Individual studies involving concomitant carotid and coronary disease suffer from great variation in the definition of a stroke, selection bias, patient demographics, and surgical techniques that limit the widespread application of study recommendations. To make up for these deficiencies, large systematic reviews of the studies have attempted to provide insight into the optimal practice of concomitant carotid and coronary disease. A review found no advantage in outcomes for staged or combined procedures.[360] Staged procedures had lower rates of stroke (2.7% vs 4.6%) and death but were not statistically significant. Others have not only found combined surgery unnecessary but potentially detrimental. Gerraty and associates[363] studied prospectively a series of 358 patients undergoing peripheral vascular procedures or CABG surgery that underwent ultrasonography preoperatively. If the carotid stenosis was asymptomatic, then the risk of stroke was so low that it did not merit prophylactic CEA. An audit of one institution's last 5 years with the combined CEA-CABG procedure for asymptomatic carotid stenosis (>50%) found no perioperative strokes at 30 days postoperatively in the 61 patients who had unilateral stenosis that were not revascularized. This finding led to an institutional halt to the performance of combining the procedures.[362] Unfortunately, their studies can do no more than challenge the hypothesis that a combined or staged CEA and CABG surgery will reduce the risk of stroke in asymptomatic, unilateral carotid disease.

A major concern for those who do not support a combined or staged approach for carotid and coronary disease is that some data demonstrate a stroke rate for the combined CEA-CABG procedure of approximately twice the stroke rate of each procedure alone.[342] Safety of the combined CEA-CABG procedure was recently evaluated in 277 patients (3.34%) with carotid stenosis of greater than 70% unilaterally or bilaterally who underwent some form of the combined CEA-CABG procedure, compared with a control group of 8000 isolated CABG surgeries.[364] No statistical difference was found in the mortality or incidence of stroke of those undergoing combined procedures, as compared with those undergoing CABG surgery alone. The increased risk of stroke or even death found in some studies regarding the combined CEA-CABG procedure may be related to the overall severity of the atherosclerotic disease and the likelihood of embolic plaque in the aorta in this particular population of patients. Ricotta and associates[341] were able to define a stroke model through multivariate logistic regression analysis in patients undergoing CABG surgery without carotid stenosis greater than 80%. The risk factors for stroke were age, CPB duration, aortoiliac disease, electrocardiographic evidence of left ventricular hypertrophy, and an extensively calcified aorta. An examination of patients who underwent the combined CEA-CABG procedure revealed three of the four risk factors for postoperative stroke. Although the stroke rate for the combined group was 3.9%, compared with 1.7% for control subjects, the rate was not different from the expected stroke risk based on the inherent risk factors of the patients. One could conclude that patients with combined disease are at higher risk for stroke not attributable to the combined CEA-CABG procedure but from the individual preoperative risk factors. The high-grade carotid disease may be a marker for higher cardiovascular morbidity in these patients and less related directly to the carotid disease.

The risk of mortality and morbidity associated with the combined CEA-CABG procedure was also compared with patients undergoing an isolated CABG surgery in New York state for a control group.[346] Surprisingly, once propensity scores could be matched between isolated CABG surgeries and the combined CEA-CABG procedure, no significant differences were found in the occurrence of stroke, MI, or death between the combined and the isolated CABG groups. Another

important factor in looking at patients for combined procedures is that although, as a group, the mortality may be higher in the combined procedure, compared with an isolated CABG surgery, the risk for the patients vary greatly within their own groups.[364] In a comparison of isolated CABG surgery with the combined procedure, the stroke, mortality, and MI rate was very low in patients who had either unilateral or bilateral carotid stenosis, but those with previous stroke and more advanced age or contralateral internal carotid artery occlusion were at a significantly higher risk of stroke, mortality, and MI, compared with the other patients undergoing the combined procedure.

In conclusion, the intrinsic risk factors of patients who undergo combined procedures contribute more to postoperative stroke than the addition of CEA. The important issue is that the data indicate that combined procedures can be safely performed without an increase in complications attributable to the combination of procedures.

