benefit of therapies applied uniquely. Potential therapies are presented broadly in later sections, but these may not be applicable in all situations.

BOX 51.2 MEDICAL THERAPY IN ACUTE CORONARY SYNDROME

- Oxygen to maintain normoxia
- Aspirin 162-325 mg
- $P2Y_{12}$ antiplatelet therapy
- Systemic anticoagulation (if no contraindication)
- Nitroglycerin for pain (if no contraindication)
- Opioid analgesics as needed
- Beta-blockers if stable
- Statin therapy as soon as possible

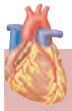
Patients suffering from ACS perioperatively must first be clinically stabilized. Therapies to augment cardiac output (CO) may be needed (Box 51.2). Administration of β-adrenergic agonists (eg, dobutamine [2.5–5 μg/kg/min] or epinephrine [1–2 μg/min]) can be effective. Mechanical augmentation with devices such as intraaortic balloon pump may be considered in severe cases. Arrhythmias may occur and should be managed according to known treatment modalities. Prophylactic lidocaine is not indicated.[42]

Medical therapy with aspirin (162–325 mg) should be initiated if not contraindicated. Additional antiplatelet therapy with a P_2Y_{12} receptor blocker is indicated in ACS, but may not be safe in the perioperative period.[42] In patients with non-ST elevation infarctions, systemic anticoagulation (ie, heparin infusion) may be indicated, but in the perioperative setting the risk of surgical bleeding must be weighed against the risk of advancing ACS. Oxygen should be administered to all hypoxemic patients in concentrations needed to achieve normoxia. There are no data to support the use of oxygen in patients with normal oxygen saturation. Although controversial, some have proposed a harmful effect of hyperoxia owing to direct coronary vasoconstriction.[44–46] Nitroglycerin may be administered to patients with angina symptoms but should be avoided in patients with severe aortic stenosis, RV infarctions, hypotension, or a history of phosphodiesterase inhibitor use in the last 24 hours.[47] Caution should also be used with this medication in patients under neuraxial anesthesia because the combination could precipitate hypotension. Pain control with opioid analgesics may be considered; however, newer evidence suggests that morphine may be detrimental in patients with ACS.[48] Proposed mechanisms include a morphine induced impaired absorption/effectiveness of some antiplatelet therapies.[49] Statin therapy is indicated as soon as possible, because several studies support improved patient outcomes with statin therapy (specifically atorvastatin, 80 mg).[42,50,51] In addition, laboratory evaluation of lipid levels is recommended before discharge.

β-Blocker therapy is perhaps the most controversial perioperative cardiac therapy. Although several studies have shown improved cardiac morbidity and mortality with the administration of perioperative β-blockers, concern for increased stroke risk and all-cause mortality was noted.[40,52] Current guidelines, recommend patients on chronic β-blocker therapy continue this perioperatively.[9] In the setting of perioperative ACS, β-blocker therapy may decrease demand ischemia by improving oxygen supply and demand imbalance and is indicated in stable patients with ACS.[42] The use of β-blockers in unstable patients or patients with acute cocaine intoxication should be cautioned[53,54] (see Chapters 11, 20, 43, and 51).

Angiotensin converting enzyme (ACE) inhibitor therapy should be considered in ACS once patients are stabilized. Indications include all patients with left ventricular ejection fraction (LVEF) of less than 40%, hypertension, diabetes mellitus, or stable chronic kidney disease. Angiotensin receptor blockers may be substituted in patients with HF with an LVEF less than 40% or significant kidney dysfunction (creatinine > 2.5mg/dL for men, > 2.0 mg/dL for women).[42]

The optimum hemoglobin level in patients with perioperative MI is not known. Several studies have evaluated transfusion thresholds in ACS patients, bleeding patients, and critically ill patients.[55,56,57] Routine



BOX 51.3 CARDIAC CONSULTATION TO AID IN RISK STRATIFICATION AND MANAGEMENT IN STEMI AND NSTEMI PATIENTS

- Patients with atherosclerotic heart disease or cerebrovascular disease presenting for noncardiac surgery require extensive communication and collaboration with primary care doctors, cardiologists, and surgeons.
- This communication should be present throughout the perioperative period.
- Presence of coronary stents, use of anticoagulants, and perioperative myocardial ischemia and infarction are examples of scenarios in which such a "team" approach is absolutely essential for good outcome.

red blood cell transfusion in stable, nonbleeding patients is not recommended when the hemoglobin is above 8 g/dL[42] (see Chapters 34, 35, and 51).

More aggressive interventional therapy with cardiac catheterization or fibrinolytics is dependent on the type of myocardial injury and risk of surgical bleeding. ST-elevation myocardial infarctions (STEMIs) present a high mortality if left untreated. In the nonsurgical setting, patient outcome is clearly related to time to reperfusion and a "door to reperfusion time" of less than 90 minutes is recommended.[58] The mainstays of reperfusion therapy include cardiac catheterization and angioplasty/stent placement or fibrinolytic therapy. Multiple studies have shown an improved survival, less bleeding complications, and reduced recurrent MI with catheterization.[59] Both present significant concerns in the perioperative period due to an increased risk of bleeding (see Chapters 3, 20, and 51).

Fibrinolytic therapy is often reserved for centers without percutaneous coronary intervention (PCI) capabilities. It is recommended when symptom onset is less than 12 hours before presentation and PCI would not be available within 120 minutes.[58] However, in the perioperative setting, fibrinolytics will almost universally be contraindicated because of bleeding risk. PCI may be better suited for the treatment of perioperative STEMI. This is not without risk, however, because angioplasty or stent placement often requires dual antiplatelet therapy and anticoagulation. Finally, emergent coronary artery bypass graft (CABG) surgery is an option. This is rarely used for STEMI patients because it is associated with increased mortality when performed in the first 7 days after STEMI.[58] Close consultation with cardiology and surgery is needed to weigh the risks and benefits of therapeutic options in perioperative STEMI patients (Box 51.3).

Patients with non–ST-elevation myocardial infarction (NSTEMI) may be managed more conservatively. However, in patients with low CO or arrhythmias, emergent PCI and reperfusion may be warranted. In stable NSTEMI patients, noninvasive studies may be the first approach. Again, close consultation with cardiology will aid in risk stratification and management (see Box 51.3).

Heart Failure

Heart failure represents a significant perioperative complication presenting in up to 10% of patients after major noncardiac surgery.[60] A preoperative history of HF increases cardiac risk substantially, especially in the presence of risk factors such as CAD and diabetes. HF is broadly defined as a syndrome of impaired cardiac function[61] and is often categorized into two groups: systolic failure associated with depressed left ventricular function (low LVEF) or diastolic failure with a preserved EF.[62]

Like perioperative ACS, care pathways for the perioperative management of HF are ill defined and poorly studied. Retrospective cohort studies using data from large national databases have helped elucidate risk factors, but it remains unclear how specific therapies may affect outcome in the perioperative period.[61] Patients may present with dyspnea, orthopnea, tachypnea, and/or clinical signs such as pulmonary crackles or decreased oxygen saturation. Signs of right-sided heart failure, such as nausea and vomiting, lower extremity edema, and hepatic congestion may also be present. This may result in a confusing clinical picture, because many of the signs and symptoms of HF seen in the perioperative period could also be due to other causes such as surgical insult, pain, and medication side effects.

Clinical suspicion of HF should prompt further investigation, including ECG, chest x-ray, and cardiac biomarkers. Although troponin and creatine kinase may be important in elucidating an etiology, they are not diagnostic of HF. Elevated B-type natriuretic peptide (BNP) is supportive of the diagnosis.[62] Some patients with chronic HF may have a baseline abnormal level of BNP. In such patients an elevation of BNP from baseline may be diagnostic of an acute exacerbation.[63] Echocardiography, either TTE or TEE, can be invaluable in making the diagnosis of HF and monitoring therapeutic effect. Laboratory evaluation should include electrolytes, renal and liver function tests, and hemoglobin.

Therapies are tailored to specific causes and must be directed at managing concomitant respiratory failure. Adequate oxygenation and ventilation is paramount to normalizing cardiac function. Electrolyte imbalances and acid/base disturbances should be corrected to minimize potential detrimental effects on ventricular contractility, pulmonary arterial pressure, and cardiac rhythm. Preload, contractility, and afterload must also be optimized.

In patients with signs of volume overload, diuretic therapy and fluid restriction are mainstays of therapy. Furosemide, a common loop diuretic, may be administered intravenously. Systolic HF with clinical signs and symptoms of low CO may benefit from inotropic therapy.[64,65] In the setting of failed pharmacotherapy, mechanical devices may be used to treat severe HF (eg, intraaortic balloon pump, ventricular assist devices) (see Chapters 11 and 38).

In patients with stable hemodynamics, ACE inhibitor and β-blocker therapy is recommended by the American College of Cardiology (ACC). Additionally, in patients with LVEF less than 35%, aldosterone antagonists are recommended[62] (see Chapter 11).

Valvular Heart Disease

Concomitant valvular disease may be common in the perioperative period. Depending on the severity of valvular disease, surgery and anesthesia may present a significant physiologic challenge. An understanding of the type and severity of valvular disease can help the clinician tailor care appropriately. Preoperative echocardiographic evaluation may help guide perioperative management. A clinical suspicion of undiagnosed valvular disease or recent changes in clinical history should prompt preoperative echocardiographic testing if none has been performed in the last 12 months.[9] A broad overview of specific valvulopathies and management principles in the setting of noncardiac surgery is discussed later. A summary of hemodynamic goals in each valvular disease is presented in Table 51.3 (see Chapter 21).

Aortic Stenosis

Aortic stenosis (AS) is a major predictor of morbidity in noncardiac surgery.[9] In patients 75 years or older, AS is a common finding with an incidence of 3% to 8%. Decreased cardiac reserve blunts the ability to respond to the physiologic stressors of surgery and anesthesia likely accounting for an increased perioperative morbidity and mortality.[66–68] Additionally, AS may be associated with an increased risk of bleeding due to acquired von Willebrand dysfunction.[69] Perioperative management may require invasive monitoring to ensure proper loading conditions and avoid potentially catastrophic decreases in afterload that may lead to ischemia, LV failure, and cardiac demise

Therapeutic goals are similar both intraoperatively and postoperatively. Hypovolemia should be avoided as the LV is often hypertrophied and noncompliant, thus more dependent on elevated filling pressures to maintain preload. Sinus rhythm should be maintained as LV filling

TABLE 51.3 Perioperative Hemodynamic Goals by Type of Valvular Disease

	Heart Rate	*Blood Pressure*
Aortic stenosis	Slow normal	High normal
Aortic regurgitation	Fast normal	Low normal
Mitral regurgitation	Fast normal	Low normal
Mitral stenosis	Slow normal	Normal

is increasingly dependent on atrial contraction in the setting of AS. Tachycardia should be avoided to allow adequate filling time in diastole and ejection time in systole. Systemic vascular resistance (SVR) should be maintained and sudden drops in blood pressure should be avoided because they may cause dangerous reductions in coronary perfusion. Neuraxial anesthesia may cause a decrease in SVR and preload; therefore caution should be used in the setting of AS.[70,71] Phenylephrine and vasopressin are effective medications for maintaining SVR.[72,73]

Aortic Regurgitation

The risk of noncardiac surgery in patients with aortic regurgitation (AR) relates directly to the severity of valvular disease, the cause of AR, and the surgical risk. Moderate to severe AR and intermediate- to high-risk surgery are risk factors for increased pulmonary edema, prolonged intubation, and hospital death.[74] Understanding the degree of AR preoperatively is key when caring for these patients. In patients with severe AR and low LV function (EF <50%), valve repair or replacement should be considered before elective surgery.[75]

Many anesthetic agents cause a decrease in SVR, reducing regurgitant fraction and improving AR. Nevertheless, careful management is necessary. To maintain forward CO, adequate avoidance of bradycardia is important because it may increase regurgitation due to increased diastolic time. Similarly, hypertension and volume overload should be avoided. The use of diuretics and afterload reduction medications may be helpful.

Mitral Stenosis

Patients with moderate to severe mitral stenosis (MS) undergoing noncardiac surgery present a significant challenge to clinicians. LV filling is impaired because of obstructed flow across the stenotic mitral valve. Supraventricular arrhythmias may develop as a result of structural changes in the LA. Pulmonary hypertension can develop because high LA pressures are transmitted backward to the pulmonary vasculature. Eventually, patients with severe MS can develop pulmonary edema and RV failure.

Caring for patients with MS in the perioperative period involves maintaining LV filling pressures and optimizing conditions for RV function. Care must be taken to avoid hypercarbia, hypoxemia, and acidosis, all of which can increase pulmonary vascular resistance and impair RV function. Inotropic support of the RV may be needed. Dobutamine is a reasonable choice with phosphodiesterase inhibitors such as milrinone reserved for more critical scenarios.

Medications that cause tachycardia such as ketamine and anticholinergics may best be avoided. Bradycardia allows for improved LV filling across the stenotic mitral valve. β-Blockers such as esmolol should be available. Anxiolysis to avoid tachycardia is important, but care must be taken to avoid hypercarbia or hypoxemia that may occur with sedation. Avoidance of hypotension may be achieved with "hemodynamically stable medications" such as etomidate. Regional and neuraxial anesthesia may be employed, but clinicians should attempt to avoid hypotension. Epidural anesthesia with gradual dosing of medication may reduce the risk of sudden hypotension.

Mitral Regurgitation

Patients with moderate to severe mitral regurgitation (MR) undergoing surgery are at increased risk of perioperative morbidity and mortality. This is especially true for patients with low EF or AF.[75,76] Patients with chronic MR suffer long-standing volume overload of the LV, which leads to dilation of the ventricle and left atrium. Because of compensatory mechanisms, chronic MR is often well tolerated by patients. Acute MR, on the other hand, is not well tolerated and is often complicated by overt HF, pulmonary hypertension, and pulmonary edema. The most common cause of acute MR is ischemia causing papillary muscle dysfunction although other causes exist. Addressing the underlying cause of acute MR is the mainstay of management.

Key management principles for patients with chronic MR undergoing noncardiac surgery include maintaining sinus rhythm and avoiding bradycardia, hypertension, and volume overload. Sinus rhythm is crucial because atrial contraction may account for 30% to 40% of LV end-diastolic volume. Atrial fibrillation significantly decreases LV filling and can lead to HF and shock. Most anesthetic agents improve MR by decreasing afterload and, thus, decreasing LV systolic pressure. Anesthetic agents that decrease SVR (eg, volatile anesthetics) may be useful; however, those agents associated with bradycardia may worsen MR (eg, remifentanil). Regional or neuraxial anesthesia may be reasonable in the absence of contraindications for placement. Diuretics and afterload reduction should be considered if volume overload or hypertension is encountered.

Arrhythmias

Atrial Fibrillation

Perioperatively, a multitude of factors can precipitate AF, including direct surgical irritation of the atria or pulmonary veins, fluid shifts, electrolyte imbalance, or excess catecholamines related to pain or the physiologic stress of surgery. AF is associated with an increased risk of stroke because slow blood flow through the atria can lead to thrombus formation, particularly in the left atrial appendage.

In patients with AF, the decision of when to stop oral anticoagulants preoperatively is a source of continued concern. Patients at particular risk of stroke may be "bridged" from the time of cessation of oral anticoagulants to surgery with LMWH or unfractionated heparin (UH).[77] The duration of cessation and timing of bridging therapy is decided on an individual basis based on surgical risk of bleeding and patient risk of thromboembolism. At this time, there is limited available evidence for the optimal type and duration of bridging therapy.[78] Those patients in sinus rhythm on chronic warfarin may discontinue it 5 to 7 days before surgery.[77] Higher-risk patients with mechanical valves, a history of stroke, or elevated stroke risk scores may require bridging with LMWH or UH. The management of anticoagulation therapy should be coordinated with the primary care doctor or cardiologist.

Newer oral anticoagulants such as direct thrombin inhibitors and factor Xa inhibitors pose a significant concern in surgical patients.[79] There is far less experience regarding the safe timing of cessation, and standard coagulation studies do not detect the effect level of these newer medications. Furthermore, unlike warfarin, reversal with an antidote is challenging. It is recommended that cessation of these drugs be based on the pharmacologic properties (half-life) of the drug and relative surgical and patient risks. The American Society of Regional Anesthesia has published guidelines on the timing of regional or neuraxial anesthesia in the setting of oral anticoagulants.[80]

Perioperatively, the hemodynamic consequences of AF are of particular concern, especially in the setting of preexisting cardiac conditions. The loss of atrial contraction coupled with beat-to-beat changes in ventricular filling can lead to suboptimal ventricular preload and decreases in CO and blood pressure. Irregular electrical transmission through the atrioventricular (AV) node can lead to rapid ventricular response (RVR) further reducing ventricular filling.

The patient with AF in the operative or critical care setting should initially be evaluated for signs of hemodynamic compromise and categorized as stable or unstable. The unstable patient should undergo immediate cardioversion. It should be recognized that cardioversion might increase the risk of stroke, especially in patients with a history of AF and not on anticoagulation. If possible, evaluation for existing intracardiac thrombus with TEE should be considered. In stable

TABLE 51.4 Rate Control for Perioperative Atrial Fibrillation

Beta-Blockers	*Calcium Channel Blockers*	*Other Agents*
Esmolol 0.5 mg/kg bolus; 50-200 μg/kg/min infusion	Diltiazem 0.25 mg/kg; 5-15 mg/h infusion	Digoxin
Metoprolol 2.5-5 mg up to 15 mg	Verapamil 5-10 mg; 0.125 mg/min infusion	Amiodarone

Data from January CT, Wann LS, Alpert JS, et al. 2014 AHA/ACC/HRS guideline for the management of patients with atrial fibrillation: a report of the American College of Cardiology/American Heart Association Task Force on practice guidelines and the Heart Rhythm Society. *Circulation.* 2014; 130:e199–267.

patients, rate control with medications and anticoagulation are the mainstay of therapy.

Several different classes of medication can be used for rate control. The most common medications are calcium channel blockers, β-blockers, amiodarone and digoxin (Table 51.4). Therapy must be individualized to the patient and clinical scenario (see Chapter 11).

Intravenous β-blocker therapy is useful in the perioperative period where a high catecholamine state may drive RVR. Esmolol has a rapid onset and offset, making it an attractive choice, because patient response to β-blockade can be unpredictable. If hemodynamic instability is precipitated by therapy, the short-acting effect of esmolol is beneficial. Metoprolol is a longer-acting β-blocker available in oral and intravenous form. Side effects of β-blockers include the potential for airway hypersensitivity, hypotension, or worsening HF.

Calcium channel blockers (CCBs) are also a well-known therapy for AF with RVR. Nondihydropyridine CCBs such as diltiazem or verapamil are medications of choice. Diltiazem has a rapid onset and offset. A bolus dose of 0.25 mg/kg followed by an infusion of 5 to 15 mg/hour is an effective method of rate control.[81] Verapamil is less commonly used in the perioperative setting and is associated with more negative inotropy than diltiazem. Caution should be used in HF patients given the negative inotropic properties of CCBs.

Amiodarone is commonly used for rhythm control in AF but can be used for rate control.[82] Its pharmacologic profile (prolonged action) and long-term side effects (thyroid dysfunction, hepatic and pulmonary toxicity) make it less attractive in the perioperative setting. Despite this, some advocate its use in the ICU, citing less hypotension when compared with other regimens.[83]

Supraventricular Tachyarrhythmia

The term *supraventricular tachyarrhythmia (SVT)* refers to any arrhythmia originating above the AV node. It can be subdivided into irregular and regular rhythms with irregular rhythms largely consisting of AF or atrial flutter. Regular SVT includes AV nodal reentry, AV tachycardia in both orthodromic and antidromic forms, AV junctional tachycardia, and other less common types. In the perioperative period, several pathophysiologic mechanisms may precipitate SVT. Common causes include acidosis, hypercarbia, hypoxemia, electrolyte disturbances, hypotension, mechanical irritation of the atria or pulmonary veins, medications, and myocardial ischemia. Investigation into the precipitating factor is a key component in the management of SVT. This includes laboratory analysis and ECG. Resolution of the arrhythmia may be prompt with correction of the underlying disturbance.

Treatment is determined by the stability of the patient. Unstable patients require synchronized cardioversion and should be managed with advanced cardiac life support (ACLS) guidelines. In stable patients, vagal maneuvers (eg, Valsalva maneuver) may be attempted first. Although carotid massage is a known vagal stimulant, caution should be used because inadvertent carotid injury and stroke have been described.[84] Adenosine temporarily slows conduction through the sinoatrial (SA) node and renders the AV node refractory to depolarization. This transient effect makes adenosine a reasonable choice for the treatment of narrow-complex SVT. In the absence of underlying structural heart disease (eg, AS, MS), SVT is often stable and rate control with β-blockade, CCBs, or amiodarone is reasonable.