The use of carotid artery stenting (CAS) has gained popularity in recent years as a substitute for CEA in a staged approach but currently only represents a small part of prophylactic carotid revascularization (3.3%), compared with CEA for patients scheduled for CABG surgery.[347] In a comparison with the combined CEA-CABG procedure using a Nationwide Inpatient Sample database including 5 years of patients, the postoperative stroke rate for CAS and CABG surgery was significantly less (2.4%), compared with CEA and CABG surgery (3.9% $P < 0.001$) but no difference in the incidence of death. It was significant that symptomatic patients undergoing both prophylactic procedures before cardiac surgery reported a fivefold increase in stroke associated with CAS and CABG surgery versus CEA and CABG surgery. When CAS was used as the only form of prophylactic treatment of carotid stenosis before CABG surgery in 52 patients in a staged manner, the combination of minor stroke, major stroke, and death rate for this study was 19.2%.[365] Increased stroke rates with CAS and CABG surgery may be attributable to inadequate anticoagulation without clopidogrel to minimize postoperative bleeding after the CABG procedure. The combined CAS-CABG procedure has been performed with an acceptable stroke and death rate if the patient is neurologically asymptomatic; however, Timaran and associates[347] found a fivefold increase in the risk of CAS with CABG surgery for neurologically symptomatic patients, compared with CEA.

A benefit of CAS is that myocardial events may occur less frequently than CEA, perhaps because CAS can be performed with conscious sedation and is less invasive. A serious disadvantage with CAS is the need for multiple antiplatelet therapy and an occasional hemodynamic depression associated with CAS that may limit its role in those with unstable coronary artery disease. Complications from stenting can be as high as 5.7%, and the delay in CABG surgery may be responsible for deaths that occurred; consequently, a more frequent future use of CAS may depend on additional studies. It may be that CAS and CABG surgery will necessarily be less risky if performed as a staged procedure instead of a combined one.

Anesthetic Considerations

Anesthetic management of patients with carotid and coronary disease must provide optimal conditions for the brain and myocardium. Beyond the routine monitoring for cardiac surgery, electroencephalography or other modalities to assess neurophysiologic integrity are useful but have a high false-positive rate. For the anesthesiologist, it is helpful to know that the majority of strokes cannot be ascribed to an adverse intraoperative event such as hypotension or low flow.[350] However, it is more difficult to differentiate a *true* stroke from other states of temporary neurologic impairment associated with CABG surgery, such as heavy sedation, residual muscle weakness from a paralyzing agent, or encephalopathy secondary to cerebral edema. By using general anesthesia for CEA, clinical methods to determine neurologic integrity are delayed, as well as a delay in treatment. In contrast, the use of mild sedation with local anesthesia for CEA has proven to be a more reliable means to detect intraluminal shunting during CEA than other measures of neurologic testing.[366] The sensitivity and specificity of CEA with local anesthesia to detect neurologic deficits has been established. The use of a local anesthetic for CEA in the combined procedure has proven to be valuable in reducing exposure to anesthesia and reducing shunt-related complications, allowing repair with less risk of damage.[367] The use of local anesthesia for the CEA instead of one continuous general anesthetic has become more popular in recent years. The added ability to identify the timing of the neurologic insult may prove valuable, compared with general anesthesia. This is especially true as the neurologic examination in the conscious patient is more reliable than other methods such as stump pressure and electroencephalography. However, anxiety and pain must be controlled to minimize myocardial ischemia during CEA with local anesthesia.

Mean arterial pressure should be maintained in the middle-to-upper normal range without large increases in afterload or heart rate. Normocapnia is recommended. Techniques often used during anesthesia for cerebral protection such as barbiturates, inhalation anesthetics, benzodiazepines, or propofol to decrease cerebral metabolic rate have not been proven beneficial in clinical trials. Attempts to provide cerebral protection should not be used at the expense of myocardial perfusion and function. Usually, if the CEA is performed before CABG surgery, then the site of the CEA will be left open until the cardiac surgery is completed to ensure that bleeding at the site of the CEA is minimal.

Early extubation is desirable to allow earlier neurologic evaluation in combined cases. Fast-track anesthetic management to achieve early extubation is routine. Prompt tracheal extubation after cardiac surgery with CPB may be accomplished with various anesthetic agents. Short-acting opioids have been characterized as achieving more rapid extubation than fentanyl.[368] However, Engoren and colleagues[369] found no difference in the time to extubation with sufentanil or remifentanil, compared with fentanyl with the median time to extubation of 4.75 hours, 3.90 hours, and 2.78 hours, respectively. The combination of remifentanil and propofol was associated with mean extubation times of 163 minutes after arrival in the ICU.[370]

Extubation in the surgical unit is possible with high-thoracic epidural,[371] but early risks of hypothermia, bleeding, and hemodynamic instability may outweigh any benefit of prompt neurologic examination. Furthermore, the need for rapid institution of CPB during an awake CEA may prove challenging. Another possibility is the use of general anesthesia for the CEA, followed by a wake-up test,[372] to allow for the evaluation and treatment of any apparent neurologic injury before initiating CPB. This approach may be more feasible in the low-risk CABG patient who is less likely to have more labile hemodynamics upon waking. Aggressive vasoactive management is frequently required to treat hypertension and tachycardia, resulting from reduced opioids. Shorter-acting muscle relaxants than pancuronium have also been considered to shorten the duration of intubation; however, a large multicenter trial of more than 1100 patients undergoing CABG surgery did not demonstrate a difference in the duration of mechanical ventilation with either vecuronium or pancuronium and a fast-track anesthetic regimen.[368] Postoperatively, hypertension should be aggressively treated to avoid hyperperfusion syndromes leading to transient seizures or intracerebral hemorrhage and to avoid exacerbating bleeding at the site of the CEA.

Coronary Arteriovenous Fistula

Coronary arteriovenous fistula is a rare anomaly that frequently has a silent clinical course. It is an abnormal communication between a coronary artery and another cardiac chamber or venous structure, bypassing the myocardial capillary network. Common sites include coronary sinus, cardiac vein, pulmonary artery, SVC, pulmonary vein, or any one of the cardiac chambers. The incidence in the overall population is 0.002%.[373] Coronary artery fistula is the most common significant coronary artery anomaly and occurs in 0.3% to 0.8% of angiographic series.[374] Coronary arteriovenous fistula is usually congenital but may also occur from acquired (coronary atherosclerosis, Takayasu arteritis), traumatic, or iatrogenic causes. Interestingly, 10% to 30% of

patients with coronary fistulae may have another congenital anomaly such as tetralogy of Fallot, atrial septal defect, and partial anomalous pulmonary venous connection. It is not gender specific. Most congenital arteriovenous fistulas (60%) involve the right coronary artery, are small, and have no clinical significance. The left coronary artery is the site of the fistula in 35% of cases, although more recent studies have suggested that asymptomatic coronary fistulas originate from the left coronary system.[375] Multiple coronary fistulas occur in 5% of patients.[376] The most common distal connection of the fistula with the right coronary artery is the RV that represents 41% of the distal fistula sites. Low-pressure structures are the most common connections for coronary fistula with left-sided connections rarely occurring.[373] Most fistulas are single connections. The most proximal part of the fistula does develop some aneurysmal dilation and is often up to three times the normal diameter of the coronary.[375]

The clinical importance is generally associated with adulthood during which larger fistulas cause significant left-to-right shunts and CHF. Fistulas that connect to the left side do not shunt but cause an effect similar to mitral regurgitation. However, finding a degree of shunting significant enough to see an oxygen step-up effect during right-sided catheterization is rare. Fifty percent of patients with large fistulas develop complications.[373] The most common symptom is dyspnea that occurs in 30% of patients. Most adults are thought to be asymptomatic, but more recent reports suggest that nearly 50% are symptomatic at the time of presentation. The average age of the patient with symptoms is 18 years. Other problems that may lead to the diagnosis are arrhythmias, infective endocarditis, and myocardial ischemia. Usually, myocardial blood flow is not compromised because the shunt is so small, but coronary arteriovenous fistulas may cause angina pectoris by stealing blood from the normal coronary circulation. Usually, this occurrence is limited to exercise.[377] Additional complications of coronary fistulas, such as thrombosis, embolization, PAH, aneurysmal dilation of the involved vessel and even sudden death, may occur in patients diagnosed at later ages. Coronary fistulas rarely lead to aneurysmal rupture. Coronary arteriovenous fistulas can occur after a penetrating injury to the chest and exhibit symptoms of pericardial tamponade.