The treatment of wide-complex SVT and reentrant tachycardia may be more complex. Disorders with accessory pathways such as Wolff-Parkinson-White may respond paradoxically when conduction through the AV node is slowed. This is mediated by increased conduction through the accessory pathway. Every effort to distinguish wide complex SVT from ventricular tachycardia should be made. Amiodarone may be considered in these situations, along with cardiology consultation for use of more advanced antiarrhythmic medications.

Ventricular Arrhythmias

Ventricular arrhythmias arise below the AV node and are typically a wide-complex rhythm. This most commonly originates in scarred or damaged ventricular muscle, creating a conduction pathway outside the normal His-Purkinje system. Wide-complex ventricular rhythms should be differentiated from SVT with aberrancy as the treatment may differ. Baseline ECG characteristics may offer differentiating clues.

Ventricular tachycardia (VT) can be subdivided into nonsustained VT (NSVT) and sustained VT. NSVT is defined as three or more premature ventricular contractions with a rate of 120 beats per minute or more, lasting less than 30 seconds.[85] The incidence may be as high as 50% in patients undergoing major surgery.[86] However, in the absence of underlying disease (MI), aggressive therapy is not indicated. Nevertheless, a search for precipitating causes may be prudent (electrolyte imbalance, ischemia). In patients with myocardial injury and reduced ventricular function, more aggressive therapy with antiarrhythmics or implantable defibrillators may be indicated and consultation with cardiology is recommended.[87–89]

Sustained VT can be subdivided into monomorphic and polymorphic types. Monomorphic VT demonstrates a consistent QRS amplitude and is often related to a reentrant pathway within scarred myocardium.[85] Urgent synchronized cardioversion (50–100 joules, biphasic) is often required. As with other arrhythmias, treatment of the underlying cause should be established. Rate control with medication such as β-blockers and CCBs may be useful, but the risk of hypotension is high, and prompt cardioversion is often preferred. ACLS guidelines provide a framework for management.[90]

Polymorphic VT may be associated with normal or long QT intervals and causes may vary. Normal QT polymorphic VT is often associated with myocardial ischemia. Prolonged QT forms may be related to medications or precipitated by underlying genetic predisposition or both.[91] Treatment includes correction of underlying electrolyte disturbances, intravenous magnesium (2–4 grams), and asynchronous cardioversion. More advanced therapies with antiarrhythmics and, potentially, overdrive pacing may be needed.[91] Consultation with cardiology is warranted.

Pulmonary System

There is a broad spectrum of critical care issues involving the pulmonary system in the perioperative setting. This may arise from primary pulmonary disease, such as COPD, or secondary manifestations, such as cardiogenic pulmonary edema or neuromuscular weakness. This section will focus on key perioperative respiratory diseases, including pulmonary edema, COPD exacerbations, and acute lung injury/acute respiratory distress syndrome, as well as management strategies for these syndromes in the perioperative setting of noncardiac surgery.

Respiratory Failure

Respiratory failure can be categorized into two broad types (Table 51.5).

Type 1: Respiratory Failure—Hypoxemic

Hypoxemic respiratory failure is typically associated with parenchymal lung diseases that affect oxygen exchange at the alveolar level. It is defined as a Pa_{O_2} less than 50 mm Hg on room air. Five pathophysiologic mechanisms can explain hypoxemia, including low oxygen admixture, ventilation and perfusion mismatch, shunting, diffusion

TABLE 51.5 Mechanism and Risk Factors for Respiratory Failure, by Type

	Definition	*Mechanism*	*Common Diseases and Risk Factors*
Type 1	Hypoxemic	Low O_2 admixture	Cardiogenic pulmonary edema
		V/Q mismatch	Acute respiratory distress Syndrome
		Shunting	Pulmonary embolism
		Diffusion impairment	Pneumonia
		Alveolar hypoventilation	Shunts (right to left)
Type 2	Hypercarbic	Central respiratory depression	Neuromuscular disorders Amyotrophic lateral sclerosis Guillain-Barré syndrome
		Respiratory system mechanical failure	
		Respiratory muscle fatigue	Chronic obstructive pulmonary disease

impairment, and alveolar hypoventilation.[92] Shunt physiology is unique because it is nonresponsive to supplemental oxygen. Pulmonary edema and acute respiratory distress syndrome (ARDS) are two examples of hypoxemic respiratory failure and will be discussed later.

Type 2: Respiratory Failure—Hypercarbic With or Without Hypoxemia

Hypercapnic respiratory failure is associated with ventilatory failure and inadequate carbon dioxide elimination. It occurs when the $PaCO_2$ increases above 50 mm Hg in patients without chronic CO_2 retention[93] and may be associated with hypoxemia. There are three main causes of ventilation failure: depression of the respiratory centers in the brainstem, mechanical dysfunction of the respiratory muscles and associated structural tissues (ie, the chest wall and diaphragm), and respiratory muscle fatigue associated with increased work of breathing.[94] Depressed respiratory drive from medication effects (ie, narcotics, inhalation anesthetics) is a classic cause of hypercapnic respiratory failure in the perioperative period. In the ICU, COPD is the most common etiology of type 2 respiratory failure. Rare neuromuscular diseases (ie, amyotrophic lateral sclerosis, muscular dystrophy, and myasthenia gravis) may lead to chronic hypercapnic respiratory failure.[95]

Postoperative Respiratory Failure

Postoperative respiratory failure may be defined as unplanned intubation and mechanical ventilation within 48 hours of surgery.[96] It is a serious complication associated with an 18-fold increased risk of death.[96] Postoperative respiratory failure may be either hypoxemic or hypercarbic depending on the underlying pathophysiology. Patients may also require intubation for impending respiratory failure before hypercarbia or hypoxemia develops. Risk factors for postoperative respiratory failure are either patient related or procedure/anesthesia related. Patient factors include ASA score higher than 3, advanced age, ethanol use, tobacco use, COPD, insulin-dependent diabetes mellitus, HF, hypertension, cancer, liver dysfunction, cachexia and weight loss, and morbid obesity (body mass index [BMI] > 40).[97,98] Surgical and anesthesia factors include emergency surgery, medium- to high-risk surgery, surgery for sepsis, surgical location (upper abdominal or thoracic surgery), and surgery lasting greater than 2 hours.[97–100] General anesthesia may pose a higher risk of postoperative respiratory failure than regional/neuroaxial anesthesia, although this remains controversial.[97–100] Residual neuromuscular blockade is an important risk factor for immediate perioperative respiratory failure.[101]

Respiratory Failure in Circulatory Shock

Circulatory shock–associated respiratory failure develops when an imbalance between respiratory muscle oxygen supply and demand occurs. Respiratory compensation for metabolic acidosis requires an increased minute ventilation to decrease the $PaCO_2$.[102] Increased work of breathing requires greater oxygen supply, which is compromised in shock. Respiratory muscles fatigue and fail when the oxygen supply is insufficient to maintain the higher respiratory workload.[93]

Pulmonary Edema

Starling forces control the net flow of fluid across the alveolar membrane and are proportional to the permeability and surface area of the alveolar membrane, as well as the balance between hydrostatic and oncotic pressures of both the capillaries and alveoli. In the normal lung, the extravasation of fluid from the capillaries into the alveoli is matched by the lymphatic systems ability to drain the lung water. Imbalances in the Starling forces cause pulmonary edema[103] and occur primarily from a high hydrostatic pressure in cardiogenic pulmonary edema or increased alveolar capillary permeability in noncardiogenic pulmonary edema. The endothelial glycocalyx layer normally provides resistance to fluid movement out of the intravascular space. Damage to the glycocalyx layer by ischemia, inflammation, and hypervolemia promotes pulmonary edema.[104] Restoration of the normal ebb and flow of alveolar lung water is often rapid in cardiogenic pulmonary edema as the elevated hydrostatic forces are normalized with diuresis. In contrast, the resolution of noncardiogenic pulmonary edema can be prolonged and requires the restoration of the integrity of the alveolar membrane. In severe cases, the alveolar membrane may not heal and is replaced by fibrotic scar tissue.[105] The patient with pulmonary edema typically presents with tachypnea, dyspnea, and hypoxemia. Differentiating between cardiogenic and noncardiogenic pulmonary edema can be challenging, and the use of echocardiography or other means of evaluating cardiac function may be necessary.

Cardiogenic Pulmonary Edema

Cardiogenic or volume overload pulmonary edema can present with slowly progressive dyspnea or an acute dyspnea referred to as flash pulmonary edema. Slowly progressive edema is caused by a decline in cardiac function and progressive accumulation of intra- and extravascular fluid. Contributing factors include medication effects (noncompliance or inadequate dose), renal dysfunction, and respiratory infection.[106] Flash pulmonary edema is caused by abrupt physiologic derangement, such as a sudden increase in blood pressure, acute myocardial ischemia, acute myocarditis, acute valve dysfunction (ie, mitral regurgitation), or arrhythmia.[106] Elevated filling pressures in the left heart cause an increase in pulmonary venous pressures. Increased hydrostatic pressure in the pulmonary capillary bed forces a transudative edema fluid into the interstitium and the alveoli when the left atrial pressure increases above 18 mm Hg.[103] Alveolar fluid impairs oxygen exchange and results in hypoxemia.

Evaluation of the patient with pulmonary edema should focus on the severity of the respiratory distress and required respiratory support, then shift to an assessment of etiology. Precipitating factors and associated symptoms should be investigated. Patient symptoms such as breathlessness, orthopnea, reduced exercise tolerance, fatigue, and ankle swelling are suggestive of cardiogenic pulmonary edema. Chest radiograph and 12-lead ECG are standard, and laboratory evaluation should include cardiac troponins, complete blood count, complete metabolic panel, and BNP level.[107] An elevated BNP can be useful in the initial diagnosis of cardiogenic versus noncardiogenic pulmonary edema. BNP provides a high sensitivity and specificity for acute HF, and low levels may exclude cardiogenic pulmonary edema.[107–109] BNP trends as a marker of improvement in cardiogenic pulmonary edema, and HF must be used with caution, because it may not correlate with invasive hemodynamic measurements of volume status.[110] Transthoracic echocardiography is recommended for definition of cardiac structure and function (see Chapter 46).

Urgent treatment of pulmonary edema focuses on correction of hypoxemia and stabilization of respiratory distress. Patients with mild to moderate dyspnea and hypoxemia can often be treated with supplemental oxygen via nasal cannula; however, more severe dyspnea may require noninvasive or invasive mechanical ventilation. If not

contraindicated, noninvasive ventilation (NIV) is often attempted before intubation and mechanical ventilation. Compared with patients using a nasal cannula or facemask, those who receive NIV have quicker resolution of their respiratory symptoms and decreased need for intubation.[111] It remains unclear whether there is a mortality benefit from NIV.[112] After respiratory stabilization, diuresis and afterload reduction should be considered. Loop diuretics are the mainstay of therapy for volume overload in cardiogenic pulmonary edema. Hypoxemia and respiratory distress improve as pulmonary edema resolves with a negative fluid balance.[113] Afterload and preload reduction with vasodilators, often nitroglycerin, reduces cardiac workload and may hasten recovery.[114] Inotropes and advanced mechanical heart failure therapies may also be necessary.

Noncardiogenic Pulmonary Edema

The most important cause of noncardiogenic pulmonary edema is ARDS. Less common etiologies of noncardiogenic pulmonary edema include neurogenic, diffuse alveolar hemorrhage, medication-induced (naloxone), and negative-pressure pulmonary edema.[115] Initial treatment of these disorders is similar to the therapy of cardiogenic pulmonary edema and includes stabilization of the respiratory distress with oxygen therapy, NIV, or invasive mechanical ventilation, and loop diuretics are often employed for a negative fluid balance as described earlier.

Negative-Pressure Pulmonary Edema

Negative-pressure pulmonary edema occurs when extreme negative intrathoracic pressure (deep breath) occurs against an obstructed airway. The obstruction can be due to an obstructed endotracheal tube, laryngospasm, or an upper airway obstruction. The large negative inspiratory force against an obstructed airway creates a vacuum effect and draws fluid into the alveoli resulting in pulmonary edema characterized by pink, frothy sputum. The presentation can be immediate or delayed. The incidence may be as high as 11% in patients with complete airway obstruction.[116] The notion that negative-pressure pulmonary edema is typically associated with individuals who are capable of generating significant negative intrathoracic force may be misleading. Many patients who develop this disorder have preexisting cardiac disease (eg, valvular disorders and hypertrophic cardiomyopathy), and the pulmonary edema may be multifactorial.[117]

Acute Respiratory Distress Syndrome

ARDS is a common cause of respiratory failure, affects approximately 200,000 people a year, and is associated with 15% of all ICU admissions.[118] ARDS is characterized by diffuse alveolar damage leading to increased alveolar capillary permeability resulting in pulmonary edema, hypoxemia, and respiratory distress.[119] The most common causes are pneumonia (viral or bacterial), sepsis, trauma, gastric aspiration, transfusion related, medications, and, pancreatitis.[119] The historic diagnosis of ARDS has required three classic criteria: Pa_{O_2}/F_{IO_2} less than 200, bilateral patchy opacities on chest radiograph, and a pulmonary capillary wedge pressure less than 18 mm Hg to exclude cardiogenic pulmonary edema.[120] More recent criteria were established in 2012 by the Berlin Task Force on ARDS because of an increasing awareness that patients with ARDS may have elevated left-heart filling pressures. The diagnosis of ARDS now requires hypoxemia, bilateral opacities on chest radiograph, and the pulmonary edema must be associated with a clinical insult and *not* fully explainable by cardiac function.[121] The Berlin Task Force defined ARDS severity by the degree of hypoxemia with Pa_{O_2}/F_{IO_2}: mild, 200–300; moderate, 100–200; severe, less than 100. These classifications are correlated with increasing mortality rates,[121] which range from 26% to 35%.[122] The cause of death in ARDS is most often related to multisystem organ failure and bacterial sepsis. However, the severity of hypoxemia, dead space fraction, and RV dysfunction are risk factors of poor prognosis.[123]

In contrast to the transudative fluid seen in cardiogenic pulmonary edema, the edema fluid seen in ARDS is exudative and is slower to resolve. Treatment of ARDS is supportive and requires treatment of the underlying condition (eg, antibiotics and source control for sepsis). The mainstay of therapy for ARDS is lung protective ventilation and conservative fluid management. Lung protective ventilation consists of low tidal volume ventilation (6 mL/kg), maintaining plateau pressures less than 30 cm H_2O, and permissive hypercapnia to avoid ventilator-induced lung injury (volume trauma and barotrauma). Lung protective ventilation has been shown to decrease mortality by 22% compared with standard tidal volume ventilation (12 mL/kg).[124] Less iatrogenic injury from mechanical ventilation has led to decreased mortality rates for ARDS.[125]

Conservative fluid therapy in ARDS begins after circulatory shock has resolved (no longer requiring fluid boluses or vasopressors for 12 hours). The goal for conservative fluid therapy is a net negative fluid balance of 500 mL/day achieved through diuresis.[126] This has been shown to decrease ventilator-dependent days and ICU length of stay without increasing the need for renal replacement therapy.[127] Several adjuvant therapies may lead to an additional decrease in mortality from severe ARDS, including short-term muscle relaxation,[128] prone positioning in the ICU,[129] and extracorporeal membrane oxygenation[130] (see Chapters 33 and 39).

Chronic Obstructive Pulmonary Disease

COPD is a very common disorder and is projected to be the third leading cause of death by 2020.[131] Tobacco smoke inhalation continues to be the leading risk factor, and 70% of patients with COPD have a cardiovascular comorbidity requiring medication.[132] COPD is known to cause a constant, low-grade inflammatory response that accelerates atherosclerosis and is associated with a two- to threefold increased risk of cardiovascular death.[133] COPD is a major risk factor for postoperative complications, including pneumonia, respiratory failure, MI, cardiac arrest, sepsis, reoperation, and kidney injury/failure.[134]

COPD is characterized as chronic and progressive airflow limitations from damage to the lung parenchyma or inflammation of the airways. Patients often present with dyspnea, respiratory signs of distress (ie, accessory muscle use), increased sputum production, and chronic cough. Exposure to tobacco smoke is nearly universal, although there are other risk factors such as environmental exposures and rare genetic defects (α_1 antitrypsin deficiency). Common physical findings suggestive of COPD include expiratory wheezing, increased expiratory time, diminished breath sounds, and a barrel chest.[135] The diagnosis of COPD is confirmed with spirometry showing a post-bronchodilator FEV_1/FVC ratio less than 0.7 and FEV_1 less than 80% predicted value.[135] Assessment of COPD severity is important because disease severity directly relates to increased risk of exacerbation.[136] The Global Initiative for Chronic Obstructive Lung Disease has developed a simple disease severity scale based on FEV_1 with the assumption that the patient has an FEV_1/FVC less than 0.7. Patients with an FEV_1 less than 80% predicted value have mild disease; those with FEV_1 50–79, moderate; FEV_1 30–49, severe; and FEV_1 less than 30, very severe.[137] Other risk factors for exacerbation include GERD, asthma, HF, cancer, and respiratory infections.[138]

It is important for the anesthesiologist to recognize the severity of COPD in patients presenting for surgery. Preoperative pulmonary function testing should be considered for those who are at risk for COPD or have an established diagnosis of COPD. A specific level of functional status and spirometric data points have not been established for COPD patients who require an operation; however, information from pulmonary function testing may be beneficial in preoperative medical optimization. The risks/benefits discussion for an operation should include the potential need for postoperative mechanical ventilation. Medical records should be reviewed with a focus on medical management of COPD and propensity for exacerbation. Standard medical therapies for COPD include smoking cessation and inhalers for symptom alleviation. Bronchodilator therapy with a β_2-agonists (ie, albuterol, salmeterol) and/or antimuscarinics (ie, tiotropium) is

commonplace, as is inhaled corticosteroid. Oxygen therapy is added when patients develop resting hypoxemia, pulmonary hypertension, or HF.[137] These medications should be continued in the perioperative period.

COPD exacerbations are characterized by worsening of symptoms ranging from increased wheezing to hypercarbic respiratory failure. Treatment includes respiratory support with oxygen, noninvasive or invasive mechanical ventilation, and medical management. NIV is the mainstay of therapy in severe COPD exacerbations and has been shown to decrease mortality, need for intubation, and hospital length of stay.[139] Common initial settings for NIV are an inspiratory pressure of 12 cm H_2O and expiratory pressure of 5 cm H_2O with F_{IO_2} as needed. In the perioperative period, the anesthesiologist should be cognizant of the relative contraindications to NIV such as diminished mental status, ability to protect the airway/aspiration risk, recent and severe facial surgery or trauma, hemodynamic instability, and upper gastrointestinal surgery. Once NIV is initiated, frequent patient assessment is required. An arterial catheter may be considered for serial blood gas analysis. NIV failure is defined as no improvement or worsening of the respiratory acidosis within one hour of initiation and intubation should be considered.[140] Declining mental status and increased work of breathing are additional signs of NIV failure, suggesting intubation and mechanical ventilation. Similar to ARDS, the goal of mechanical ventilation in respiratory failure from COPD is avoidance of ventilator-induced lung injury from volume trauma and barotrauma. It may be prudent to adjust the inspiratory-to-expiratory ratio to account for a prolonged expiratory phase.[139] Pharmacotherapy for acute COPD exacerbations includes antibiotics for respiratory infection if needed, inhaled β_2-agonists (eg, albuterol), and anticholinergic agents (eg, ipratropium). Systemic corticosteroids are recommended.[137]

Hematology

Many aspects of perioperative medicine and anesthesia critical care involve the hematologic system. In the perioperative period, clinicians are often challenged by perturbations in the hematologic system, which may impair oxygen delivery and/or the coagulation cascade. This section will focus on three clinical challenges that the anesthesiologist may face in all phases of the perioperative period: management of chronic anticoagulation, massive hemorrhage, and venothromboembolism (VTE) prophylaxis and treatment.

Perioperative Management of Anticoagulation

A variety of disorders are treated with long-term anticoagulation; these range from prothrombotic disorders such as factor V Leiden to AF to problems with mechanical heart valves. The perioperative management of these anticoagulants must balance the need for anticoagulation with the increased risk of surgical bleeding. Risk factors for bleeding in chronically anticoagulated patients include mechanical mitral valve prosthesis (requires higher level of anticoagulation), cancer, history of bleeding complications from anticoagulation, restarting heparin anticoagulation within 24 hours of surgery, and heparin bridging.[141] The decision to stop, continue, or bridge anticoagulant therapy must be considered in the context of patient- and procedure-related risk factors such as a high-risk of stroke from AF or low surgical bleeding risk (ie, cataracts). This section will review the anticoagulants, the suggested timing of cessation before elective surgery, and anticoagulation reversal agents for emergent surgery or bleeding complications. Alterations in these medications should be coordinated with the managing physician (see Chapters 34 and 35).