A continuous murmur with diastolic accentuation suggests an arteriovenous fistula. The murmur is continuous in a crescendo-decrescendo manner that persists through both systole and diastole. The murmur does not peak at the second heart sound, as do most of the other continuous murmurs. The murmur is the loudest at the site of entry into the heart for the fistula. Discovery of a continuous murmur along the upper left sternal border after CABG surgery is an indication for angiography to verify the proper placement of a saphenous vein graft into a coronary artery. Angiography is useful to differentiate this condition from other causes of continuous murmurs, such as patent ductus arteriosus, VSD, and atrial septal defect. Many of these fistulas are found incidentally during angiography. If the coronary artery is significantly enlarged, then echocardiography may be diagnostic. TEE is useful to identify drainage sites of a coronary arteriovenous fistula. More recently, MRI and a CT angiogram have contributed to the diagnostic process, because although angiography is the gold standard for imaging the coronary arteries, it may not provide the course and relationship to other structures as accurately as MRI and CT angiography.[374]

The majority of small symptomatic fistulas do not require intervention.[377] Often with infants who do not demonstrate CHF, medical management may reduce symptoms and, with growth, the size of the fistula and shunt will become smaller and less symptomatic. The natural history of these fistulas is variable. Spontaneous closure has been reported but is very rare and mostly in infants.[373] In some asymptomatic patients, the size of the shunt may reach a pulmonary-to-systemic flow (Qp:Qs) ratio of 1.5 but rarely more than 2, leading to severe fluid overload.

Management is controversial, in part, because treatment is based on anecdotal reports or small case series. Some will start antiplatelet medication, but others oppose it.[373] Symptoms are the primary impetus for closure of the coronary fistula. Asymptomatic patients may be considered for treatment, but the concern is the possibility of future complications. Treatment options to close the fistula include the long-standing therapy of surgery or a variety of percutaneous techniques such as coils, balloons, double-umbrella devices, and vascular-occlusion devices. With any technique, long-term follow-up of the patient is necessary, because recanalization is possible.

Surgical treatment of the coronary fistula with direct endocardial ligation has proven safe with no morbidity or mortality and effective with excellent long-term results of 10 years without problems.[378] Fistulae can be closed either from external placation on a beating heart or from an intracardiac location using CPB. To eliminate the fistulous tract, the distal end of the fistula from within the recipient cavity is closed during CPB.[379] Selected fistulas may be ligated without CPB. The use of coronary revascularization without CPB may be effective to protect the myocardial territories subtended by the fistula.[377] In approximately 50% of cases, when the fistula is corrected with surgery, CPB is used.[375] Cardioplegic arrest may be difficult with aortic cross-clamping of the aorta; therefore the option for temporarily clamping the fistula is acceptable unless the fistula is calcified. Intraoperative TEE can localize fistulas, verify complete repair, and monitor ventricular function to avoid ischemic complications of ligation.[380] Encountering major problems with surgery for coronary fistula is rare, but MI, arrhythmias, and stroke can occur.

The first successful transcatheter closure of a coronary fistula occurred in 1983.[374] This catheter-based technique of closing coronary fistulas has enjoyed success. Although many techniques are available to close the fistula, most have been done with coils.[381] The use of the coils results in thrombosis of the fistula to the level of the first branch, reducing the left-to-right shunt and returning myocardial blood flow. This technique has compared favorably with the surgical option in terms of morbidity, mortality, and effectiveness.[374,375] Series have noted approximately 10% of patients may develop leaks from transcatheter closure.[375] Long-term follow-up care has not been as rigorous or able to determine problems, but nearly one half of follow-up contacts are associated with persistent abnormalities.

Anesthetic Considerations

Anesthetic management of arteriovenous fistulas is similar to anesthetic management for CABG surgery. ECG monitoring for the detection of ischemic changes is invaluable for the ligation of coronary arteriovenous fistulas. The use of echocardiography is extremely valuable to determine myocardial ischemia and the degree of shunt.

Case Study 4: Coronary Artery Fistula

A 56-year-old woman with a history of hypertension reported new onset of dyspnea on exertion. Her physical examination was unremarkable with the exception of a continuous, soft murmur heard on auscultation of the chest. Preoperative TTE revealed normal valves, normal ventricular function, and no regional wall motion abnormalities. However, an area of turbulent flow in the RV raised concern for the presence of a right coronary artery fistula communicating with the RV. This finding was confirmed with a preoperative angiogram, and surgery was recommended. In the surgical unit, the site of communication between the fistula and the RV was identified with TEE. Using color-Doppler imaging, a site of turbulent flow was identified entering the RV. Turbulent flow was also seen outside of the ventricle, presumably occurring within the fistula. The surgeon placed a suture around the coronary fistula at its site of entrance to the RV. As the suture was tightened, the turbulent flow entering the RV was no longer seen with TEE. The result was considered acceptable, and the surgeon proceeded to ligate the fistula. The right coronary artery was assumed to remain intact.