Warfarin

Warfarin impairs the coagulation cascade by interrupting the carboxylation of factors II, VII, IX, and X, as well as the synthesis of protein C and S. The resultant anticoagulated state can be monitored with the prothrombin time (PT) or international normalized ratio (INR). Cessation of warfarin 5 days before surgery is a recognized strategy.[142] After surgery, warfarin can be reinitiated when the risk of thromboembolic disease outweighs the risk of bleeding. Patients may require bridging therapy with LMWH. The continuation of warfarin throughout the perioperative procedure may be acceptable in certain situations (ie, cataract surgery), and warfarin may be beneficial in some procedures such as catheter ablation of AF, in which the perioperative stroke risk is high and surgical bleeding risk is low.[143]

Several modalities of warfarin reversal exist, including vitamin K, fresh-frozen plasma, and prothrombin complex concentrates (PCCs). Activated factor VII may be considered as well. Reversal agents should be chosen based on the relative level of urgency, pharmacologic properties, and their associated side effect profile.

New Oral Anticoagulants (NOACs)

New pharmacologic agents have been developed with more specific inhibition of the coagulation cascade than warfarin. Several potential advantages over warfarin have been reported, including no requirement for serial laboratory testing (no laboratory testing is available), less dietary restrictions, and less potential for drug interaction. These agents include direct thrombin inhibitors (ie, dabigatran) and direct factor Xa inhibitors (ie, rivaroxaban, apixaban, and edoxaban). Notably, these medications have been shown to have a decreased risk of intracranial hemorrhage versus warfarin.[144] However, these agents have a decisive disadvantage to warfarin in the perioperative period because no specific antidotes exist and the treatment of serious and life-threatening bleeding is difficult.[145] Four-factor PCCs are nonspecific, but potentially useful reversal agents for the NOACs should hemorrhagic complications occur.[146,147]

Direct Thrombin Inhibitors

There are several direct thrombin inhibitors (DTIs), including hirudin, argatroban, and bivalirudin.[148] The most commonly used intravenous agent is argatroban, which is often used in patients who develop heparin-induced thrombocytopenia. Argatroban undergoes hepatic metabolism, and its elimination is independent of the kidneys, making it ideal for critically ill patients at risk for kidney injury. The anticoagulation effect can be measured by the PTT with a goal 1.5 to 3 times the patient's baseline. Argatroban infusion should be stopped 2 to 4 hours before an intervention or surgery. Confirmation of normal coagulation can be made by a normalization of PTT.[149] Bivalirudin has been used increasingly for similar indications and has the advantage of a very short half-life.

Dabigatran is an oral direct thrombin inhibitor. Of note, it can be reversed with idarucizumab (Praxbind) in emergency situations. Dabigatran is indicated for treatment of AF and VTE prophylaxis/treatment. Dabigatran use in artificial mechanical valves is unproven.[150] Caution should be used in patients with renal impairment because the half-life may be increased from 12 to 24 hours.[150] Routine coagulation tests such as PT and aPTT may be altered with dabigatran; however, the degree of alteration and the presence of a normal test does not exclude impaired coagulation. A normal dilute thrombin time suggests that the anticoagulation activity of dabigatran has resolved (Table 51.6).[151] The American Heart Association suggests that dabigatran should be held for at least 2 days before surgery and a dilute thrombin time obtained to confirm normalization. It is recommended that patients with renal dysfunction have surgery delayed at least 5 days.[150] The timing of neuraxial anesthesia in patients who have stopped dabigatran is not well defined. Dabigatran should be restarted after surgery when the risk of thrombosis outweighs the risk of bleeding because the onset of anticoagulation is very rapid.[150]

Treatment of serious and life-threatening bleeding is difficult with DTIs because there are no specific antidotes, with the exception of dabigatran. Key measures in the management of bleeding are cessation of DTIs and supportive care. In life-threatening bleeding, dialysis may facilitate faster removal of dabigatran from plasma. Four-factor PCCs and activated factor VII can be considered in life-threatening bleeding from dabigatran but have unproven efficacy.[150] Antifibrinolytics may

TABLE 51.6 New Oral Anticoagulants

	Mechanism of Action	*Half-Life (Hours)*	*Last Dose Before Surgery (Days)*	*Anticoagulant Monitoring*	*Safety of Neuroaxial Anesthesia*	*Reversal Agents in Hemorrhagic Complications (Nonspecific)*

also be considered. The risk of hemorrhage and thrombosis should be considered before the use of these agents. Consultation with a hematologist is warranted.

Factor Xa Inhibitors

Factor X is produced in the liver by a vitamin K–dependent process, and the activated form converts prothrombin to thrombin. Oral inhibitors of activated factor X, rivaroxaban, apixaban, and edoxaban have been shown to be effective in the prevention of stroke in patients with nonvalvular AF. In addition, a decreased rate of major bleeding is associated with these inhibitors when compared with warfarin.[152,153] Factor Xa inhibitors are indicated for VTE treatment and prophylaxis, including in postsurgical patients after major joint arthroplasty. Factor Xa inhibitors are associated with a decreased incidence of bleeding compared with LMWH.[154–157] As with dabigatran, they are not indicated for treatment of artificial heart valves. No standard or specific laboratory assays of factor Xa inhibitors are available; thus routine monitoring of anticoagulation effects is not required. Factor Xa activity assays are under evaluation.[158] The safety of these drugs with neuroaxial anesthesia is unknown, and no recommendations exist regarding the time from discontinuation to the time of neuroaxial anesthesia. Bridging for procedures is not necessary for oral factor Xa inhibitors because they have short half-lives.

There are no specific reversal agents to oral factor Xa inhibitors in patients with bleeding complications. The mainstay of treatment is cessation of the anticoagulant and supportive care. A normal factor Xa activity assay suggests no anticoagulant effects.[158] Four-factor PCC and activated factor VII can be considered in life-threatening bleeding, but these have unproven efficacy.[159,160] The risk of thrombosis should be considered before the use of these reversal agents, and they should generally be titrated to effect. Antifibrinolytics may be considered. Consultation with a hematologist is strongly suggested.

Massive Hemorrhage

Massive hemorrhage is a significant cause of morbidity and mortality worldwide. The anesthesiologist is confronted by massive hemorrhage in a variety of clinical settings, including trauma, obstetric hemorrhage, gastrointestinal bleeding, and major operations (spine, transplantation).[161] Massive hemorrhage is defined as the need for more than 10 units of packed red blood cells (PRBCs) or approximately a patient's total blood volume in 24 hours, transfusion of more than 4 units of PRBCs in 1 hour, and/or replacement of more than 50% of total blood volume in 3 hours.[161] Coagulopathy of massive transfusion can develop quickly from hypothermia, dilutional coagulopathy, platelet dysfunction, fibrinolysis, and hypofibrinogenemia.[162] The pathophysiologic changes associated with massive transfusion have led to a clinical interest in higher ratios of blood product transfusion (plasma-to-platelets-to-red blood cells such as 1:1:1) and have been shown to be effective in preventing early mortality (within 24 hours) of trauma patients.[163] The exact ratio of plasma-to-platelets-to-red blood cells has not yet been delineated, and a large study of trauma patients that compared a ratio of 1:1:1 with a ratio 1:1:2 showed no difference in mortality at 24 hours or 30 days. However, more patients in the 1:1:1 group achieved hemostasis, and fewer died of exsanguination in the first 24 hours.[164] Furthermore, a systematic review showed no strong evidence to use a precise blood product transfusion ratio.[163,165] Notably, the data on massive transfusion have been geared toward trauma patients. It is unclear if the high platelet-to-plasma-to-red blood cell ratios is generalizable to other patient populations experiencing massive hemorrhage, specifically those with cardiac disease undergoing noncardiac surgery (see Chapters 34 and 35).

The treatment of massive transfusion relies on a multidisciplinary approach fostering excellent communication and efficiency between the care team and supportive services such as the blood bank and laboratory. Massive transfusion protocols have been developed to overcome institutional barriers and help facilitate the care of these critically ill patients. Multiple protocols exist and vary in the ratio of platelets-to-plasma-to-red blood cells but are related in their formula-based approach (no laboratory tests) to coordinate care and improve efficiency.[166] Adherence to formula-driven massive transfusion protocols has been associated with improved survival from massive hemorrhage.[167] Laboratory-driven transfusion protocols have been created, but they are limited by long laboratory turnaround times and subsequent questioning of the relevancy of the laboratory tests. Massive transfusion protocols based on point-of-care testing such as thromboelastography (TEG) or thromboelastometry (TEM) have been shown to be noninferior to formula-driven protocols.[168] TEG- and TEM-based protocols may actually decrease the amount of blood product administration, which may lead to a decrease in transfusion-related morbidity and mortality. TEG and TEM may elucidate a specific pathology of massive transfusion coagulopathy and lead to targeted therapy such as antifibrinolytics, cryoprecipitate, PCCs, or activated factor VII.[169]

One of the main complications of massive hemorrhage is death by exsanguination or inadequate transfusion, which accounts for approximately 40% of associated mortality.[170] The coagulopathy of massive transfusion and the treatment are addressed in the preceding section. Transfusion-related reactions can also account for significant morbidity and include hemolytic and nonhemolytic reactions, immunologic reactions such as transfusion-related acute lung injury (TRALI), circulatory affects such as transfusion-associated circulatory overload (TACO), and metabolic effects including hypocalcemia, hypomagnesemia, hyperkalemia, metabolic acidosis from hypoperfusion, and hypothermia.[161] Complications are more likely in patients with preexisting comorbidities including those with cardiac disease.

Venothromboembolism Prophylaxis and Treatment in the Perioperative Setting

Venothromboembolism is a common and serious complication in the postoperative setting. The overall risk of VTE with appropriate prophylaxis is approximately 1%, but it can be as high as 2.5% in high-risk procedures such as joint replacement.[171] Risk factors include age greater than 60, history of VTE or thrombophilia, cancer, comorbid medical conditions such as HF or infection, bed bound or decreased activity

level for three or more days, obesity, and ICU admission. High-risk patients may have as much as a 6% risk of VTE.[172,173] Guidelines from the American College of Chest Physicians regarding VTE prophylaxis fall into four patient categories: very low, low, moderate, and high-risk with corresponding risk of VTE at less than 0.5%, 1.5%, 3%, and 6% percent, respectively. Very-low-risk patients require no pharmacologic or mechanical VTE prophylaxis. Sequential compression boots are recommended for low risk patients. Moderate-risk patients should receive sequential compression boots and pharmacologic prophylaxis with a heparinoid. The recommendation for high-risk patients is mechanical and pharmacologic prophylaxis that is extended 4 weeks postoperatively.[174] Patients undergoing joint arthroplasty are at especially high risk of VTE complications postoperatively, and it is recommended that chemoprophylaxis of VTE be extended to 35 days with LMWH, warfarin, dabigatran, apixaban, edoxaban, or rivaroxaban.[175] IVC filters may be considered for patients at high-risk of VTE with contraindications to anticoagulation.

Treatment of VTE can be separated into two subsets: isolated deep venous thrombosis (DVT) and pulmonary embolism (PE). Both scenarios require anticoagulation in the absence of contraindication; however, PE with major impact on cardiovascular and pulmonary systems may benefit from thrombolytic therapy. The CHEST guidelines for initial therapy of DVT and PE recommend intravenous anticoagulation (ie, heparin or argatroban in HIT) or oral rivaroxaban. Treatment of initial VTE should be for 3 months with LMWH, fondaparinox, or warfarin.[176] The NOACs also have gained approval for VTE treatment. Patients who have VTE but are unable to be anticoagulated may benefit from an IVC filter.

The presentation of PE consists of dyspnea, chest pain, and occasionally hemoptysis. Massive PE is defined as PE associated with hypotension (SBP < 90) and shock. It occurs in approximately 4.5% of all PEs and is associated with a very high mortality rate (~50%).[177] The gold standard diagnostic tool of PE is pulmonary angiography, but it is typically not required because CT angiography of the chest has high sensitivity and specificity.[178] Ventilation-perfusion nuclear medicine scan is occasionally used for diagnosis of patients with suspected PE who are hemodynamically stable, but have contraindications to CT angiography of the chest. Echocardiography for PE may be useful in hypotensive patients who are unable to have a CT angiography of the chest. Echocardiography is neither sensitive nor specific, but new RV dilation and dysfunction is suggestive of massive PE in the setting of suspected PE. Thrombus may be identified in the right-sided heart structures or in the pulmonary artery. Furthermore, a normal RV in a hypotensive patient makes PE an unlikely etiology.[178]

Hemodynamically stable PE requires no additional treatment beyond anticoagulation . Treatment of massive PE focuses on reperfusion of the lung and dissolution of the thrombus and systemic thrombolytic therapy as recommended by the Chest Guidelines and European Society of Cardiology.[176,178] If contraindications exist to systemic thrombolytic therapy, then catheter-guided thrombolytic therapy, catheter-guided embolectomy, or surgical embolectomy is recommended given the high mortality rate.[176,178] If evidence of thrombus is found in the RV, surgical embolectomy may be preferred to catheter-guided embolectomy.[177] Supportive care includes respiratory support with intubation and mechanical ventilation and hemodynamic therapy with vasopressors and inotropes.

Sepsis

Infection and sepsis account for approximately 21% of all admission to the ICU with approximately 750,000 cases per year.[179,180] The most common sites of infection are respiratory, blood stream, genitourinary, abdominal, and prosthetic device infections.[180] Mortality from severe sepsis has improved significantly but remains approximately 18% to 30%.[181] Anesthesiologists encounter patients with sepsis in several settings, including the operating room for source control of the infection (ie, ureteral stents for pyelonephritis/hydronephrosis, exploratory laparotomy for gastrointestinal derived sepsis), off-site locations (ie, diagnostic radiology, interventional radiology, GI lab for ERCP), and the ICU for supportive procedures and management (ie, intubation, vascular access procedures, arterial catheter placement).

Sepsis is defined along a spectrum that requires suspected or confirmed infection and the systemic inflammatory response syndrome (SIRS). SIRS criteria include temperature dysregulation (>38.3°C or < 36.0°C), tachycardia (HR > 90), tachypnea (RR > 20), and leukocytosis or leukopenia.[181] Severe sepsis includes the criteria for sepsis and objective evidence of organ dysfunction. Septic shock is vasodilatory shock unresponsive to aggressive fluid resuscitation.[182] Sepsis is a syndrome, and its presentation can vary as widely as the infections that cause sepsis. Presentation also depends on associated organ system dysfunction and preexisting medical conditions such as cardiac disease and COPD.

The initial treatment of sepsis revolves around three concepts: source control, antibiotics, and early goal-directed resuscitation. Initial evaluation of the patient with suspected sepsis should focus on anatomic etiology of the infection. A detailed history and physical examination can help guide the diagnostic workup. Intravenous access should be obtained and laboratory inquiries may include blood cultures, CBC, CMP, lipase, coagulation parameters, and lactate. Radiographic workup will likely involve chest radiography and imaging such as computerized tomography. If an anatomic infection is identified, source control by surgery, interventional radiology, or ERCP may be required.[183]

Empiric broad-spectrum antibiotics should be started early for a patient with suspected sepsis.[183] Antiviral and antifungal agents should be considered in patients at risk for such infections. Targeted antibiotic therapy should be delayed until a causative organism is identified and sensitivities to antibiotics are determined.

The Surviving Sepsis Campaign recommends protocolized resuscitation in patients presenting with sepsis-associated hypotension and elevated blood lactate levels.[183] Treatment goals include a central venous pressure of 8 to 12 mm Hg by aggressive crystalloid administration, a mean arterial pressure of 65 mm Hg by vasopressors as needed, urine output greater than 0.5 mL/kg/hr, and a central venous oxygen saturation of 70% by PRBC transfusion to a hematocrit greater than 30%. Inotropic support should be considered as needed.[184] Early GDT improves mortality rates and decreases organ system dysfunction. Norepinephrine is considered the vasopressor of choice in septic shock, and vasopressin is often added as a second-line agent if needed.[185,186] Lactate clearance is also a well-defined goal of sepsis resuscitation.[187]

It must be noted that the resuscitation and recommendations from the Surviving Sepsis Campaign have been questioned with emerging data from large randomized controlled trials. Two large trials were published in 2014 (1600 patient trial in Australia and New Zealand and 1341 patient trial in the United States) comparing nonprotocolized care to protocolized early GDT in early sepsis patients and found no difference in mortality, length of hospital stay, or duration of organ system support.[188,189] In light of this new information, the sepsis guidelines may be modified.

Sepsis presents a major challenge for patients with preexisting cardiac disease because the vasodilatory state places increased workload on the heart. Patients with compromised hearts may have significant difficultly meeting this demand, and mortality of patients with HF in sepsis may be as high as 70%.[190] Furthermore, it is well established that the septic state is a potent myocardial depressant. Advanced hemodynamic monitoring with pulmonary artery catheter (PAC), TEE, transpulmonary thermodilution, or pulse waveform analysis may be useful for hemodynamic optimization.[191]

Perioperative anesthetic management of septic patients includes all of the considerations discussed earlier, including antibiotics and resuscitation with intravenous fluids and vasopressors. The induction and maintenance of anesthesia can be a considerable challenge because most agents are vasodilatory in nature. Consideration can be given to ketamine and etomidate, although concern about adrenal suppression after single-dose etomidate exists.[192] If propofol is used, dose reduction should be strongly considered. The minimum alveolar concentration (MAC) of anesthetic gases is decreased in sepsis.[193] Hemodynamic

monitoring with an arterial catheter, CVP and PAC pulse pressure variation, and/or TEE should be considered. Recovery in the ICU and postoperative intubation should also be considered.

In patients with preexisting cardiac disease, infections of cardiac implantable electronic devices (CIEDs) may cause sepsis. Infections of CIEDs are relatively common with an infection rate of 4%.[194] CIED infections consist of pocket infections, bloodstream infections, or CIED-related endocarditis. The majority of infections are from gram-positive skin flora; however, gram-negative bacteria may account for 20% of infections, and broad-spectrum antibiotic coverage should be strongly considered. Survival is improved in patients who have their device explanted.[194] Supportive treatment for sepsis in these patients should consider that there is coexisting cardiac disease, and advance monitoring should be strongly considered.

Perioperative Care to Reduce Major Adverse Cardiac Events and Mortality in Noncardiac Surgical Procedures

GIOVANNI LANDONI, MD | ALBERTO ZANGRILLO, MD | ANTONIO PISANO, MD | MICHELE OPPIZZI, MD

KEY POINTS

1. Major adverse cardiac events (MACE) are relatively common in patients undergoing noncardiac surgical procedures. The incidence of perioperative myocardial infarction (PMI) is 1% to 5%, whereas approximately 8% of patients experience a perioperative increase in cardiac troponins without other criteria for MI (myocardial injury after noncardiac surgery [MINS]).
2. Preventive and therapeutic strategies for acute coronary syndromes are well established in the nonsurgical setting, but clear evidence about the impact of such strategies on both incidence and outcomes of perioperative myocardial injury or PMI is lacking. Many therapeutic interventions that have cardioprotective properties may be difficult to apply, or even harmful, in the perioperative period.
3. Factors associated with an increased risk of MACE are patient specific (advanced age, high American Society of Anesthesiologists class, renal failure, anemia) and surgery specific (type of procedure, urgency, complexity, intraoperative complications). Several scoring systems allow clinicians to predict, both preoperatively (Revised Cardiac Risk Index, National Surgical Quality Improvement Program) and intraoperatively (ANESCARDIOCAT), the risk of cardiac adverse events and to identify patients who need preventive measures and strict intraoperative and postoperative monitoring.
4. Risk stratification is pivotal in patients with PMI or MINS because therapeutic options also depend on a careful balance between the risk of mortality associated with the cardiac complications and the risks (primarily bleeding) of therapeutic strategies (dual antiplatelet therapy, percutaneous coronary interventions).
5. Thrombolysis in Myocardial Infarction and Global Registry of Acute Cardiac Events scores allow reliable prediction of 30-day, 6-month, and 12-month mortality rates in patients with ST-segment elevation MI (STEMI) and non–ST-segment elevation MI (NSTEMI), respectively. Conversely, the risk of bleeding may be predicted according to the type of surgical procedure and patient-related factors (CRUSADE [Can Rapid Risk Stratification of Unstable Angina Patients Suppress Adverse Outcomes With Early Implementation of the ACC/AHA Guidelines] score).
6. NSTEMI is the most common type of PMI. Unlike STEMI, it is often caused by an impaired balance between myocardial oxygen supply and demand in the absence of complete occlusion of a coronary vessel. Accordingly, the need for urgent revascularization is less stringent as compared with STEMI, whereas prevention or prompt treatment of conditions such as anemia, hypotension, hypoxia, pain, and tachycardia is of primary importance.
7. Percutaneous coronary intervention should always be considered in patients with perioperative STEMI, especially in patients with good life expectancy and moderate-to-large infarctions. Probably, only patients at low risk of death and at high risk of bleeding should be treated with medical therapy alone.
8. High-dose statins, aspirin, and low-dose oral β-blockers should be initiated within 24 hours in all patients with MINS, unless contraindicated. A platelet receptor P_2Y_{12} inhibitor (clopidogrel, prasugrel, ticagrelor) may be added when bleeding risk is decreased sufficiently. Angiotensin-converting enzyme inhibitors should be started in patients with an ejection fraction of less than 40%, hypertension, diabetes, and stable chronic kidney disease.
9. A novel Web-enabled, "democracy-based" approach to consensus building has been used to summarize the best-quality and most widely agreed-on evidence about mortality reduction in different settings, including the noncardiac surgical perioperative period.
10. Hemodynamic optimization, noninvasive ventilation, neuraxial anesthesia, selective decontamination of the digestive tract, and avoidance of β-blocker initiation shortly before surgical procedures may improve survival in patients undergoing noncardiac operations. Statins, tranexamic acid, and liberal transfusion strategies may also be considered to reduce mortality rates, but further investigations are needed.
11. Levosimendan, intraaortic balloon pump, volatile anesthetic agents, remote ischemic preconditioning, leukocyte depletion, and protective ventilation have been shown to reduce mortality rates in other settings, especially in cardiac surgical procedures. It is reasonable to suspect that these interventions will have similar beneficial effects in noncardiac surgical patients.

Despite technical improvements, major surgical procedures currently remain associated with high mortality and morbidity rates. In Europe, an overall 30-day mortality rate of 4% has been reported after major noncardiac operations, and the rate can reach 6% in high-risk populations.[1,2]

More than half of these deaths are attributable to *major adverse cardiac events* (MACE) including nonfatal cardiac arrest, acute myocardial infarction (AMI), congestive heart failure (HF), or new cardiac arrhythmias.[3] Cardiac complications are the most common causes of postoperative morbidity and death; they occur in up to 5% of adult patients undergoing surgical procedures, and they have a major impact on both length and costs of hospitalization.[4] Perioperative myocardial infarction (PMI) is the most dangerous cardiac complication, and coronary artery disease (CAD) is a major determinant of both early and late mortality rates.

Perioperative Myocardial Infarction or Injury

According to the third universal definition,[5] *myocardial infarction* (MI) is defined as a rise and fall in cardiac troponin (cTn) with at least one value above the 99th percentile upper reference limit (>0.014 ng/mL), together with at least one of the following:

- Ischemic chest pain
- New and significant electrocardiographic (ECG) changes such as ST-segment or T-wave changes, left bundle branch block, Q waves
- New regional wall motion abnormalities (echocardiography)
- Intracoronary thrombus (angiography or autopsy)

Myocardial injury after noncardiac surgery (MINS) is defined as (1) an elevation of postoperative troponin with an ischemic origin, (2) without other criteria of PMI, (3) that is prognostically relevant.[6] Two different mechanisms lead to PMI:[5] PMI type 1 is caused by spontaneous rupture of a vulnerable coronary plaque or, uncommonly, by severe coronary vasospasm, leading to platelet aggregation, occlusive (ST-segment elevation, STEMI) or nonocclusive (ST-segment depression, NSTEMI) thrombus formation, and prolonged myocardial ischemia resulting in cell death. Plaque disruption is demonstrated in autopsy studies in approximately 50% of patients who died of PMI.[7] PMI type 2 usually results from a sustained imbalance between myocardial oxygen supply (decreased) and demand (increased) combined with the presence of significant, obstructive, but not occlusive, CAD. Most patients with PMI type 2 have ST-segment depression (NSTEMI).

Patients undergoing major operations are particularly prone to ischemic adverse events because of the surgery-associated inflammation and hypercoagulable state, as well as perioperative factors that increase the risk of plaque rupture (pain, hypertension, elevated levels of catecholamines), increase myocardial oxygen demand (hypertension, tachycardia, elevated left ventricular [LV] diastolic pressure), or decrease myocardial oxygen supply (blood loss, anemia, hypotension, hypoxia, tachycardia, coronary vasoconstriction).[4] NSTEMI is the most common type of PMI. Compared with patients with STEMI, patients with NSTEMI are generally older, have multivessel and/or left main CAD more frequently, and often have multiple risk factors and comorbidities.[8]

Epidemiology of Perioperative Myocardial Infarction

In most studies the incidence of PMI is between 1% and 5%, whereas the incidence of MINS is 8%.[9,10] The rather wide variability in the rate of PMI reflects the different populations and type of surgical procedures (major or minor, vascular or nonvascular) considered, as well as the different definitions of PMI or ischemia (ST-segment deviation or troponin elevation) and troponin cutoff values used. Most PMIs (≈80%) occur on the ward, 48 to 72 hours postoperatively, whereas only 20% of PMIs develop in the operating room.[11,12] However, the risk remains elevated during the first 2 postoperative weeks in patients undergoing orthopedic surgical procedures.[11] Patients usually exhibit the strongest stress reaction within 72 hours postoperatively. Several factors may affect the myocardial oxygen delivery (DO_2)/myocardial oxygen consumption ($M\dot{V}O_2$) balance, including discontinuance of medications or decreased doses, preoperative diet, electrolyte disorders, pain, anxiety, stress reactions, bleeding, neuroendocrine changes (increased catecholamine release triggered by postoperative pain and other stresses), and alterations in the coagulation mechanism.

Diagnosis of Myocardial Ischemia and Infarction

The diagnosis of myocardial ischemia may be overlooked in the perioperative period. Indeed, some patients with myocardial injury do not meet the diagnostic criteria for PMI. Typical anginal symptoms occur in less than one-half of patients, and the symptoms are often masked by analgesics, advanced age, and diabetes. Some patients experience vague chest pain, shortness of breath, hemodynamic instability, and palpitations. ST-segment depression is quite common, occurring in approximately 30% of patients, whereas 20% of patients have T-wave inversion, and 10% have ST-segment elevation. Conversely, ECG changes may be only minor or transient in approximately 40% of patients.[4] However, continuous ECG monitoring is not widely used, and its implementation is difficult.

Because neither clinical symptoms nor ECG changes can guarantee early recognition of PMI, the best diagnostic tool is cTn. It is also a strong independent predictor of short-term and intermediate-term mortality rates. However, the interpretation of cTn increase can be troublesome in some cases because of the interference of renal dysfunction, cerebral disease, and inflammation.

Outcome After Perioperative Myocardial Damage

Perioperative myocardial damage has been linked to short-term, midterm, and long-term cardiac morbidity and death.[9] Because perioperative myocardial damage is most often silent, many patients remain untreated. This may also contribute to an increased risk of long-term cardiovascular (CV) death. Accordingly, perioperative cardiac monitoring should be implemented to allow early diagnosis and treatment.

Short-Term Outcome

An 11% to 25% 30-day mortality rate has been reported in patients with PMI.[10,11,13] In the large Perioperative Ischemic Evaluation Study (POISE) trial,[10] the 30-day mortality rate was 11.6% among patients who had a PMI and 2.2% among patients who did not.[14] Nonfatal cardiac arrest (odds ratio [OR], 14.5), HF (OR, 10.3), and coronary revascularization interventions are more common in this population.[6] Sixty percent of patients die within 7 days after MI occurrence, most of them within 48 hours. Acute HF, cardiogenic or septic shock, and multiorgan failure are the most common causes of death.

A simple score including three independent predictors of death—age 75 years or older (1 point), anterior ischemic findings (1 point), ST-segment elevation or new left bundle branch block (2 points)—showed a good correlation with 30-day mortality rates in patients with MINS.[6] According to this scoring system, predicted 30-day mortality ranged from 5.2% if none of the aforementioned predictors were present (0 points) to 49.8% if all of them were present (4 points) (Table 52.1). Patients with MINS have a lower risk of fatal cardiac events than do patients with PMI, but a higher risk of death than patients with no elevated cardiac biomarkers. In a large, international study, the 30-day mortality rate among patients with MINS was 9.8%, as opposed to 1.1% among patients without MINS.[6,11]

Long-Term Outcome

In addition to early adverse events, cTn also predicts late mortality rates. The 1-year mortality rate following vascular surgical procedures was shown to be 20% in patients with pathologic troponin increases, as compared with 4.7% in patients with normal values.[14] Identifiers of outcome included preoperative creatinine level greater than 2.0 mg/dL (OR, 2.55), preoperative history of HF (OR, 1.96), and age older than

TABLE 52.1 A Mortality Score in Patients With Myocardial Injury After Noncardiac Surgery[a]

Predictor	*Points*
Age ≥75 y	1
Anterior ischemic findings	1
ST-segment elevation or new left bundle branch block	2

[a]Expected 30-day mortality rates: 0 points = 5.2%; 1 point = 10.2%; 2 points = 19.0%; 3 points = 32.5%; 4 points = 49.8%.

Modified from Botto F, Alonso-Coello P, Chan MT, et al. Myocardial injury after non cardiac surgery: a large, international, prospective cohort study establishing diagnostic criteria, characteristics, predictors and 30 day outcomes. *Anesthesiology.* 2014;120:564–578.

70 years (OR, 1.62). These data show that in a homogeneous group of patients with documented CAD who undergo elective vascular surgical procedures, a combination of preoperative risk variables, including age, renal function, and previous HF, along with postoperative elevations in cardiac biomarkers in diabetic patients, predicts long-term outcome.

Risk Stratification and Prevention

The treatment of patients who develop a cardiac ischemic complication during or after noncardiac surgical procedures starts with prevention, through the identification of those factors and markers that can predict a complicated course. Variables significantly associated with an increased risk of MACE are as follows: (1) patient-specific: old age, high American Society of Anesthesiologists (ASA) class and cardiac risk indexes, renal failure, and anemia; and (2) surgery-specific: type of procedure (emergency or urgent, major operation, particularly vascular) and intraoperative complications (severe hypotension, serious bleeding, increased heart rate).

Patient's Age

The incidence of PMI and MINS increases significantly in patients more than 70 years old, especially in men with CV risk factors.[11,12] The OR is 1.84 and increases by 1.5 per decile. Mortality and death from CAD are strongly associated with age. As a consequence of the aging population, it is estimated that this problem will increase in future decades. Older patients are more frail, have multiple comorbidities, and exhibit more severe CAD. They also tend to present greater technical challenges during percutaneous coronary intervention (PCI) because of heavier coronary artery calcification, tortuous anatomy in coronary and peripheral arteries, increased risk of procedure-related complications (eg, contrast-induced nephropathy, vascular or neurologic complications), and reduced tolerance to bleeding problems.

Cardiac Risk Indexes

Two clinical indexes have been developed to estimate patients' risk of perioperative cardiac complications. The Revised Cardiac Risk Index (RCRI) incorporates six independent variables that predict the risk of cardiac complications: history of ischemic heart disease, HF, cerebrovascular disease, diabetes mellitus, chronic renal failure (serum creatinine >2 mg/dL), and major operations (suprainguinal vascular, intrathoracic, and intraperitoneal). Perioperative risk of both cardiac complications (eg, nonfatal AMI and nonfatal cardiac arrest) and death increases with index scores.[15–17] For example, in a large cohort study including 782,969 patients,[15] the in-hospital mortality rate was 1.4% for RCRI of 0, 2.2% for RCRI of 1, 3.9% for RCRI of 2, 5.8% for RCRI of 3, and 7.4% for RCRI of 4 and greater.

The RCRI is currently the most widely used cardiac risk stratification tool. However, it has several limitations, including its relatively low discriminative ability. In fact, although the RCRI has a moderately good ability to discriminate patients who develop cardiac events from those who do not after mixed noncardiac surgical procedures (area under the curve [AUC], 0.75), it is less accurate in patients undergoing vascular surgical procedures (AUC, 0.64), and it is less able to predict all-cause mortality (AUC median, 0.62).[18]

To overcome these limitations of RCRI, the National Surgical Quality Improvement Program (NSQIP) score was developed and validated on 211,410 surgical patients.[19] This model includes age, ASA class, functional status, abnormal serum creatinine, and a novel and more appropriate organ-based categorization of surgery. Risk may be quantified by a risk calculator on the Internet. The discriminative or predictive ability of the NSQIP score is significantly better as compared with RCRI (AUC, 0.88 vs 0.75). This risk index works well in vascular surgical patients.

Renal Failure

The most important comorbidity associated with poor postoperative outcome is chronic kidney disease (CKD). The rate of adverse cardiac events and the length of hospital stay increase significantly in patients with impaired renal function. A post hoc analysis of a large, prospective, multicenter investigation revealed that the rate of major adverse CV and cerebrovascular events was increased (OR, 3.9) in patients with CKD from stage 3b onward (estimated glomerular filtration rate <45 mL/min).[20]

Most of the CV disease risk factors, such as older age, diabetes mellitus, systolic hypertension (longer and more severe exposure), and low levels of high-density lipoprotein cholesterol, in addition to an inflammatory and thrombogenic milieu, are highly prevalent in patients with CKD. CAD and valvular disease are more common and severe in these patients, with one-half of all deaths resulting from cardiac causes. CKD-associated anemia also reduces myocardial oxygen supply and is associated with cardiomyopathy. LV hypertrophy increases myocardial demand and evolves toward diastolic dysfunction that impairs subendocardial perfusion and may be complicated by diastolic HF. The stiff ventricle is more vulnerable to preload and afterload changes, tachycardia, and loss of atrial kick during atrial fibrillation or other arrhythmias.

Some precautions may be useful to reduce the risk of perioperative cardiac events in patients with CKD. Stress testing can identify patients with CAD. The use of short-term statins is controversial (see later), but it is part of standard care in many centers. Discontinuation of angiotensin-converting enzyme inhibitor (ACEI) therapy for at least 10 hours before general anesthesia is recommended to reduce the risk of postinduction hypotension. Anemia may require preoperative blood transfusion, supplementation with iron, or administration of erythropoietin. Patients with end-stage renal disease should undergo dialysis the day before the operation.

The main goals during surgical procedures include a mean arterial pressure greater than 65 to 70 mm Hg (or higher for the uncontrolled hypertensive patient) and adequate volume status. Particular attention should be paid to analgesic requirements in the perioperative period. Opioids may accumulate in patients with CKD, with increased risk of respiratory depression, whereas nonsteroidal antiinflammatory drugs are not recommended because of the risk of worsening renal function.[21]

In patients with renal impairment, it is appropriate to measure baseline values of troponin to compare them with the postoperative values. Troponin values may be elevated in the setting of even mild renal failure, probably reflecting microinfarctions or LV hypertrophy.[22] However, patients undergoing dialysis who have elevated troponin levels are more likely to have severe angiographic CAD and high mortality risk.[23]

Anemia and Blood Transfusion

The prevalence of preoperative anemia (hemoglobin [Hb] <13 g/dL for men and <12 g/dL for women) is increasing in the surgical population, especially in older patients. In a large (39,309 patients) European study, anemia was found in 31% of men and 26% of women.[24] Preoperative anemia is commonly associated with comorbidities such as renal failure, CAD, HF, diabetes mellitus, and hepatic cirrhosis and is known to increase mortality rates. In fact, anemia reduces D_{O_2}, increases heart rate, and may be complicated by hypotension.

After adjustment for major confounders including transfusion, preoperative anemia has been shown to be strongly associated with a more

than twofold increase in 90-day mortality rates, as well as increased postoperative intensive care unit (ICU) admission and greater use of ICU resources (hemodynamic monitoring, mechanical ventilation, inotropic and vasoactive agents).[24–26] In particular, in-hospital mortality rates increase linearly with the reduction in hematocrit.[27]

Although anemia increases mortality rates, the consequent need for transfusions also may contribute to increased mortality (according to the "second hit" theory). However, some data suggest that blood transfusions may not necessarily be harmful and, particularly, that more liberal transfusion strategies may even be associated with reduced mortality rates in certain settings.[28–31]

Patients at risk for anemia who are undergoing elective surgical procedures should be screened 4 to 8 weeks preoperatively, and the causes of anemia (eg, blood loss, nutritional deficiencies, renal failure, chronic and/or inflammatory diseases) should be identified and treated. Iron supplementation (oral or intravenous [IV], depending on iron status or tolerance and timing of the operation) is recommended (grade 1C recommendation) in patients with iron deficiency (serum ferritin <30 μg/L). The efficacy of iron supplementation in raising Hb concentration and decreasing perioperative transfusion rate is well demonstrated. If iron deficiency is ruled out, erythropoietin-stimulating agents administered up to an Hb concentration of 12 to 13 g/dL are suggested (grade 2A recommendation). The need for blood transfusions has been shown to be reduced by approximately 50% in patients treated with these drugs (data from pooled studies including mainly orthopedic surgical patients). The risk of thrombotic complications, particularly in patients with CAD, coronary stenting, or risk of venous thrombosis, should be considered.[32,33]

Type of Surgical Procedure

The type of surgical procedure is a strong risk factor for MACE and death. Urgent or emergency operation has been well recognized as the strongest predictor of death, with an increase of more than three times in 30-day mortality rates (OR, 3.5). Unfortunately, it is a largely unmodifiable risk factor.[2,5,34]

Vascular surgical procedures are associated with a twofold to fourfold higher risk of adverse cardiac events (PMI, cardiac death) as compared with other types of noncardiac operations. In fact, CAD is more common among patients undergoing vascular surgical procedures (with a prevalence ranging from 37% to 78%) than in other noncardiac surgical patients.[35] Aortic cross-clamping and declamping, abrupt changes in systemic arterial pressure, fluid shifts, hypoxia induced by one-lung ventilation, acute anemia secondary to major bleeding, and inflammatory or hypercoagulable states induced by both surgical procedures and transfusions can trigger perioperative ischemia and MI, especially in patients with CAD, acute HF, or LV dysfunction.

The vascular procedure with the highest associated mortality rate is operation for abdominal aortic aneurysmal rupture, followed by elective thoracoabdominal aortic replacement, lower extremity arterial bypass, and carotid endoarterectomy.[16,36] Patients requiring lower extremity amputation also have diffuse and severe CAD (up to 92% in a pathologic study).[37] Accordingly, perioperative risk is high in these patients, with reported 30-day mortality rates of up to 17%[38] and PMI as the leading cause of postprocedural death. Conversely, endovascular aortic repair procedures are associated with reduced myocardial stress and, accordingly, with a decreased incidence of perioperative myocardial damage.[39] However, an increase in troponin levels after endovascular aortic repair procedures has been shown to be associated with a higher long-term incidence of adverse cardiac events (49 vs 15% in a follow-up period of 3 years).[40]

Cardiac Biomarkers

Preoperative Troponin

cTn has high sensitivity for detection of small amounts of myocardial necrosis. Increased cTn levels indicate the presence of, but not the underlying reason for, myocardial injury. Besides AMI, troponin release may be associated with many other disorders including HF, sepsis, and end-stage renal disease (Box 52.1). Regardless of the cause of cTn release, elevated cTn levels almost always imply a poor prognosis.

BOX 52.1 CAUSES OF TROPONIN ELEVATION IN THE ABSENCE OF MYOCARDIAL ISCHEMIA

Cardiac Causes
- Heart failure
- Cardiac arrhythmias
- Cardioversion
- ICD shock
- Myocarditis
- Pericarditis
- Cardiac amyloidosis

Noncardiac Causes
- Sepsis and septic shock
- Pulmonary embolism
- Primary pulmonary hypertension
- Pulmonary edema
- Chronic renal failure
- Stroke
- Subarachnoid hemorrhage
- High dose of chemotherapy
- Sympathomimetic drugs

ICD, Implantable cardioverter-defibrillator.

Elevated preoperative cTn values are found in a variable proportion of patients undergoing vascular surgical procedures. In the largest trial available,[41] the preoperative finding of increased cTn (high-sensitive troponin T, hsTnT) was present in up to 24% of patients, and it was independently associated with a significantly higher risk of PMI, cardiac death, and all-cause death. Moreover, hsTnT showed an additive value (AUC, 0.80) in association with cardiac risk index (AUC, 0.65) and natriuretic peptide levels (AUC, 0.76). A combined end point (including all-cause death, PMI, acute HF, and cardiac arrest) occurred in 9.4% of patients with hsTnT levels higher than 0.014 ng/mL, as compared with 1.9% in patients with hsTnT levels of up to 0.014 ng/mL ($P < .001$).

Possible causes of elevated cTn associated with adverse outcomes include silent myocardial ischemia or microinfarction, LV dysfunction, cerebrovascular disease, renal impairment, sepsis, pulmonary hypertension, and pulmonary embolism. The need to add cTn to routine preoperative tests performed in high-risk surgical patients is still debated. According to the 2014 European Society of Cardiology/European Society of Anaesthesiology (ESA/ESC) guidelines,[42] the assessment of cTn in high-risk patients, both before and 48 to 72 hours after major surgical procedures, may be considered (class IIb, level B), even if the suboptimal specificity of this test should be taken into account.