After a short period of observation, it was noted that the ST segments in the inferior leads had become elevated. Ischemia was considered but could not be confirmed as the source of mild ST elevation. When the heart was re-imaged with TEE, right ventricular function was

described as normal. However, new regional wall motion abnormalities were clearly revealed in the inferior wall of the LV. Considering these new wall motion abnormalities, combined with ST segment elevation, it was believed that the right coronary artery had been compromised. CPB was instituted, and a vein graft was placed from the aorta to the distal right coronary artery, followed by easy separation from CPB. Biventricular function was normal, and the wall motion abnormalities were no longer present. The patient had an uncomplicated postoperative course.

In this case, TEE not only guided ligation of the fistula but also confirmed damage to the coronary artery, requiring CABG surgery during the ongoing anesthesia and avoiding another separate procedure and anesthesia.

Cardiac Surgery During Pregnancy

Heart disease is a major risk factor for maternal and fetal death during pregnancy with an incidence of 1% to 3%.[382] It is the most common cause of nonobstetric mortality during pregnancy, accounting for 10% to 15% of maternal mortality. Although maternal cardiac disease represents only 15% of obstetric ICU admissions, it accounts for 50% of the obstetric ICU deaths.[383] Obstetric patients with heart disease are at great risk for serious complications as a result of hemodynamic changes associated with pregnancy and delivery. If cardiac surgery is required during or immediately after pregnancy, then anesthetic management demands an appreciation for the many changes of pregnancy and their effects on the corresponding heart disease and well-being of the fetus.

Certain physiologic changes of pregnancy negatively affect the woman with heart disease. Heart rate and stroke volume are each increased by 25% by the end of the second trimester. Early in the third trimester, intravascular volume has expanded by nearly 50%.[384] These three changes during pregnancy cause a 50% increase in CO that is aggravated by physiologic anemia and aortocaval compression. Labor contractions can rapidly increase the already elevated CO. Such increases in blood volume and CO are especially difficult for a parturient with valvular heart disease. Elevated CO will increase myocardial oxygen demand exacerbating CHF, and low SVR will worsen coronary perfusion, causing myocardial ischemia. Low SVR may also compromise maternal pulmonary blood flow or alter shunt physiologic functioning with certain congenital heart defects. It is not uncommon to see a nonpregnant woman with well-compensated cardiac disease acutely or gradually decompensate as cardiac demands increase during pregnancy.

Cardiovascular morbidity and mortality is strongly associated with maternal functional status. Four major risk factors predict poor maternal outcomes according to a prospective evaluation of more than 600 pregnancies complicated by maternal cardiac disease: (1) CHF and/or a history of transient ischemic attacks, stroke, or arrhythmias; (2) prepregnancy NYHA class higher than II; (3) left-sided heart obstruction; and (4) an ejection fraction greater than 40%.[383] The likelihood of complications rises to 75% if more than one risk factor is present. Most commonly, the complication takes the form of pulmonary edema or arrhythmias.

Rheumatic heart disease accounts for nearly 75% of maternal heart disease, but CHD is increasing its share as more women with CHD are reaching childbearing years. Native valve disease and prosthetic valve dysfunction comprise most of the surgical procedures during pregnancy. Dissecting or traumatic rupture of the aorta, pulmonary embolism, closure of PFO, and cardiac tumors comprise only a small percentage of cases.[385] Mitral valve disease is the most common valvular disorder that requires surgery in pregnancy. Chronic mitral or aortic regurgitation may actually be associated with a small symptomatic improvement, secondary to the normal physiologic changes of pregnancy. In contrast, stenotic valvular lesions tolerate these changes poorly.[382] Aortic and mitral stenosis are common problems that may lead to hemodynamic deterioration, forcing emergency delivery before cardiac surgery. The most frequent indication for emergency cardiac surgery during pregnancy is decompensation from CHF attributable to mitral stenosis.[386] New onset of atrial fibrillation with mitral stenosis causing severe hypotension and decreased CO is one of the more common potentially life-threatening situations to the mother and fetus.