A practical approach in patients with preoperatively increased troponin levels involves a baseline transthoracic echocardiogram (primarily assessing ventricular function and regional wall motion), a cardiologic consultation, and when feasible, deferral of operation until the troponin levels fall (Fig. 52.1). If it is not possible to postpone the procedure, a less invasive surgical approach, targeted perioperative monitoring, and careful cardiac optimization should be recommended. Moreover, patients should be informed about the increased risk.

Postoperative Troponin

Evaluation of peak cTn level during the first 3 days after noncardiac surgical procedures improves the ability to identify patients with myocardial damage, even in the absence of symptoms or ECG changes. This value is also an independent predictor of 30-day mortality rates. In a recent large international cohort study involving 15,065 patients

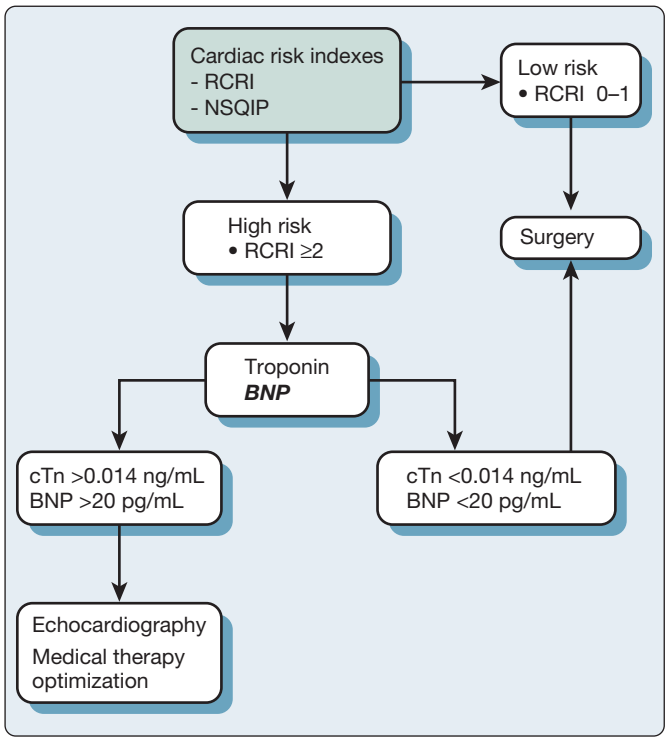

Fig. 52.1 Preoperative risk stratification. *BNP,* Brain natriuretic peptide; *cTn,* cardiac troponin; *NSQIP,* National Surgical Quality Improvement Program; *RCRI,* Revised Cardiac Risk Index.

aged 45 years old or older from five continents, an abnormal value of TnT (≥0.04 ng/mL) was found in 8% of patients within 3 days after noncardiac surgical procedures, and it was an independent predictor of 30-day mortality rates (9.8% vs 1.1%; adjusted ratio 4.82).[6] In another cohort study including 2216 subjects older than 60 years of age who were undergoing medium-risk to high-risk noncardiac surgical procedures, an elevation of cTnI (>0.06 ng/mL) was recorded in 19% of patients. The 30-day mortality rate in these patients was 8.6%, as compared with 2.2% in patients without cTnI elevation ($P < .001$). The relative risk of death was 2.4 for patients with lower increases in cTnI (0.07–0.59 ng/mL) and 4.2 for patients with higher increases (≥0.60 ng/mL). The median time to death was 12 days.[43] Perioperative cTn surveillance thus may be useful for early identification of patients at increased risk of death and may also allow prompt initiation of appropriate therapeutic interventions.

B-Type (Brain) Natriuretic Peptides

B-type (brain) natriuretic peptides (BNPs) are released from myocardium in response to multiple physiologic stimuli, including ischemia, myocardial stretch, inflammation, and other neuroendocrine triggers. Preoperative BNP levels are strong independent predictors of adverse short-term CV outcome. The preoperative addition of BNPs to the widely used risk stratification systems (RCRI and functional capacity assessment) leads to a significantly improved risk discrimination (AUC from 65% to 80%).[18,44] The predictive value of N-terminal pro–brain natriuretic peptide (NT-proBNP) seems to be higher as compared with BNP, probably because it is more indicative of baseline conditions and is less affected by transient fluctuations in concentrations, given its longer half-life.

Although the optimal cutoff of BNPs to predict CV events after surgical procedures is not well defined, converging results from several studies and metaanalyses suggest a cutoff value of approximately 20 to 30 pg/mL for BNP (with 95% sensitivity and 44% specificity), and of approximately 125 pg/mL for NT-proBNP.[44] In a relatively small prospective study in high-risk patients undergoing major noncardiac operations, a preoperative BNP level greater than 40 pg/mL allowed identification of patients with an almost sevenfold increased risk of cardiac events. In particular, each 100 pg/mL increase in BNP levels was associated with a 35% increase in the relative risk of death.[45]

The utility of BNP testing in patients with renal failure is controversial. In fact, the prognostic value of BNPs seems to be reduced as patients' glomerular filtration rate decreases. NT-proBNP has been shown to have no prognostic value when the glomerular filtration rate is less than 30 mL/1.73 m^2 per minute.[46] Conversely, one review suggested that the NT-proBNP cutoff does not require adjustment in patients with renal dysfunction.[47]

Finally, the negative predictive value of normal BNP levels (<20 pg/mL) to indicate a favorable postoperative outcome is as high as 96%,[48] a finding suggesting that patients with normal levels of BNPs may proceed directly to operation with no additional preoperative cardiac testing.[49,50]

Postoperative (days 1 to 3) measurement of BNPs in addition to preoperative values significantly improves the prediction of death or nonfatal MI at both 30 days (OR, 3.7) and more than 180 days.[51] An individual patient data metaanalysis including 2051 patients demonstrated that patients with postoperative BNP values of 0 to 250 pg/mL, greater than 250 to 400 pg/mL, and greater than 400 pg/mL reached a composite end point including 30-day death and nonfatal MI at a rate of 6.6%, 15.7%, and 29.5%, respectively. Similarly, patients with NT-proBNP values of 0 to 300, greater than 300 to 900, and greater than 900 pg/mL reached the same composite end point at a rate of 1.8%, 8.7%, and 27%, respectively.[52]

No prospective randomized controlled trials (RCTs) have investigated the use of BNP-guided management in perioperative medicine. Nevertheless, according to a metaanalysis of RCTs that showed a 48% reduction in all-cause mortality rates with BNP-guided therapy in nonsurgical patients with HF,[53] the following approach seems reasonable.[54] In the presence of clinical risk factors and/or reduced physical capacity, measurement of BNPs should be performed 4 to 5 weeks before a scheduled major operation. If BNP levels are lower than the optimal cutoff (20 pg/mL), the patient can proceed with the surgical procedure without the need for further testing. Conversely, if BNPs levels are higher than this threshold, further testing, primarily echocardiography and (BNP-guided) optimization of medical therapy (eg, fluid restriction, diuretics, ACEIs or nitrates, β-blocking agents, switching atenolol to carvedilol or bisoprolol) may be recommended.

Worsening of renal function and hypotension, sometimes also induced by ACEIs themselves, must be prevented. Specific therapeutic interventions may be considered in selected cases; for example, cardiac resynchronization therapy in patients with symptomatic NYHA functional class III disease with an LV ejection fraction (LVEF) of less than 35% and a large QRS complex (>120 ms) or transcatheter mitral clip implantation in patients with severe functional mitral regurgitation. Repeating assessment of BNPs shortly before the surgical procedure may allow for adjustment of perioperative treatment strategies (eg, choice of surgical and anesthetic techniques, perioperative monitoring, fluid, drugs, and management of devices).

Perioperative Risk Indices

Intraoperative factors identified as independent predictors of adverse postoperative cardiac events are related to surgical type (vascular surgical procedures), complexity (eg, duration of the procedure, need for blood transfusions), and urgency, as well as to physiologic insults (tachycardia, prolonged hypotension or hypertension, hypothermia).[34,55]

A metaanalysis of 14 studies, including mainly nonrandomized evidence, found a strong association between the need for blood transfusions and postoperative cardiac events. Unfortunately, it was not possible to define an accurate point estimate associated with the risk of adverse cardiac events. CV physiologic variables (eg, >20 mm Hg fall in mean arterial pressure lasting >60 min, >30% increase in baseline systolic pressure, tachycardia in the recovery room, and transmitral flow propagation <45 cm/s) were shown to be independently

BOX 52.2 THE SEVEN ANESCARDIOCAT SCORE FACTORS[a]

1. History of coronary artery disease
2. History of chronic congestive heart failure
3. History of cerebrovascular disease
4. Chronic kidney disease
5. Preoperative abnormal ECG (LV hypertrophy, LBBB, ST-T abnormalities)
6. Intraoperative hypotension (≥20 mm Hg or ≥20% fall in MAP for >1 h)
7. Blood transfusion

[a]Risk of major adverse cardiac and cerebrovascular events: 0 factors = 1.5%; 1 factor = 4.5%; 2 factors = 8.9%; ≥3 factors = 20.6%.
ECG, Electrocardiogram; *LBBB*, left bundle branch block; *LV*, left ventricular; *MAP*, mean arterial pressure; *ST-T*, ST-segment and T-wave.

associated with adverse outcomes in some of the included studies. In the only investigation that controlled for blood transfusions, the aforementioned association was not observed. This finding suggests that changes in physiologic variables (eg, hypotension, tachycardia, and hypothermia) may jointly contribute with anemia to the increased cardiac risk observed in patients needing blood transfusions; however, these variables become independently predictive only in the absence of the need for blood transfusions.[34]

The ANESCARDIOCAT score stratifies patients undergoing elective or emergency noncardiac interventions of intermediate-to-high surgery-specific risk in four groups with different (very low, low, intermediate, and high) degrees of risk of major adverse cardiac and cerebrovascular events (MACCE). This scoring system is based on the following factors: intraoperative hypotension, defined as 1 hour of a 20 mm Hg or greater decrease or a 20% change in mean arterial pressure; need for blood transfusion; history of CAD, HF, and/or cerebrovascular disease; CKD; baseline ECG abnormalities including LV hypertrophy, left bundle branch block, and ST-segment and T-wave abnormalities (Box 52.2). The predicted rate of MACCE was 1.5% if none of these factors was present (very low risk), 4.5% in the presence of one factor (low risk), 8.9% in the presence of two factors (intermediate risk), and 20.6% when three or more factors were present (high risk).[3] Among the foregoing predictors of postoperative adverse cardiac events, physiologic variables (and, to a certain extent, transfusions) are the main factors potentially modifiable by anesthesiologists and may thus offer an opportunity to improve patients' outcomes.

Postoperative Management

In patients at high risk for PMI, an electrocardiogram and a blood sample for troponin should be obtained at baseline, immediately postoperatively, and after 6 and 12 hours, as well as once a day for the first 3 postoperative days to detect early myocardial damage. As mentioned, ECG abnormalities such as ST-segment depression, transient ST-segment elevation, and/or prominent T-wave inversions may be present, but they are not required for the diagnosis of PMI or perioperative myocardial injury. Consultation with a cardiologist is always appropriate. Echocardiography is helpful for detecting the site and extension of regional wall motion abnormalities and to quantify global cardiac function.

Adequate analgesia and sedation are pivotal to prevent or minimize the deleterious effects of sympathetic stimulation on myocardial ischemia. Of course, hemodynamic stability plays a key role in preventing adverse cardiac events: adequate DO_2 should be maintained by adequate Hb levels (≥8 g/dL at least, although higher Hb values, for example between 9 and 10 g/dL, may be desirable to improve outcome).[28,29,31]

Finally, active prevention of infection may help reduce the incidence of PMI, given both the "hemodynamic" changes induced by sepsis, or simply by fever (eg, tachycardia), and the myocardial dysfunction associated with severe sepsis and septic shock.[56]

Medications and Percutaneous Interventions to Prevent and Treat Perioperative Major Adverse Cardiac Events

Few RCTs have evaluated the efficacy of medical or interventional treatments in reducing in-hospital and long-term outcomes after PMI in noncardiac surgical procedures. Accordingly, the following considerations about drug therapy and PCI for PMI are mainly extrapolated from evidence on management of acute coronary syndromes in the nonsurgical setting,[57–60] by adapting the strategies generally used in the coronary care unit (CCU) to the scenario of perioperative ICU.

Statins

Statins (3-hydroxy-3-methyl-glutaryl–coenzyme A reductase inhibitors) have a strong protective effect against cardiac complications in patients undergoing surgical procedures.[61–69] A large, retrospective cohort study including 77,082 patients showed significantly reduced in-hospital mortality rates following major noncardiac surgical procedures in statin-naïve patients treated with statins (OR, 0.62; 95% confidence interval [CI], 0.58–0.67).[61] These findings were confirmed by a metaanalysis of RCTs that found a significant reduction in both MI rate (relative risk [RR], 0.53; 95% CI, 0.37–0.77; $P = .001$) and 30-day mortality rate (RR, 0.50; 95% CI, 0.27–0.91; $P = .02$) in the subgroup of patients undergoing noncardiac surgical procedures who were treated with statins for longer than 1 week preoperatively.[62] In a retrospective study, symptomatic patients undergoing carotid endarterectomy and taking statin therapy at the time of hospital admission had a significantly lower mortality rate as compared with patients who were not treated with statins (OR, 0.25; 95% CI, 0.07–0.90).[63]

Statins contribute to plaque stability by means of reducing plaque size (through lipid lowering), modifying the physicochemical properties of the lipid core, and decreasing oxidative stress and inflammation (by inhibition of macrophage accumulation and metalloprotease production). Moreover, statins improve endothelial function and inhibit thrombogenic response. High doses of atorvastatin (80 mg daily; 40 mg/day in older adults) seem to be more effective than standard doses in reducing CV mortality rates and rates of recurrence of unstable angina and MI, as well as the need for myocardial revascularization (class 1 recommendation, level of evidence A). A metaanalysis of 4 large trials including a total of 27,548 patients found a significant 16% reduction in both coronary death or MI ($P < .00001$) and any CV event in patients treated with high-dose statin therapy, as compared with patients receiving standard doses.[70] Treatment with high doses should be continued for at least 1 year. However, benefits occur as early as 30 days. Lack of perioperative use of statins was found to be one of the clinical variables, along with peak postoperative troponin levels, associated with 2.5-year death after vascular surgical procedures (OR, 0.19; 95% CI, 0.07–0.49; $P < .001$).[71]

Among the drugs used for the treatment of PMI, statins are the easiest to handle. Indeed, contraindications (ie, pregnancy, acute hepatic injury, porphyria) are uncommon, and high doses are usually safe (rhabdomyolysis and myopathy are infrequent) and well tolerated. Furthermore, statins may exert a protective effect on both the brain (prevention of delirium and stroke) and the kidneys (enhanced recovery of renal function after acute kidney injury) in vascular surgical patients, and they may also have a therapeutic role in sepsis and venous thrombosis.[72,73]

However, critically ill patients with a complicated course should be closely monitored because they represent a population at increased risk of important statin side effects or drug interactions that may go unnoticed. In patients who require treatment with drugs that increase the plasma concentration of statins through interaction with CYP3A4 (eg, calcium channel blockers, antifungal agents, and macrolides), the use of pravastatin or fluvastatin may be preferable because these statins are not primarily metabolized by CYP3A4. Conversely, rifampicin, phenobarbital, carbamazepine, and phenytoin induce both CYP3A4 and CYP2C9, thus leading to increased metabolism of liver-metabolized statins. Accordingly, the lipid-lowering effect of statins can be reduced by concomitant use of these drugs. Finally, when statin therapy is initiated or whenever any change in statin use occurs (except for pravastatin), careful monitoring of the international normalized ratio (INR) is recommended in patients taking warfarin because of the potential risk of bleeding complications. In practice, perioperative initiation of high-dose statins to prevent PMI is reasonable (class IIa, level B) before vascular surgical procedures and may be considered (class IIb, level C) in other high-risk surgical procedures.

β-Blockers

It is generally accepted that patients previously treated with β-blockers should receive these drugs in the perioperative period. β-Blocker therapy can be a double-edged sword, however. β-Blockers exert a cardioprotective effect by reducing $M\dot{V}O_2$, the rate of atrial and ventricular arrhythmias, and mechanical stress on vulnerable plaques. However, they may cause hypotension and hinder an increase in cardiac output (CO) when it is required. Probably because of this ambivalence, in a large trial (POISE) the *intraoperative* use of β-blockers in *unselected patients* was shown to lead to a reduction of PMI, as well as to a dangerous increase in stroke and mortality rates.[10] In patients with intermediate-risk or high-risk myocardial ischemia as documented by preoperative stress testing and who accordingly are *at increased risk of PMI*, the risk/benefit ratio appears to be favorable. Therefore preoperative (2–7 days before the operation) β-blocker therapy is indicated for reduction of PMI in these patients, although the grade of recommendation is weak (class IIb, level C). The rationale for the use of β-blockers *in patients with ongoing MI* is twofold: in the early hours, these drugs reduce infarct size; in the following days, they have an antiremodeling effect. Regarding the use of β-blockers in CCU, the recommendations of American Heart Association (AHA) and those of ESC differ.

AHA guidelines suggest that it is reasonable to administer IV β-blockers at admission, unless they are contraindicated, in patients with MI who are hypertensive or have ongoing ischemia, and that an oral β-blocker should be initiated in any patient, with no contraindications, within the first 24 hours (class 1, level A).[57] The main contraindications to β-blocker therapy include symptomatic HF, low-output states, a PQ interval greater than 0.24 milliseconds, second- or third-degree atrioventricular block without a cardiac pacemaker, active asthma, and the presence of risk factors for cardiogenic shock (ie, late diagnosis [>12 h] of AMI, age >70 years, systolic arterial pressure <120 mm Hg, heart rate <60 bpm, and heart rate >110 bpm).

ESC guidelines are less categorical because most trials were conducted before the advent of modern reperfusion strategies. The role of routine early IV β-blocker administration is less clearly established, and higher IV doses may be associated with early hazard and increased mortality rates.[59]

β-Blocker use has been associated with reduction of adverse events, including death, in patients who do not undergo reperfusion. Conversely, in patients who underwent myocardial revascularization, the benefits are limited to a reduction of MI and angina, but at the price of an increased risk of HF and cardiogenic shock.[74]

Anemia is a cause for concern, particularly in older adults, when using β-blockers. In a large, single-center, propensity-matched cohort study including 4387 patients and focusing on acute surgical anemia, β-blocker therapy was found to be associated with a greater incidence of MACE (RR, 2.38; 95% CI, 1.43–3.96; $P = .0009$) only when Hb levels dropped by more than 35% from baseline.[75] Anemia may worsen the perioperative adverse effects of β-blockade by further limiting $D\dot{O}_2$. Conversely, the ability of the heart to increase stroke volume (SV) at an Hb value between 9 and 10 g/dL is rate dependent. An animal study found that cerebral oxygenation was maintained during hemodilution, but it was reduced after short-term administration of metoprolol because the compensatory increases in both CO and cerebral blood flow were severely attenuated.[76] Given the circulatory abnormalities of older patients, anemia and decreased CO are potential mechanisms for the increased stroke rate found in the POISE trial.[77]

Perioperative β-Blocker Strategy

β-Blockers may be started in ICU patients *with PMI* (without contraindications). However, some precautions should be taken to make the use of these drugs safer.

Oral administration of β-blockers is indicated in all patients not undergoing PCI because of the antiischemic effect of these drugs. Oral β-blocker therapy is also indicated, in association with ACEIs and aldosterone antagonists, in patients who have undergone coronary revascularization with a moderate-to-large MI (LVEF <40%), to achieve an antiremodeling effect. It is advisable to start *2 or 3 days postoperatively* with *low doses* of a β_1-selective antagonist (bisoprolol 1.25 mg daily, metoprolol 25 mg twice daily [bid]) or an α_1/β-antagonist (carvedilol 6.25 mg bid) and gradually titrate doses over time.

Early IV administration should be limited to patients with tachycardia and hypertension (to decrease $M\dot{V}O_2$) and to patients with atrial fibrillation when rate control is needed. The indication for use is more compelling in patients not undergoing PCI. Before IV administration of β-blockers, any risk condition that may underlie (compensatory) tachycardia should be excluded or treated. Patients with acute anemia may need blood transfusion rather than (or before) β-blockers. Echocardiography should be performed to rule out severe impairment of LV function, particularly if associated with functional mitral regurgitation and/or right ventricular dysfunction. An attractive choice, because of its very short half-life, is esmolol (a test dose of 20 mg; bolus injection of 0.5–1 mg/kg over 30 s; followed by continuous infusion of 50 μg/kg per min, up to 300 μg/kg per min).

Oral (2.5–5 mg bid) or IV (5 mg bolus followed by 5 mg infusion over 8 h) ivabradine, a cardiac pacemaker "funny channel" (I_f) inhibitor, could be an attractive alternative to β-blockers for patients at risk of hypotension. The efficacy and safety of IV ivabradine administration in STEMI were demonstrated in a pilot study of 124 patients treated with PCI, in which heart rate was reduced by 22 bpm, on average without hypotension, and LV volumes were lowered (anti–adverse remodeling effect) as compared with patients not receiving ivabradine.[78]

Angiotensin-Converting Enzyme Inhibitors and Aldosterone Antagonists

ACEIs and aldosterone antagonists (spironolactone, eplerenone) are highly recommended (class 1, level A) in patients with a large PMI, reduced LV systolic function (LVEF <40%), or diabetes mellitus. ACEIs can be used safely in patients with stable renal insufficiency (up to a creatinine level of 3 mg/dL). Aldosterone blockade is contraindicated in patients with severe renal dysfunction (creatinine >2.5 mg/dL in men and >2 mg/dL in women; or serum potassium levels >5 mEq/L). In patients who are intolerant of ACEIs (cough), the angiotensin receptor antagonist valsartan (80 mg bid, up to 160 mg bid) is recommended and well tolerated. During the first weeks of treatment, serum potassium and creatinine levels should be monitored closely. The greatest benefits in patients with large MI (antiremodeling effect) are obtained when administration of ACEIs is started within 24 hours. However, the hemodynamic impact of aggressive ACEI (as well as β-blocker) therapy in the early postoperative period remains to be investigated.

Nitrates

Nitrates such as nitroglycerin reduce $M\dot{V}O_2$ by decreasing LV preload and afterload, and they increase coronary blood flow by dilating capacitance vessels. However, the main limitations of nitrate therapy are the reflex increase in heart rate and contractility induced by peripheral vasodilation that reduce the hemodynamic benefits of nitrates on $M\dot{V}O_2$, the early occurrence of tolerance, and the lack of proven benefits on MACE. For these reasons, IV administration of nitrates is indicated for a short period (usually <24 h) and only for the treatment of persistent myocardial ischemia (ST-segment elevation or depression), particularly when complicated by systemic hypertension or HF. Nitroglycerin should not be administered to patients with myocardial ischemia and hypotension unless it is used concomitantly with an arterial vasoconstrictor such as phenylephrine, and it should be used with caution in patients with right ventricular infarction (as a result of the preload dependence of pulmonary output). Because no improvement in outcomes has been shown, long-term (oral or transdermal) administration of nitrates should be restricted to patients with HF who cannot tolerate ACEIs.

Antithrombotic Agents

Antiplatelet drugs comprise the cornerstone of management of acute coronary syndromes in the nonsurgical setting. Early and aggressive treatment with dual antiplatelet therapy (DAPT) is routinely used to prevent complete coronary occlusion or stent thrombosis after revascularization. Adverse cardiac events have been shown to be significantly reduced with DAPT, whereas the absence of antithrombotic therapy is an independent risk factor for death.[58–60] However, this therapeutic strategy has the untoward effect of increasing the risk of bleeding events, especially gastrointestinal (GI) bleeding as a result of direct damage to the gastric mucosa and inhibition of prostaglandin production, and it may be particularly hazardous in the perioperative period. Aspirin is the established first-line therapy (class 1 recommendation, level of evidence A). The initial loading dose is 162 to 325 mg daily, subsequently reduced to a maintenance dose of 81 to 162 mg to minimize the risk of bleeding. A platelet receptor P_2Y_{12} inhibitor (clopidogrel, prasugrel, or ticagrelor) is usually administered in addition to aspirin because DAPT has been shown to be superior to aspirin alone in reducing adverse events.[79] Approved P_2Y_{12} inhibitors (class 1 recommendation) include the following:

- Clopidogrel, 600 mg loading dose, then 75 mg daily (level of evidence B in the United States, C in Europe)
- Prasugrel, 60 mg loading dose, then 10 mg daily (level of evidence B)
- Ticagrelor, 180 mg loading dose, then 90 mg twice daily (level of evidence *B*)

Compared with aspirin alone, clopidogrel was found to reduce the incidence of a composite end point of CV death, nonfatal MI, and stroke at 30 days by 20%.[79] The efficacy of clopidogrel, however, is limited by the delayed onset of its effect (several hours after ingestion), secondary to the slow biotransformation from prodrug to the active metabolite, as well as by the substantial interpatient variability in the response to the drug. Another limitation of clopidogrel is its irreversible platelet inhibition.

Ticagrelor and prasugrel have a faster onset of action and provide greater and more consistent platelet inhibition. These pharmacokinetic and pharmacodynamic advantages translate to greater outcome improvement. In fact, as compared with clopidogrel, ticagrelor and prasugrel were found to reduce the same composite end point by 16% and 24%, respectively.[80,81] Ticagrelor has some advantages over prasugrel. Prasugrel is not recommended (at the dose of 10 mg daily) in patients with a history of transient ischemic attack or stroke because of an increased risk of fatal intracranial bleeding, and it has neither clinical benefit nor greater sensitivity to bleeding in patients with a body weight of less than 60 kg or in patients older than 75 years of age. In patients older than 75 years of age or patients weighing less than 60 kg, a dose of 5 mg daily of prasugrel can be given, but its efficacy and safety have not been prospectively assessed. Moreover, administration of prasugrel before coronary angiography in patients with NSTEMI did not lead to a reduction in the primary end point when compared with the drug's administration at the time of PCI.[58]

Consistent with the more pronounced antiplatelet effects, major bleeding is more common with ticagrelor and prasugrel than with clopidogrel. Nevertheless, the balance between safety (bleeding) and efficacy (reduction of adverse outcomes) favors prasugrel and ticagrelor.

Unfortunately, PMI usually occurs within 3 days after surgical procedures, and this timeline limits the early and widespread use of these drugs in the postoperative ICU setting because they may lead to significant bleeding both at the surgical site and in the GI tract. To date, no specific studies have addressed the risks of surgical bleeding in patients treated with antiplatelet agents for PMI. Available data mostly come from investigations performed in cardiac surgical patients in stable condition and *without PMI* who are treated shortly after surgical procedures with antiplatelet drugs because of previous coronary stents; these investigations showed an increased risk of bleeding, reexploration, and transfusions. In a large study involving 4998 noncardiac surgical patients (65% of whom were undergoing orthopedic or general operations; only 6% vascular operations) without PMI, perioperative aspirin administration increased the risk of major bleeding by approximately 20% (4.6 vs 3.8%; hazard ratio [HR], 1.23; 95% CI, 1.01–1.49; $P = .04$).[82]

The decision to administer DAPT, as well as its timing, in patients with PMI is challenging. Perioperative bleeding itself is an independent predictor of adverse outcome. In-hospital mortality rates are approximately 10% to 20% for major bleeding, as compared with 10% for reinfarction and 3% for stroke.[83] The reason for such high mortality rates is multifactorial and includes the burden of comorbidities, bleeding-related hemodynamic instability, the possible unfavorable impact of blood transfusions on outcome, and the risk of stent thrombosis or reinfarction resulting from discontinuation of antithrombotic agents. Clinical factors that carry additive risk for GI bleeding are advanced age (>70 y), diabetes mellitus, HF, a history of ulcers and previous GI bleeding, alcohol abuse, and renal failure.[84,85] Advanced age predisposes patients to a greater risk of bleeding because of vessel injuries caused by aging, whereas patients with renal failure have advanced and diffuse arterial disease and coagulation abnormalities, and they are more prone to antithrombotic overdose resulting from reduced clearance.

Strategy for Using Antithrombotic Agents While Minimizing the Risk of Bleeding

Several strategies may help prevent bleeding in patients who require antithrombotic therapy, including the following: prophylaxis of GI bleeding with high doses of proton pump inhibitors; tailoring antithrombotic drug doses according to age and renal function; use of fondaparinux or bivalirudin, which are proven to have a lower rate of bleeding complications; and the adoption of radial access, vascular closure devices, and ultrasound-guided femoral access in patients undergoing PCI. In particular, the use of proton pump inhibitors in patients receiving antiplatelet drugs, including clopidogrel, has been associated with a significant reduction in the risk of GI bleeding, erosions, and ulcers.[86–88] The use of point-of-care platelet function monitoring may have the potential to guide antiplatelet therapy in the early perioperative period to optimize the balance between cardiac protection and the risk of bleeding. However, no aggregometry targets have been identified that could be clinically useful for this purpose in the noncardiac surgical perioperative period.

Blood transfusion is reasonable (benefits probably exceed the risks) in patients with hemodynamic instability and hematocrit lower than 25% or Hb lower than 8 g/dL. Controversies still remain for higher Hb concentrations. Restrictive transfusion strategies were formerly thought to be associated with better outcomes, but newer data seem to suggest that more liberal transfusion triggers may reduce mortality rates in certain patients. In patients receiving antiplatelet therapy,

platelet transfusion may be considered even when the platelet count is normal if hemorrhage continues despite the usual hemostatic techniques.

Postoperative patients admitted to the ICU may be intubated and unable to swallow. In these cases, antiplatelet drugs can be administered through a nasogastric tube after crushing the tablets (and mixing the resulting powder with 50 mL of water). In healthy volunteers, the administration of crushed tablets resulted in faster and greater bioavailability as compared with whole tablets.[89] However, careful attention should be paid to those conditions of reduced enteral absorption or impaired hepatic metabolism that may affect both pharmacokinetics and pharmacodynamics of orally administered antiplatelet drugs.

Percutaneous Coronary Intervention

Early primary PCI with stenting, performed by an experienced team, is the preferred therapeutic option for STEMI. Normal anterograde flow is restored in approximately 90% to 95% of patients. DAPT is mandatory to prevent stent thrombosis, but it increases bleeding risk in the perioperative period. Before excluding PCI because of the risk of bleeding, however, the following data coming from CCU cases should be considered. As compared with thrombolysis, primary PCI resulted in a 25% reduction in mortality rate and in a 64% reduction in reinfarction.[90] Conversely, thrombolytic therapy was shown to reduce hospital mortality rates by 18% (10.7% vs 13%; OR, 0.81), as compared with medical therapy (without DAPT).[91] Accordingly, the overall reduction in mortality rates with PCI, as compared with medical therapy, may be estimated to be 50%. Despite the lack of specific evidence, PCI should always at least be considered in patients with perioperative STEMI. Coronary angioplasty without stenting with a medicated balloon (to avoid the immediate need for DAPT) may be an option in patients at high-risk of bleeding.

Treatment of Perioperative Myocardial Infarction

Treatment should be individualized according to the following: (1) age, comorbidity, and life expectancy of the patient; (2) hemodynamic status; (3) type of PMI (STEMI, NSTEMI) or MINS; and (4) the balance between the risks of death and bleeding (Fig. 52.2). Patients with significant ST-segment changes, hemodynamic or electrical instability, recurrence of angina are admitted to the ICU or CCU. High-dose atorvastatin and low-dose aspirin, when the bleeding risk is acceptable, are recommended in all patients.

Age and Comorbidity

Age is one of the most important predictors of risk with a PMI. Patients older than 75 years of age have a mortality rate at least doubled that of younger patients. Moreover, the risk of complications of MI increases with age. Older patients are also at higher risk of side effects of medical treatment, particularly bleeding from antithrombotic agents, hypotension and bradycardia from β-blockers, and renal failure. Accordingly, drugs should be used with caution, generally at lower doses, and adapted to estimated glomerular filtration rate. Nevertheless, older patients have the largest survival benefit from an invasive rather than a conservative strategy, although at the price of an increased risk of major bleeding and need for transfusions. Age therefore should not constitute a contraindication to aggressive treatment. The advice of all of the clinical team about risks and benefits of aggressive versus medical treatment of PMI, as well as the patient's perspective, is important for both frail older patients and patients with serious comorbidities (eg, severe hepatic, pulmonary, or renal failure, active or inoperable cancer).

Patients in Unstable Condition

Patients with PMI and hemodynamic instability require a rapid and aggressive diagnostic and therapeutic approach. First, major surgical bleeding leading to MACE must be excluded as the primary cause of instability. Most cases of PMI complicated by hemodynamic instability are caused by severe ischemic LV dysfunction associated with extensive or proximal CAD. Hypotension in the presence of critical coronary artery stenosis dramatically reduces coronary blood flow, whereas tachycardia increases $M\dot{V}O_2$, thus creating a vicious cycle that can lead to cardiogenic shock. In-hospital mortality rates can reach 30% to 50%. In view of the high mortality rates with medical treatment, immediate coronary angiography and PCI are recommended after administration of DAPT. PCI in patients in unstable condition may be limited by the no-reflow phenomenon, as well as by the greater risk of stent thrombosis associated with a low-flow state, although in some cases the improvement in 6-month survival rate, compared with medical therapy, is significant.[92] Patients in cardiogenic shock with multivessel CAD may have the best chance of survival with PCI of all proximal critical stenoses.

The supportive treatment of patients with ongoing ischemia, cardiac dysfunction, and hypotension is particularly difficult because catecholamines may increase infarct size and produce atrial or ventricular arrhythmias, and they are poorly tolerated in patients with right ventricular dysfunction.

Intraaortic balloon pump (IABP) counterpulsation is used in this situation to increase both myocardial perfusion and CO. However, data showing improved survival in noncardiac surgical settings are lacking.[93] The risk/benefit ratio of IABP use should be carefully evaluated in patients with aortic aneurysms or peripheral vascular disease. Particular attention should be paid to patients with peripheral vascular disease who are at risk of ischemia of the lower limb. Finally, if an atrial arrhythmia is present in the patient in unstable condition, synchronized electrical cardioversion is mandatory.

Patients in Stable Condition

In hemodynamically stable patients, the choice of the best therapeutic strategy should take into account the balance between the risk of death from PMI and the risk of major bleeding in the perioperative period. *Risk of death* can be easily calculated at the bedside (also with the aid of specific mobile phone applications) by using TIMI (Thrombolysis in Myocardial Infarction) or GRACE (Global Registry of Acute Cardiac Events) risk scores (Tables 52.2–52.4). These scoring systems, validated in nearly 35,000 patients with both STEMI (TIMI and GRACE) and NSTEMI (GRACE), show a strong predictive ability and an excellent concordance with observed 30-day, 6-month, and 12-month mortality rates.[94–98] Both TIMI and GRACE scores identify a subgroup of patients at high risk of cardiac death who probably need an aggressive invasive therapeutic strategy despite the risk of bleeding, as well as a subgroup of low-risk patients, who may be managed with medical therapy, especially if the bleeding risk is high.

TABLE 52.2 TIMI (Thrombolysis In Myocardial Infarction) Score (ST-Segment Elevation Myocardial Infarction)

Factor	*Points*
Age 65–74 y; ≥75 y	2; 3
Systolic arterial pressure <100 mm Hg	3
Heart rate >100 bpm	2
Killip class 2–4	2
Anterior STEMI or left bundle branch block	1
Diabetes or hypertension or angina	1
Weight <67 kg	1
Time to treatment >4 h	1

STEMI, ST-segment elevation myocardial infarction.

The *risk of bleeding* is related to surgical factors and patient factors. With regard to the hemorrhagic risk, surgical interventions can be classified into low-risk, medium-risk, and high-risk procedures (Table 52.5), according to previous studies and expert opinion. A patient's individual risk may be predicted using the CRUSADE (Can Rapid Risk Stratification of Unstable Angina Patients Suppress Adverse Outcomes With Early Implementation of the ACC/AHA Guidelines) bleeding score (Table 52.6, Fig. 52.3), developed in approximately 89,000 patients with STEMI or NSTEMI.[85]

ST-Segment Elevation Myocardial Infarction

Elevation of ST segments usually results from an *acute coronary thrombotic occlusion*. In this setting, urgent coronary angiography and PCI lead to a significant reduction in mortality rates. Accordingly, these procedures should always be considered in patients with perioperative STEMI, especially in those with good life expectancy and moderate-to-large infarctions. In our opinion, only patients at low risk of death (<3%–5%) and, at the same time, at high-risk of bleeding should be treated with medical therapy alone.

Infarction size can be quantified by echocardiography and by both clinical and ECG parameters. Signs of large infarctions include the presence of pulmonary rales, ECG changes involving more than three leads, ST-segment elevation in aVR (which suggests left main or proximal left anterior descending artery stenosis), new onset of bundle branch block or arrhythmias in inferior infarction, a reduction of LVEF (< 40%), or right ventricular involvement.

Before a PCI procedure, a loading dose of aspirin (162–325 mg), together with a loading dose of a P_2Y_{12} inhibitor (clopidogrel 600 mg, prasugrel 60 mg, ticagrelor 180 mg), should be administered as early as possible. Clopidogrel may cause less bleeding, but it is also the least effective. Prasugrel should be avoided in patients with a history of transient ischemic attack or stroke, body weight less than 60 kg, and age older than 75 years.

Non–ST-Segment Elevation Myocardial Infarction

Three characteristics distinguish NSTEMI from STEMI. First, NSTEMI may result from a *myocardial oxygen supply/demand mismatch* induced by extracardiac causes. The treatment of these causes may reverse ischemic changes. Second, in most cases *no complete thrombotic occlusion* of a coronary artery is accountable for the infarction, but only a critical stenosis often involving multiple coronary vessels. Accordingly, as compared with STEMI, the need for urgent PCI is less compelling, especially if the hemorrhagic risk is high, as in the perioperative period. Finally, the incidence of adverse events at 1-year follow-up is higher in NSTEMI than in STEMI. As a consequence, a strategy of routine invasive therapy before hospital discharge has been shown to be generally superior to medical therapy alone.

Myocardial oxygen supply/demand mismatch is typically induced by hypotension, acute anemia, or hypertension and tachycardia, usually in patients with CAD, LV hypertrophy, and/or aortic stenosis. Before antiischemic therapy is begun, these causes must be found and treated vigorously. Moreover, anemia from acute bleeding is an absolute contraindication to reperfusion and antiplatelet therapy. After underlying causes are excluded (ie, pain, anemia, hypoxemia), tachycardia should be treated to reduce infarct size. IV β-blockers are then continued orally to control heart rate and hypertension.

Coronary angiography is recommended before hospital discharge in patients at high cardiac risk (diabetes, renal failure, significant ST-segment depression, LVEF <40%, previous PCI or coronary artery bypass graft, GRACE risk score >109).

Myocardial Injury After Noncardiac Surgery

High-dose statins (atorvastatin 80 mg daily), aspirin (325 mg day 1, then 100 mg daily), and low-dose oral β-blockers (eg, bisoprolol 1.25 mg daily) should be initiated within 24 hours in all patients without contraindications. A $P2Y_{12}$ inhibitor (eg, ticagrelor 90 mg bid) may be added to low-dose aspirin in the postoperative period. ACEIs should be started in patients with an LVEF of less than 40%, hypertension, diabetes, and stable CKD.

An invasive strategy (coronary angiography and PCI) before hospital discharge is indicated in patients in whom angina or hemodynamic or electrical instability develops during mobilization. PCI is also reasonable in patients without severe comorbidities who are asymptomatic but who have a high risk of short-term cardiac events (GRACE score >140). In the remaining low-risk patients, an ischemia provocative test during medical therapy is recommended before discharge; coronary angiography is performed if myocardial ischemia is documented unless the patient has extensive comorbidities.