Because cardiac surgical morbidity and mortality is higher in the parturient than the nonpregnant patient undergoing the same cardiac surgical procedure, every effort is made to manage the patient without surgery. Extensive exposure to radiation may, however, limit therapeutic invasive catheterization procedures. If nonsurgical therapy conflicts with fetal interests, cardiac surgery and CPB is reasonable because delaying surgery until after delivery carries a higher maternal mortality than proceeding with the surgery.[382] If the fetus is 24 weeks' gestation, the obstetrician may perform cesarean section just before CPB because of the greater fetal mortality associated with cardiac surgery. Although general anesthesia is recommended for patients requiring cesarean section before CPB, volatile agents may induce uterine atony, resulting in serious bleeding; consequently, total intravenous anesthesia merits consideration.

Weiss and colleagues[385] described the heart surgery requiring CPB in a pregnant patient. Maternal morbidity has fallen from 5%[386] to less than 1%.[387] Fetal mortality remains high, ranging from 16% to 33%.[385,386,388] Unfortunately, fetal mortality is related to the use of CPB, duration of the surgery, and hypothermia. The nonphysiologic nature of CPB combines with the changes of pregnancy for an uncertain response and tolerance by both the mother and the fetus. A recent series of 23 pregnant women with severe cardiac valve malfunction requiring open cardiac surgery demonstrated an in-hospital maternal mortality of 8.7% and a fetal mortality of 43.5%.[389]

CPB exposes the fetus to many undesirable effects that may have unpredictable consequences. Initiation of CPB activates a whole-body inflammatory response[390] with multiple effects on coagulation, autoregulation, release of vasoactive substances, hemodilution, and other physiologic processes that may adversely affect both the fetus and the mother. Maternal blood pressure may fall immediately after or within 5 minutes of initiating CPB, lowering placental perfusion secondary to low SVR, hemodilution, and the release of vasoactive agents.[386] Fetal heart rate variability is often lost, and fetal bradycardia (<80 bpm) may also occur at this time.[391] Because uterine blood flow is not autoregulated and relies on maternal blood flow, decreases of maternal blood pressure cause fetal hypoxia and bradycardia. Increasing CPB flows (>2.5 L/m^2 per minute) or perfusion pressure (>70 mm Hg) will raise maternal blood flow and usually return the fetal heart rate to 120 bpm.[392] A compensatory catecholamine-driven tachycardia (170 bpm) may ensue that suggests an oxygen debt existed.[391] Nonetheless, increasing CPB flow and mean arterial pressure do not always correct fetal bradycardia, and, if not, then other causes must be considered.

Problems with venous return or other mechanical aspects of extracorporeal circulation may also limit systemic flow, causing reduced placental perfusion. If acidosis persists throughout CPB, then other factors may be responsible for it, rather than low maternal blood pressure such as maternal hypothermia, uterine contractions, or medications that are transferable to the fetus. Monitoring the fetal heart rate is important to assess fetal viability and subsequent therapeutic initiatives. Fetal monitoring reduces mortality partially by early recognition of problems.[386] Immediately after delivery, the CO increases suddenly because of mobilization of extracellular fluids and removal of aortocaval compression to greatly burden the diseased cardiovascular system.[382]

Hypothermia has been used for years in cardiac surgery but is not recommended for the pregnant patient. There are reports of fetal survival with maternal core temperatures of 23°C to 25°C, and fetal survival is even documented after 37 minutes of hypothermic (19°C) circulatory arrest.[393,394] However, when hypothermic versus normothermic CPB was examined retrospectively in 69 pregnant patients who underwent cardiac surgery during 1958 to 1992, hypothermia was associated with an embryofetal mortality of 24%, compared with 0% for normothermia (Table 24.10). The fetus appears to maintain

TABLE 24.10 Fetal and Maternal Mortality and Morbidity After Cardiopulmonary Bypass

Variable	*Number of Patients*	*Embryofetal Mortality*	*Maternal Mortality*	*Embryofetal Morbidity*	*Maternal Morbidity*
Total cases	69	14 (20.2%)	2 (2.9%)	5 (7.2%)	3 (4.3%)
1958–1974	29	9 (31.0%)	2 (6.9%)	1 (3.4%)	0
1975–1991	40	5 (12.5%)	0	4 (10.0%)	3 (7.5%)
Less than 15 weeks	24	3 (12.5%)	1 (4.2%)	4 (16.6%)	1 (4.2%)
16 weeks or more	41	9 (21.9%)	0	1 (2.4%)	2 (4.9%)
Hypothermia (<35°C)	25	6 (24.0%)	0	4 (16.0%)	1 (4.0%)
Normothermia (≥36°C)	13	0	0	0	2 (15.3%)

autoregulation of the heart rate with mild hypothermia, but most functions are reduced with severe hypothermia.[391] Maternal mortality was not influenced by differences in CPB temperature.

Beyond the effect of hypothermia on acid-base status, coagulation, and arrhythmias, it may precipitate uterine contractions that limit placental perfusion and risk fetal ischemia and survival. The explanation for hypothermic-induced contractions may be related to the severe dilution that accompanies CPB and lowers progesterone levels, thus activating uterine contractions. Contractions are more likely to occur the older the gestational age of the fetus.[388,395] Accordingly, uterine monitoring is strongly recommended if CPB is required during pregnancy. If uterine contractions should begin during CPB, then stopping them is vitally important for fetal survival. Treatment includes ethanol infusion, magnesium sulfate, terbutaline, or ritodrine. However, many of these tocolytic agents have potential side effects and toxicities that can be especially detrimental to the patient with heart disease.[396] However, tocolytic agents may be necessary if the contractions are associated with significant fetal decelerations that are indicative of severe oxygen debt. Infants have died from protracted contractions.[397] Prophylactic measures, such as progesterone to prevent contractions, have been of indeterminate value. Pulsatile CPB may lessen the risk of contractions; although fewer premature contractions were noted, the mechanism is unclear and has not gained popularity.[398]

As noted previously, the initiation of CPB is accompanied by moderate hemodilution. It has been recommended that the hematocrit remain above 28% to optimize oxygen-carrying capacity for the mother and fetus.[382] Arterial partial pressure of carbon dioxide ($PaCO_2$) should be slightly hypercapnic, because this increases uterine blood flow. Anticoagulation and its neutralization for CPB should be consistent with routine management for nonmaternal patients, because unfractionated heparin does not cross the placenta and can be used safely. Anticoagulation therapy during pregnancy has been extensively reviewed.[399] A cesarean section has been advised for neonates with a gestational age of more than 28 weeks immediately after heparinization and cannulation but before the commencement of CPB,[400] because at 24 to 28 weeks' gestation, organogenesis is complete, and neonates do well. If the avoidance of CPB with the fetus is not possible, then, unfortunately, the appropriate management to achieve an optimal outcome for the mother and fetus has not been firmly established with prospective randomized trials.

Approximately 30 to 60 minutes after separation from CPB, the fetus develops a severe and progressive respiratory acidosis.[391] Although correctable, hours later, a more severe metabolic acidosis ensues with the potential for fetal death. It has been postulated that catecholamines and the fetal stress response may be responsible for poor CO, secondary to significant vasoconstriction reflected in a persistent acidosis.[388] The effects of vasopressors and inotropic agents on uterine blood flow in pregnant patients with cardiac disease are indeterminate. ACE inhibitors and ACE-receptor antagonists are contraindicated during pregnancy.[382] Current guidelines are based on animal data, not the intact human maternal-fetal unit. Uterine blood flow is directly proportional to mean perfusion pressure and inversely proportional to uterine vascular resistance. The uterine vascular bed is maximally dilated during pregnancy. Stimulation of α-adrenergic receptors increases uterine vascular resistance and potentially decreases uterine blood flow. However, improvements in maternal CO, blood pressure, and uterine blood flow by certain vasopressors may outweigh any detrimental effect on uterine vascular resistance. Ephedrine has been the vasopressor of choice for maternal hypotension for years. Ephedrine and phenylephrine are safe when treating maternal hypotension during cesarean section after spinal or epidural anesthesia.[401,402] In pregnant ewes, dopamine's effect on uterine blood flow is mixed. Epinephrine has been associated with decreased uterine blood flow, although in one clinical report an infusion of epinephrine improved maternal hemodynamics after CPB and resolved fetal bradycardia.[403] Overall, the use of these agents during CPB appear to have few negative effects.[391]