The hypothesis that providing appropriate therapy to patients with MINS may limit long-term mortality was validated in a study in 667 consecutive patients undergoing major vascular surgical procedures. Patients with postoperative elevated troponin levels, but not receiving early evidence-based CV therapy (antiplatelet agents, β-blockers, statins, ACEIs), had a significant increase in MACE (death, AMI, HF, myocardial revascularization) at 12 months (HR, 2.80; 95% CI, 1.05–24.2; $P = .04$).[99]

Perioperative Care to Reduce Mortality Rates in Noncardiac Surgical Procedures

The all-cause mortality rate after noncardiac surgical procedures has been reported to be 0.8% to 1.5%.[42] However, postoperative mortality rates may greatly increase according to patient-related and procedure-related factors, such as age (≥80 y), ASA physical status grade of 3 or greater, cancer, surgical specialty (GI, thoracic, and vascular surgical procedures are those at higher risk), and the severity and urgency (expedited, urgent, immediate) of the procedure.[100] Moreover, large differences in mortality rates exist among different countries,[2] and even among different centers. With more than 230 million major surgical procedures performed annually worldwide,[1] even small reductions in perioperative mortality rates would result in thousands of lives saved each year.[101]

In their daily clinical practice, anesthesiologists make many choices that can affect clinically relevant outcomes in the (1) preoperative period (drug continuation or discontinuation), (2) operating room (anesthetic technique, airway management, type and amount of fluids administered, hemodynamic monitoring and optimization, type and age of blood products administered and transfusion triggers); and (3) postoperative care (cardiocirculatory support, ventilation, drug prescriptions). However, for nonsurgical interventions (drugs, techniques, strategies), evidence from RCTs and consensus on their impact on postoperative mortality rates are limited.[101,102] For example, a systematic review found no evidence derived from high-quality studies even to support routine preoperative testing in unselected adults undergoing noncardiac surgical procedures.[103]

We developed a novel approach to consensus building that made it possible to summarize the best-quality and most widely agreed-on evidence about mortality reduction in different settings, including the noncardiac surgical perioperative period.[101,102,104–108]

"Democracy-Based," Web-Enabled Approach to Consensus on Perioperative Mortality Reduction

Physicians should base their clinical decisions mostly on the best evidence available in the literature. However, must always contend with the challenging issue of understanding the meaning, applicability, robustness, and biologic plausibility of clinical evidence coming from published studies.[109] Moreover, although some topics lack high-quality investigations from which to draw conclusions, at other times a plethora of often contradictory data does not allow clinically useful synthesis. In both cases, guidelines may be inconclusive or even lacking.[108] Consensus conferences are currently considered the best way to assess evidence systematically and to reach agreement among experts, particularly when no definitive conclusions can be drawn from RCTs or metaanalyses. This approach, unfortunately, has some limitations, including the high priority given to expert opinions (with a poor definition of "expertise"), the risk of influences and biases, as well as the possibility that the resulting recommendations may not be widely applicable.[108,110,111]

A "democracy-based" process, feasible thanks to the advent of the Internet, was suggested as a possible alternative to the "traditional" approach to consensus on mortality reduction.[101,102,104–109,111] This method brings together the features of consensus conferences, international surveys, and systematic reviews, thus leading to a rigorous selection of published evidence through an open, dynamic, comprehensive, and easily reproducible process that also provides insightful details on current worldwide clinical practice.[108,111]

The Five Steps of Consensus Building

1. *Literature search and analysis*. One or more search strings, together with contacting experts and authors of collected manuscripts and assessing references of recent reviews and guidelines, are used to identify all interventions with an influence on mortality. From 2010 to 2013, the "democracy-based" consensus method was applied to four different settings: cardiac surgical procedures,[104] the perioperative period of any surgical procedure,[101,102] acute kidney injury,[105] and critically ill patients,[106,107] with small differences in the article collection strategy, mostly related to the type of evidence considered. The identified articles are then reviewed by a trained team of physicians. For postoperative mortality reduction, articles are included in the subsequent step if they fulfill the following criteria: dealing with nonsurgical interventions (drugs, strategies, or techniques), reporting a statistically significant effect on mortality rates, published in a peer-reviewed journal, and including adult patients.
2. *First Internet-based survey*. Many colleagues, including professionals and experts in the field, especially corresponding authors of recently published articles, are asked through a Web-based poll whether they agree or not with the beneficial or unfavorable effect on mortality of the listed interventions. Moreover, they are invited to suggest further topics or articles and to add comments.
3. *Consensus meeting*. A task force of anesthesiologists, intensivists, surgeons, cardiologists, and epidemiologists meets to discuss and, if necessary, to vote on each topic, after it has been presented by previously designated discussants and taking into account the results of the Web polling. Moreover, new articles suggested by participants are evaluated for inclusion. A brief summary statement describing the effects on mortality and the reasons for the inclusion is finally formulated for each topic.
4. *Second Internet-based survey*. Summary statements are listed online, and voters are asked whether they agree with these statements or not. Moreover, participants in the online survey may be asked whether they use the presented interventions in their clinical practice. Topics receiving a low percentage of agreement are excluded.
5. *Publication*. An article describing the results of the consensus process is prepared, reviewed, and approved by the most active participants in the meeting before it is sent to a peer-reviewed journal for publication.

Results of the Web-Based Consensus Conference on Perioperative Mortality

In the first international Web-based consensus conference on mortality reduction in the perioperative period,[101] evidence collection was focused on RCTs and metaanalyses of RCTs (Fig. 52.4). Among the

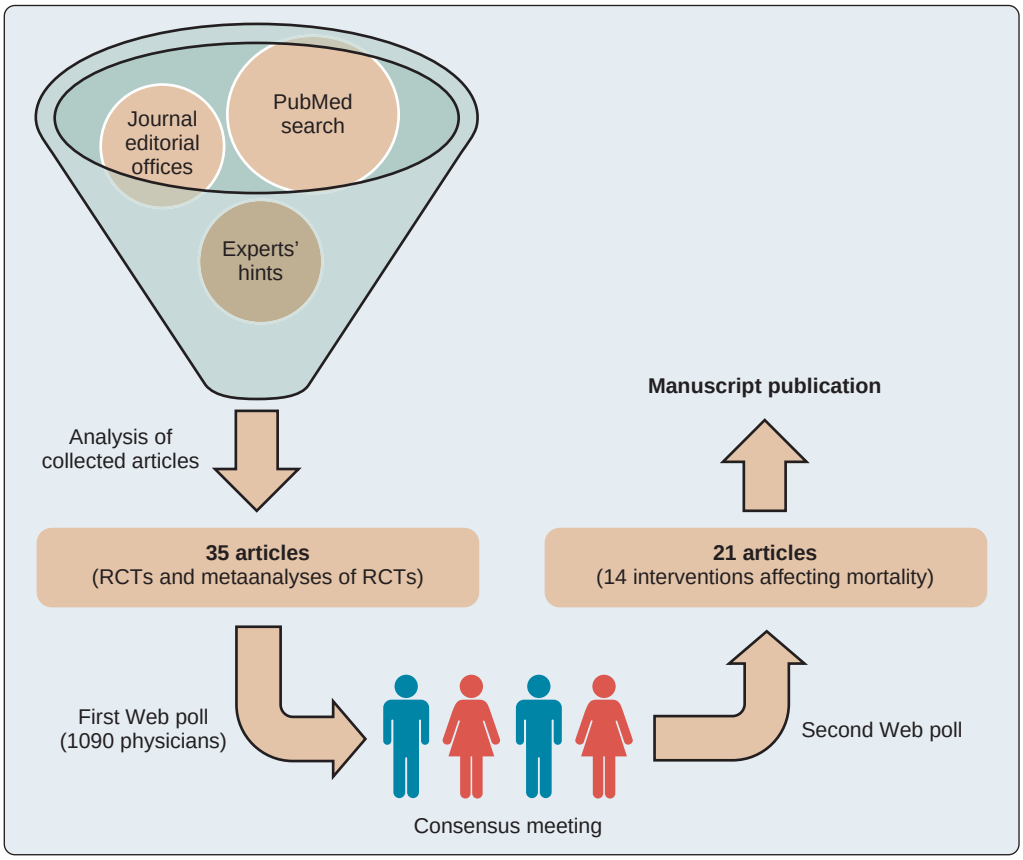

Fig. 52.4 The Web-based consensus process. *RCTs*, Randomized controlled trials.

7742 articles analyzed, only 35 (concerning 24 different interventions) fulfilled all inclusion criteria and were accordingly voted on by 1090 physicians from 77 countries. An additional 14 articles (10 topics) were excluded during the subsequent steps, for the following reasons:

- The study included nonsurgical populations, or the effect on mortality was found only in small subanalyses (antifungal prophylaxis, pexelizumab, avoidance of hyperoncotic colloids, fondaparinux).
- The effect on mortality was lost at later follow-up, was questioned by follow-up investigations, or did not strictly pertained to the perioperative period (hypotensive resuscitation, *N*-acetylcysteine, nesiritide, statins, tranexamic acid).
- The study had a low percentage of agreement at the second Web poll (dopexamine).

Of the 14 interventions that potentially increase or decrease perioperative mortality rates according to the final findings of the consensus process (Fig. 52.5), 7 have been only (or mostly) investigated in the cardiac surgical setting (chlorhexidine oral rinse,[112] insulin,[113,114] IABP,[115] leukocyte depletion,[116] levosimendan,[117] volatile anesthetic agents,[118] avoidance of aprotinin[119]). The remaining topics, concerning noncardiac operations, are discussed in the next sections and are summarized in Box 52.3. However, some of these interventions (eg, perioperative supplemental oxygen) have been questioned by newer studies, whereas some of those excluded interventions could be reevaluated (eg, tranexamic acid, statins). In addition, further strategies, such as more "liberal" transfusion triggers, have been suggested to influence perioperative mortality rates in more recent investigations. Finally, it is reasonable to assume that some of the interventions that conferred survival benefits in cardiac surgical patients may have a beneficial effect in noncardiac surgical patients as well.

May reduce mortality	*May increase mortality*	
• Chlorhexidine oral rinse • Insulin for glycemic control • Intraaortic balloon pump • Leukocyte depletion • Levosimendan • Volatile anesthetics	• Aprotinin	Cardiac surgery
• Clonidine • Neuraxial anesthesia • Noninvasive ventilation • Perioperative hemodynamic optimization • Selective decontamination of the digestive tract	• Metoprolol	Noncardiac surgery

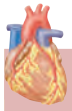
Interventions That May Reduce Mortality Rates in Noncardiac Surgical Procedures

Perioperative Hemodynamic Optimization

Referred to as goal-directed therapy (GDT), hemodynamic optimization involves the proactive administration of fluids (associated or not



BOX 52.3 PRACTICAL (EVIDENCE-BASED) SUGGESTIONS TO REDUCE MORTALITY RATES IN NONCARDIAC SURGICAL PATIENTS

- *Hemodynamic optimization* according to adequate monitoring and flow-related parameters should be pursued in high-risk patients. However, the best monitoring tools, hemodynamic goals, and resuscitation targets are yet to be defined.
- *Noninvasive ventilation* should be promptly started in patients in whom postoperative acute respiratory failure develops. Its intraoperative role, although promising, is less clear.
- *Neuraxial anesthesia*, as well as epidural analgesia in addition to general anesthesia, should be preferred whenever possible, although physicians' skills and a highly individualized choice of the anesthetic technique are probably pivotal.
- *Selective decontamination of the digestive tract* may be considered in postoperative patients in the intensive care unit, but this topic needs further research.
- *β-Blocker* initiation in unselected patients shortly before surgical procedures should be avoided. However, perioperative *continuation* of β-blockers is recommended in patients already receiving these drugs. This topic needs further research.
- *Statins, tranexamic acid,* and *liberal transfusion strategies* may be considered to improve survival. However, these topics merit further research.
- *Levosimendan, intraaortic balloon pump, volatile anesthetic agents, remote ischemic preconditioning, leukocyte depletion, and protective ventilation* have been proven to reduce mortality rates in other settings, but they may also be beneficial in noncardiac surgical patients.

with inotropic drugs) to maintain one or more flow-related hemodynamic parameters within a certain target, to match the imbalance that often occurs in the perioperative period between oxygen supply and demand or to prevent tissue hypoxia and organ injury.

Five metaanalyses of RCTs found reduced mortality rates with GDT protocols in patients undergoing noncardiac surgical procedures.[120–124] The trials included in these metaanalyses were highly heterogeneous in both their quality and design. Furthermore, hemodynamic optimization strategies investigated by different studies were extremely varied, including the following: different hemodynamic goals (ie, CO, D_{O_2}, dynamic parameters such as SV variation or pulse pressure variation, central/mixed venous oxygen saturation [S_{cO_2}/$S\bar{v}O_2$], and flow time corrected [FTc]); different monitoring devices (pulmonary artery catheter, pulse contour analysis, esophageal Doppler imaging, bioreactance); different resuscitation targets (normal or "supranormal" D_{O_2} levels); and different therapeutic interventions to achieve these goals and targets (fluids, inotropes, blood transfusions).

The metaanalyses by Cecconi and colleagues[120] (32 RCTs, 2808 noncardiac surgical patients) and by Hamilton and associates[122] (29 RCTs, 4805 patients undergoing any operation) reported reduced mortality rates with GDT as compared with standard therapy (OR, 0.2; 95% CI, 0.09–0.41; $P < .0001$ and OR, 0.48; 95% CI, 0.33–0.78; $P = .0002$, respectively). However, subgroup analyses revealed that the effect on mortality rates was restricted to studies using pulmonary artery catheters as the monitoring tool, CO or D_{O_2} as hemodynamic goals, fluids and inotropes as therapeutic strategies, and "supranormal" resuscitation targets. Moreover, Cecconi and colleagues (as well as Gurgel and do Nascimento[121]) found that the survival benefit was restricted to patients with an extremely high-risk of death (≥20%), whereas Hamilton and colleagues[122] showed that the survival benefit was lost when considering only the most recent studies (those published since 2000) and only the higher-quality RCTs. Conversely, the effect on mortality rates was not found to be related to trial quality in the metaanalysis by Poeze and associates,[124] whereas Brienza and colleagues[123] suggested that a favorable effect on outcome also may be obtained without "supranormal" resuscitation targets, although no data on mortality rates were reported.

The more recent RTCs investigating the use of GDT protocols based on minimally invasive or noninvasive monitoring devices, which are gradually replacing invasive monitoring in most noncardiac surgical settings, failed to show clinical benefit.[125–128] To conclude, it is not difficult to agree with the concept that hemodynamic status should be promptly "optimized" in the perioperative period to prevent the development of an "oxygen debt" and, probably, to reduce postoperative major complications and mortality rates. However, the best monitoring tools, hemodynamic targets, therapeutic interventions to use (including the *type* of fluids or inotropes), and the most appropriate settings are yet to be clearly defined.

Noninvasive Ventilation

Several articles reported the *intraoperative* use of noninvasive ventilation (NIV) during nearly all types of surgical procedures including abdominal, thoracic, urologic, orthopedic, obstetric, ophthalmic, and neurosurgical, as well as endovascular cardiac procedures.[129] Improved outcomes were found with the *postoperative* use of NIV.[130,131] One multicenter trial including 209 patients from 15 ICUs showed a reduced rate of tracheal intubation and a lower incidence of complications (infections, sepsis, pneumonia, and anastomotic leaks) in patients in whom postoperative hypoxia developed after abdominal surgical procedures and who were treated with 7.5 cm H_2O continuous positive airway pressure through a helmet as compared with standard care.[132]

So far, however, randomized evidence of improved survival with NIV in noncardiac surgical patients comes from only two small RCTs performed in patients undergoing thoracic and solid organ transplantation.[133,134] Auriant and associates[133] randomized 48 patients who developed acute hypoxemic lung failure after pulmonary resection and received either pressure support ventilation through a nasal mask (set to maintain exhaled tidal volumes within 8–10 mL/kg, respiratory rate <25 breaths/min, and arterial oxygen saturation >90%) or standard care. A threefold reduction in 120-day mortality rate was shown in the NIV-treated group (12.5% vs 37.5%; $P = .045$). A similar NIV strategy through a face mask was found by Antonelli and colleagues[134] to reduce ICU mortality rates from 50% to 20% ($P = .05$) in patients in whom acute lung failure developed after liver, kidney, or lung transplantation.

Nevertheless, strong indications that NIV may have a key role in reducing perioperative mortality rates derive from the critical care setting. In fact, with as many as eight multicenter RCTs in support,[135–142] NIV is the therapeutic intervention with the best evidence to have a significant impact on mortality rates in critically ill patients in the history of modern medicine.[106] A metaanalysis of RCTs by Cabrini and associates,[143] including 7365 patients, confirmed that NIV reduced mortality rates in acute care settings (RR, 0.73; 95% CI, 0.66–0.81, $P < .001$) when it was used to treat or prevent acute respiratory failure, but not as a means to allow earlier tracheal extubation. Moreover, the survival benefit is lost when NIV is started too late. Accordingly, NIV should be promptly applied whenever indicated. Most remarkably, the favorable effect of NIV on mortality rate was preserved also when only postoperative patients with acute respiratory failure were considered. This finding indicates that NIV may be pivotal in the treatment of *postoperative* respiratory failure to reduce mortality rates.

Conversely, the role of *intraoperative* NIV in reducing mortality rates is less clear. NIV may be used in the operating room to treat sudden respiratory distress, to allow continuation of the operation without tracheal intubation. More often, it is used as a prophylactic measure in patients with cardiorespiratory diseases who cannot tolerate the supine position or to avoid respiratory failure resulting from deep sedation.[129] Similarly, the use of NIV, through both a face mask and a helmet, has been described in patients undergoing diagnostic procedures (upper digestive endoscopy, fiberoptic bronchoscopy, transesophageal echocardiography) that may induce respiratory

distress and/or require deep sedation.[144–148] A full-face mask that can be opened is available (Janus, Biomedical, Florence, Italy); it can be positioned and provides NIV without stopping the ongoing endoscopic procedure.[149] Large, randomized trials are needed to assess the impact on mortality rates of intraoperative or intraprocedural use of NIV, both as a prophylactic measure and as a rescue treatment.

Neuraxial Anesthesia

Both spinal anesthesia and epidural anesthesia used alone, as well as epidural anesthesia or analgesia in association with general anesthesia, have been reported to have favorable effects (eg, antiinflammatory effects, reduction of stress response biomarkers, better functional recovery, lower cancer recurrence) and to reduce the incidence of postoperative major complications (particularly pulmonary complications and venous thromboembolism) in patients undergoing noncardiac surgical procedures.[150–157] It is reasonable to assume that the use of neuraxial anesthesia techniques in these settings may improve survival, although this is a matter of long-standing debate. In fact, no RCT has been able to show any difference in mortality rates between regional anesthesia and general anesthesia. Moreover, despite several large, observational or retrospective studies, mostly involving orthopedic surgical patients, that suggested a mortality reduction with neuraxial anesthesia,[158,159] data coming from more recent similar investigations are conflicting.[160,161]

The results of four metaanalyses, two of them more recent, suggest postoperative mortality reduction when using neuraxial anesthesia.[151,152,162–164] Rodgers and associates[151] analyzed 141 RCTs in which patients (a total of 9559) undergoing all types of surgical procedures (mainly general, gynecologic, obstetric, orthopedic, urologic, and vascular operations) were randomized to receive neuraxial anesthesia or general anesthesia. These investigators found a reduction in 30-day mortality rate of approximately one-third with neuraxial anesthesia (OR, 0.70; 95% CI, 0.54–0.90; $P = .006$), without significant differences among the different types of surgical procedures. The survival benefit observed reflected a trend toward reduction in deaths from several complications including pulmonary embolism, cardiac events, stroke, and infection. In the same year, Urwin and colleagues[152] performed a metaanalysis limited to trials involving patients with hip fracture and found a similar reduction in 1-month mortality rate in patients receiving regional anesthesia (OR, 0.66; 95% CI, 0.47–0.96). Other metaanalyses conducted thereafter had conflicting results. However, Guay and associates[162,163] performed an overview of nine Cochrane systematic reviews including RCTs that compared neuraxial anesthesia with general anesthesia alone, or combined neuraxial and general anesthesia with general anesthesia alone, in patients of any age undergoing any surgical procedures. These investigators confirmed with a moderate level of evidence that neuraxial anesthesia, as compared with general anesthesia, was associated with a reduction in up-to-30-day mortality rates (RR, 0.71; 95% CI, 0.53–0.94; heterogeneity index [I^2], 0%) in patients undergoing surgical procedures at intermediate-to-high cardiac risk. Moreover, neuraxial anesthesia was associated with a lower risk of pneumonia (RR, 0.45; 95% CI, 0.26–0.79; I^2, 0%), whereas the rate of MI was similar with the two techniques.

Finally, the metaanalysis by Pöpping and colleagues[164] focused on epidural analgesia in addition to general anesthesia, as compared with general anesthesia alone, and showed a reduction in mortality rate from 4.9% to 3.1% (OR, 0.60; 95% CI, 0.39–0.93), without significant heterogeneity among data ($P = 0.44$; I^2, 0%). Moreover, the risk of arrhythmias (atrial fibrillation and supraventricular tachycardia), respiratory depression, deep vein thrombosis, atelectasis, pneumonia, ileus, and postoperative nausea and vomiting was significantly reduced with epidural analgesia, although an increased risk of arterial hypotension, itch, urinary retention, and motor blockade was found. A metaanalysis by Landoni and associates[165] reported a reduced mortality rate with epidural analgesia in cardiac surgical patients (RR, 0.65; 95% CI, 0.48–0.86; $P = .003$), with a risk of epidural hematoma of 1 in 3552.

Unfortunately, in addition to the well-known limitations of metaanalyses, none of these investigations was able to consider the individual skills of anesthesiologists, which probably have a key role in this context.[157]

In our opinion, regional anesthesia should be the anesthetic technique of choice in noncardiac surgical procedures whenever possible. However, key factors to improve outcomes and probably to reduce mortality rates are careful and comprehensive risk assessment, anesthesiologists' skills, and a highly individualized choice of anesthetic technique. For example, especially in patients with cardiac diseases, even the degree of patients' anxiety or fear, which may increase the risk of MACE and death, should be taken into account when choosing between general anesthesia and regional anesthesia. Conversely, the indiscriminate use of a technique only because it has been shown to reduce mortality rates, with all the limitations of evidence-based medicine, may be harmful for the single patient.

Selective Decontamination of the Digestive Tract

Selective decontamination of the digestive tract (SDD) involves the use of topical and oral nonabsorbable antimicrobial agents (polymyxin E, tobramycin, amphotericin B, and vancomycin in case of endemic methicillin-resistant *Staphylococcus aureus*), possibly in conjunction with parenteral antibiotics (usually cephalosporins) to control the overgrowth of potentially pathogenic microorganisms, as often occurs in critically ill patients.[166] This prophylactic measure has been largely proven to reduce bloodstream and pulmonary infections and mortality rates in ICU patients.[167–170] The effectiveness of SDD also has been investigated in surgical ICU patients. However, the metaanalysis performed by Nathens and Marshall[171] in 1999 including 11 randomized trials is the only study showing a survival benefit with SDD in the postoperative setting.[101] Those investigators found that SDD significantly reduced mortality rates among critically ill surgical patients (OR, 0.70; 95% CI, 0.52–0.93) because of a reduced rate of bacteremia and pneumonia. Furthermore, the survival benefit was greater with the use of SDD regimens that included both oral and parenteral antimicrobial agents (OR, 0.60; 95% CI, 0.41–0.88).

Conversely, the *perioperative* use of SDD protocols outside the ICU setting has not been shown to reduce mortality rates, although it seemed to be a promising prophylactic measure, especially in patients undergoing upper GI tract surgical procedures.[171]

The use of SDD is not widespread, nor is it generally suggested, even in the critical care setting. The reason is probably multifactorial and mainly reflects concern about development of bacterial resistance to antibiotics, even if SDD seems to be safe from this point of view.[166,172] A large, multicenter RCT in patients undergoing elective colorectal cancer operations that is evaluating the role of SDD in addition to standard antibiotic prophylaxis and that includes death among its end points is currently ongoing.[173] Meanwhile, the role of SDD, both in the perioperative period and in postsurgical ICU patients, as a strategy to improve survival remains uncertain.

Interventions That May Increase *Mortality Rates in Noncardiac Surgical Procedures*

Perioperative β-Blockers

Preoperative prescription of β-blockers was formerly thought to be an effective and safe strategy to reduce cardiac risk in patients undergoing noncardiac surgical procedures.[174,175] However, the evidence about safety of perioperative β-blockade was mainly based on a set of investigations (Dutch Echocardiographic Cardiac Risk Evaluation Applying Stress Echocardiography [DECREASE]) that were accused of serious scientific misconduct.[176] Conversely, β-blockers started shortly before noncardiac surgical procedures have been shown to increase mortality rates significantly in patients with, or at risk for, ischemic heart disease, according to the large multicenter trial POISE,[10] as well as three metaanalyses.[176–179] In the POISE study,[10] 8351 patients with CV disease, or who were scheduled for major vascular operations, or with at least three of seven risk factors (intrathoracic or intraperitoneal operations, emergency or urgent procedures, previous HF, transient ischemic attack, diabetes, serum creatinine >175 μmol/L, age >70 y) were

randomized to receive oral extended-release metoprolol or placebo for 30 days starting 2 to 4 hours preoperatively. Although the rate of MI was reduced by approximately 27% (4.2% vs 5.7%; $P < .0017$), a 33% increase in the overall mortality rate (3.1% vs 2.3%; $P = .0317$) and a 100% increase in the rate of stroke (1.0% vs 0.5%; $P = .0053$) were found, mainly the result of hypotension.

The metaanalysis by Bouri and associates[176] included 11 trials in which bisoprolol (3 studies), metoprolol (5 studies), atenolol (2 studies), or propranolol (1 study) was started between 37 days and 30 minutes preoperatively and was continued for 5 to 30 days postoperatively. After excluding the DECREASE trials, these investigators found a significant increase in all-cause mortality rates with perioperative β-blockers (RR, 1.27; 95% CI, 1.01–1.60; $P = .04$), and they strongly argued for a change in guidelines.

In the revised 2014 ESC/ESA guidelines on noncardiac surgical procedures, the recommendations on perioperative β-blockers were substantially downgraded.[42,180] Although perioperative *continuation* of β-blockers is still recommended in patients already receiving these drugs, it is suggested that their *initiation* may be considered in patients with recognized ischemic heart disease and in patients undergoing high-risk surgical procedures with ASA grade 3 or higher or with two or more RCRI risk factors (class II, level of evidence B). Atenolol or bisoprolol may be preferred to metoprolol, and careful dose titration according to individualized heart rate targets is advisable. Conversely, perioperative initiation of β-blockers is not recommended in patients undergoing low-risk procedures.

Two other metaanalyses were published shortly after the 2014 update of the ESC/ESA guidelines. A Cochrane systematic review of 89 RCTs (19,211 patients) investigating the perioperative use of β-blockers in both cardiac and noncardiac surgical procedures showed, despite a significant reduction in the rate of AMI, myocardial ischemia and supraventricular arrhythmias, a potential increase in all-cause mortality rates and in cerebrovascular complications with the use of β-blockers in patients undergoing noncardiac surgical procedures that became significant (RR, 1.27; 95% CI, 1.01–1.59; and RR, 2.09; 95% CI, 1.14–3.82, respectively) after restricting the analysis to trials with a low risk of bias.[177] Hypotension and bradycardia were significantly more common in patients receiving β-blockers. Finally, Wijeysundera and colleagues[178,179] also found increased risks of hypotension, bradycardia, and nonfatal stroke with perioperative β-blockade, regardless of the inclusion or exclusion of both the POISE and the DECREASE trials. Moreover, this metaanalysis showed a significantly increased overall mortality rate (RR, 1.30; 95% CI, 1.03–1.64), after exclusion of the DECREASE studies, in patients in whom β-blockers were started within 1 day before the surgical procedure.

It is likely that the proper β-blocking agent, started early enough preoperatively (to allow adequate dose titration) and administered to the appropriate subset of patients, would effectively and safely prevent adverse cardiac events in noncardiac surgical patients. This approach may not be easy to apply, however, in several clinical contexts.

Further Strategies to Possibly Reduce Mortality Rates in Noncardiac Surgical Procedures: Evidence From Updates and Other Clinical Settings

Statins

At the time of the first international Web-based consensus conference on perioperative mortality, two relatively small RCTs suggested an improvement in survival with statins administered perioperatively in noncardiac surgical patients.[65,181] The study by Schouten and associates (DECREASE III),[65] including 250 patients who were randomized to receive 80 mg of fluvastatin or placebo for 30 days before vascular surgical procedures, reported a reduction in the composite outcome of death or MI, whereas in the investigation by Kobashigawa and colleagues,[181] conducted in 97 cardiac transplant recipients, statins were started 1 or 2 weeks postoperatively, and the survival benefit was shown only at 1-year follow-up. For these reasons, statins were excluded from the list of interventions believed to reduce perioperative mortality rates.[101,102] Moreover, the former trial belongs to the controversial group of the DECREASE investigations, whereas the latter does not include noncardiac surgical procedures.

As mentioned, a subsequent metaanalysis including 16 RCTs (2275 patients) investigated the perioperative use of statins in statin-naïve patients 18 years old or older who were undergoing cardiac, vascular, and other noncardiac surgical procedures.[67] A reduction in both MI rate and mortality rate was found in the subgroup analysis restricted to noncardiac surgical patients (RR, 0.53; 95% CI, 0.37–0.77; $P = .001$; and RR, 0.50; 95% CI, 0.27–0.91; $P = .02$, respectively), with no heterogeneity among the trials (I^2, 0%). However, only 3 of 16 studies involved noncardiac surgical patients (2 of which included vascular surgical patients). Those investigators concluded that current data were insufficient to recommend perioperative statin therapy definitively in patients scheduled for noncardiac surgical procedures. This is a promising topic that deserves further research.

Antifibrinolytic Drugs

Tranexamic acid is the only antifibrinolytic drug that seems to have a favorable effect on perioperative mortality rates. According to a metaanalysis of 129 RCTs including 10,488 patients, strong evidence indicates that tranexamic acid reduces the need for transfusions in surgical patients by more than one-third (RR, 0.62; 95% CI, 0.58–0.65; $P < .001$).[182] However, uncertainty remains about its impact on MI, stroke, deep vein thrombosis, pulmonary embolism, and mortality rates. Although a reduced mortality rate with the use of tranexamic acid was found (RR, 0.61; 95% CI, 0.38–0.98; $P = .04$), statistical significance was lost after restriction of analysis to studies with adequate concealment. Additionally, a network metaanalysis, including both randomized and observational studies aimed at investigating the effects of aprotinin on survival in patients undergoing cardiac surgical procedures, showed that tranexamic acid was associated with reduced mortality rates only when compared with aprotinin, but not when compared with ε-aminocaproic acid or no antifibrinolytic drugs.[183] Moreover, no differences in mortality rates were found among aprotinin, ε-aminocaproic acid, or no treatment. This finding confirms the results of previous investigations showing that aprotinin can be harmful in patients undergoing cardiac surgical procedures.[119] However, it also suggests that the perioperative use of tranexamic acid may reduce mortality rates, or at least is safe. Finally, indirect evidence about a possible beneficial effect of tranexamic acid on mortality rates in the perioperative period comes from the trauma setting, which is similar to that of surgery.

The large, multicenter RCT, Clinical Randomisation of an Antifibrinolytic in Significant Haemorrhage (CRASH-2), included 20,211 patients from 274 hospitals and found that a short course of tranexamic acid (1 g over 10 min, followed by continuous infusion of 1 g over 8 h, starting within 8 h from injury) significantly reduced all-cause mortality rates in bleeding trauma patients (RR, 0.91; 95% CI, 0.85–0.97; $P = .0035$), with a greater effect when tranexamic acid was started earlier.[184]

Liberal Transfusion Strategy

A growing body of evidence indicating detrimental effects of red blood cell (RBC) transfusions, including increased mortality rates,[185,186] led to the widespread adoption of restrictive transfusion policies (eg, the use of an Hb transfusion trigger ≤7–7.5 g/dL), which were not inferior to more liberal strategies.[187–190] However, a large, multicenter RCT[28] and two single-center RCTs,[29,30] all published in 2015, found improved survival with the use of more liberal transfusion triggers in patients who underwent cardiac, cancer, and orthopedic surgical procedures.

In the Transfusion Indication Threshold Reduction (TITRe2) study,[28] 2003 patients with postoperative Hb levels lower than 9 g/dL after elective cardiac surgical procedures were randomized to receive RBC transfusions when Hb was lower than 9 or 7 g/dL. Despite the significantly reduced rate of transfusion (53.4% vs 92.2%), more deaths

were observed in the restrictive group (HR, 1.64; 95% CI, 1.00–2.67; P = .045). De Almeida and associates[29] investigated the same transfusion triggers (Hb <9 g/dL vs Hb <7 g/dL) in 198 patients admitted to ICUs after major operations for abdominal cancer. Both 30-day and 60-day mortality rates were lower in the group receiving the liberal strategy as compared with the restrictive group (8.2 vs 22.8%, P = .005; and 11.3 vs 23.8%, P = .022, respectively). Finally, Gregersen and colleagues[30] enrolled 284 patients who had undergone surgical procedures for hip fracture and found an increased per-protocol 30-day mortality rate (HR, 2.40; 95% CI, 1.1–5.2; P = .03) among patients who received RBC transfusions according to a lower Hb threshold (9.7 g/dL), as compared with those who were transfused more liberally (Hb <11.3 g/dL). In addition, both per-intention-to-treat and per-protocol 90-day mortality rates were higher in the restrictive group in a subgroup analysis including only nursing home residents.

This is doubtless a very controversial topic, but a metaanalysis of RCTs confirmed a beneficial effect on survival of the liberal approach by pooling together the 17 perioperative RCTs performed.[31] RBC transfusions do have the potential to do harm even if their quality, purification, and storage is improving. However, avoiding transfusions *when they are needed* may be even more dangerous. The key point may be to assess carefully whether transfusions are really necessary in the single patient. Several factors (age, comorbidities, hemodynamic status, clinical setting) should be taken into account or used as triggers (blood lactate, D_{O_2}, $S\bar{v}O_2$, regional oxygen saturation).

Perioperative Supplemental Oxygen

One line of research has aimed to investigate the hypothesis that a deliberate increase in the perioperative fraction of inspired oxygen (F_{IO_2}) would reduce the rate of surgical site infections, based on the well-known effects of hyperoxia on both bactericidal activity of neutrophils and wound healing.[191] A metaanalysis of five RCTs that compared an F_{IO_2} of 0.8 with an F_{IO_2} of 0.3 in patients undergoing colorectal surgical procedures showed a reduced mortality rate (but not a reduction in surgical site infections) with supplemental oxygen.[192] Accordingly, this intervention was included in the consensus paper as a potential strategy to improve survival in patients undergoing noncardiac surgical procedures.[101] The design of these and other subsequent similar trials was criticized, however.[193] Moreover, the large Supplemental Oxygen and Complications After Abdominal Surgery (PROXI) trial[194] did not find any difference in the rates of surgical site infections and 30-day mortality in patients undergoing abdominal surgical procedures who were receiving 80% or 30% oxygen, but the 2-year follow-up showed an unexpected increased mortality rate in the supplemental oxygen group (HR, 1.3; 95% CI 1.03–1.64; P = .03).[195] Accordingly, a deliberately high perioperative F_{IO_2}, whose effectiveness in reducing surgical site infections is not proven, is not advised.

Levosimendan

Patients who develop postoperative low-CO syndrome may need supportive therapy with inotropes to maintain an adequate hemodynamic status. However, inotropic drugs (especially catecholamines) lead to increased $M\dot{V}O_2$ and may consequently precipitate myocardial ischemia or increase the extent of an ongoing AMI. Moreover, most inotropic drugs can cause arrhythmias. Levosimendan, an inodilating (and antiinflammatory) calcium sensitizer,[196,197] showed cardioprotective properties in patients with HF and in cardiac surgical patients.[198–200] Most remarkably, levosimendan has been shown to reduce mortality rates in patients undergoing cardiac surgical procedures, according to a small RCT[201] and five metaanalyses.[198,202–205] A Bayesian network metaanalysis found that levosimendan was the only inodilator drug associated with a reduction in mortality rates, as compared with placebo, in patients undergoing cardiac surgical procedures.[205] Finally, a large multicenter RCT (Levosimendan in High Risk Patients Undergoing Cardiac Surgery [CHEETA]) aimed at confirming these findings is currently ongoing.[206] Even if levosimendan, with more than 100 performed RCTs, is the best studied inotropic drug[207] and the only one with survival benefits,[205] no evidence exists in patients undergoing noncardiac surgical procedures. It is only presumed that a similar favorable effect may apply in this setting, especially in patients with perioperative low-CO syndrome.

Preoperative Intraaortic Balloon Pump Counterpulsation

In high-risk patients undergoing coronary artery bypass graft operations, preoperative mechanical cardiocirculatory support with IABP can reduce perioperative and 30-day mortality rates, as shown by a small RCT[208] and four metaanalyses of RCTs.[115,209–211] Although IABP placement may potentially lead to serious complications, especially vascular or infectious, the rates of lower limb ischemia and local infection were shown to be relatively low (0.94% and 0.47%, respectively) in a retrospective study including 423 cardiac surgical patients receiving perioperative IABP.[212] Whether this strategy may confer a survival advantage in carefully selected patients with high-risk CAD who are undergoing noncardiac surgical procedures should be investigated.

Volatile Anesthetic Agents

According to two metaanalyses of RCTs,[118,213] the use of modern halogenated anesthetic agents (isoflurane, desflurane, or sevoflurane) as compared with totally IV anesthesia, may reduce mortality rates in patients undergoing cardiac surgical procedures, seemingly because of a cardioprotective action whose mechanism is similar to that of ischemic preconditioning. However, some investigations failed to show any beneficial effect of volatile anesthetic agents on troponin release or mortality rates after cardiac surgical procedures.[214] Moreover, a cardioprotective action was not observed in patients undergoing coronary stenting procedures.[215]

The largest multicenter RCT comparing the use of volatile anesthetic agents with totally IV anesthesia in patients undergoing cardiac surgical procedures is currently ongoing (http://clinicaltrials.gov/show/NCT02105610: Volatile Anesthetics to Reduce Mortality in Cardiac Surgery [MYRIAD]), and it will probably make a significant contribution to the definition of the role of volatile anesthetic agents in reducing myocardial injury and mortality rates. It would be important to know whether such an effect could be used to prevent MACE and to reduce mortality rates in noncardiac surgical patients. So far, however, the available evidence in this setting is scarce and somewhat conflicting.[216–218] Large, multicenter investigations are needed to assess the potential advantages of volatile anesthetic agents in patients at risk for perioperative myocardial injury or MI, although this type of trial may be difficult to perform.[219] Moreover, the pleiotropic pharmacologic effects of anesthetic agents are unpredictable. For example, a large multicenter RCT is ongoing to investigate the beneficial effect of a propofol-based anesthetic and the detrimental effect of a volatile-based anesthetic agent in cancer surgical procedures (http://clinicaltrials.gov/show/NCT01975064: Cancer and Anesthesia: Survival After Radical Surgery—A Comparison Between Propofol and Sevoflurane Anesthesia [CAN]).

Remote Ischemic Preconditioning

Repeated short episodes of ischemia and reperfusion in a remote vascular territory (eg, by applying a blood pressure cuff on an upper limb and inflating or deflating it every 5 minutes for three cycles) may protect the heart from ischemia or reperfusion injury. This effect is possibly caused by the release of one or more substances that reach the heart and activate cell-signaling pathways, probably involving mitochondria, this resulting in greater resistance to ischemic insults.[220] Thielmann and associates[221] randomized 329 patients who were undergoing coronary artery bypass graft operations to receive remote ischemic preconditioning or not. These investigators found reduced postoperative release of cTn (cTnI:AUC, 0.83; 95% CI 0.70–0.97; P = .022) and a reduced all-cause mortality rate (HR, 0.27; 95% CI 0.08–0.98; P = .046) in the preconditioning group. The topic has possible applications in noncardiac surgical patients at risk for perioperative myocardial ischemia. However, further research is needed in both settings.

Leukocyte Depletion of Transfused Blood

Removing leukocytes from blood to be transfused is thought to prevent transfusion-related immunomodulation, probably leading to a reduced risk of infections.[222] In cardiac surgical patients, cardiopulmonary bypass may magnify the inflammatory mechanisms through which blood transfusions may lead to increased susceptibility to infections and/or to multiorgan dysfunction. Two large RCTs found a reduced mortality rate with transfusion of leukodepleted RBCs as compared with standard buffy coat–depleted RBCs.[116,223] Whether this favorable effect is restricted to the cardiac surgical population or whether it may also occur in other surgical settings is not clear. However, leukodepletion of blood products is regarded as best practice in most Western countries.

Insulin for Tight Glycemic Control

In the landmark investigation by Van den Berghe and colleagues,[113] maintaining blood glucose levels between 80 and 110 mg/dL through continuous infusion of insulin was found to reduce mortality in patients admitted to the ICU significantly after cardiac or noncardiac surgical procedures. Improved survival with intensive glycemic control also was shown in a subsequent metaanalysis of RCTs,[114] as well as in an RCT[224] in patients undergoing cardiac surgical procedures, although with less "tight" targets of blood glucose control (<180 mg/dL and 120–160 mg/dL, respectively). However, a metaanalysis including 29 RCTs performed in both medical and surgical ICU patients failed to show any survival benefit with intensive glucose control. Conversely, a higher risk of hypoglycemia was found.[225] The large Normoglycaemia in Intensive Care Evaluation and Survival Using Glucose Algorithm Regulation (NICE-SUGAR) multicenter investigation[226] also raised important concerns about tight glycemic control. An increase in mortality rates was found in ICU patients in whom blood glucose was maintained between 81 and 108 mg/dL, as compared with a higher blood glucose target (<180 mg/dL). Accordingly, caution should be used when adjusting glycemic levels in ICU patients, to avoid dangerous hypoglycemic episodes. Further studies are desirable in the perioperative setting.

Lung-Protective Ventilation

Protective ventilation, involving the use of low tidal volumes and moderate-to-high levels of positive end-expiratory pressure (with or without recruitment maneuvers), is one of the interventions shown to improve survival in critically ill patients.[106] Three multicenter RCTs found a reduction in mortality rates with protective ventilation in patients with acute respiratory distress syndrome.[227–229] Data are accumulating to support the *prophylactic* use of protective ventilation to prevent acute respiratory distress syndrome in patients without lung injury, including the *intraoperative* use of low tidal volumes in noncardiac surgical patients.[230,231] This topic is very attractive and deserves further large investigations.