Anesthesia Considerations

Medications for anesthesia must be considered in the context of the maternal heart disease, the influence of CPB, and the effects on the fetus. Maternal safety and optimal fetal outcome must be ensured. Being aware of the safety of the more commonly used drugs in cardiac anesthesia during pregnancy is important. The risk of teratogenesis with a myriad of medications and exposures of the fetus during cardiac surgery and CPB is high, but most infants have successfully avoided the effects.[394,395] No anesthetic agent has been shown to be teratogenic in humans. Fetal teratogenicity is always a concern of anesthetic management, especially during the first trimester when fetal organogenesis occurs. Commonly used induction agents and sedatives, such as thiopental, ketamine, etomidate, propofol, midazolam, and diazepam, rapidly cross the placental barrier to the fetal circulation.[50,404–406] Animal studies show that halothane, enflurane, isoflurane, and sevoflurane appear to be safe anesthetic agents and lack teratogenic effects.[407,408] Despite concerns about the action of nitrous oxide on DNA synthesis, human and animal studies indicate that it is safe to use nitrous oxide for anesthesia during pregnancy. Fentanyl and sufentanil decrease beat-to-beat variability and may mask fetal distress but do not produce teratogenic effects. Both depolarizing and nondepolarizing muscle relaxants cross the placenta to different degrees. Pancuronium, atracurium, and pipecuronium have been administered either intramuscularly or intravenously directly to the human fetus *in utero* without apparent adverse sequelae.

Many medications are administered during cardiac anesthesia that do not provide anesthesia. ß-Blockers such as propranolol, esmolol, and labetalol cross the placenta but appear safe for acute and chronic use.[409] Nitroprusside, nitroglycerin, and hydralazine appear to be safe for treating maternal hypertension. Nitroprusside rapidly crosses the placental membrane in pregnant ewes, but infusion rates of less than 2 μg/kg per minute do not generate toxic levels of cyanide in fetal lambs.[400] Mannitol and furosemide cross the placenta and induce fetal diuresis but have no apparent adverse fetal consequences. Regional anesthesia carries considerable risk in view of the degree of anticoagulation necessary for CPB, although it has been used successfully.

A team approach with the anesthesiologist, surgeon, neonatologist, and obstetrician is critical for the care of mother and fetus, especially if optimal management for the mother does not necessarily coincide with fetal interests. The decision to operate needs to be made in the context of the potential survivability of the fetus outside the uterus should delivery of the baby become probable.

Risks of Human Immunodeficiency Virus Transmission

In the United States, 1.2 million people are infected with HIV, representing 2.5% of the global infections.[410] More than 50,000 new cases occur annually in the United States.[411] Concern exists among health care workers about the risk of infection with HIV. Only 57 cases of documented occupational HIV infection in health care workers in the United States have been reported between 1981 and 2001.[410] Cardiac surgery is one of the highest risk settings for occupational HIV transmission by reason of the considerable blood exposure that often occurs with excessive bleeding after CPB. This risk is not expected to improve greatly in the foreseeable future. However, the pattern of HIV transmission is changing to include more heterosexual and progressively older individuals. New therapies and a delayed incubation time to develop AIDS after infection have extended life expectancy of those with HIV.[412] However, since the introduction of the highly active antiretroviral therapy, reduction in deaths have been slipping in response to a potential resistance to combination drug therapies. Currently, the number of cases has stabilized in the United States. As patients with HIV live longer and reach ages during which the likelihood of cardiac surgery is greater, the number of HIV patients that require cardiac surgery will also rise.

The risk of exposure of HIV for the health care worker continues to evolve. Earlier studies show transmission risks from patients were overall, minimal. Henderson and associates[413] prospectively studied 1344 health care workers over a 6-year period to assess the risk of HIV transmission during occupational activities. The authors combined data from multiple sources and stated, "the risk for HIV-1 transmission associated with percutaneous exposure to blood from an HIV-1 infected patient is approximately 0.3% per exposure." The risk after mucous membrane and cutaneous exposure to an HIV patient is 0.09%. Transmission of HIV has been reported after nonintact skin exposure, but the risk is less than mucous membrane transmission.[414] The Centers for Disease Control and Prevent prospective surveillance project found a 0.36% HIV seroconversion rate in health care workers who sustained percutaneous exposure to HIV-contaminated blood.[415] No seroconversions occurred in health care workers who had mucous membrane or cutaneous exposure to HIV-infected blood.

The rates of exposure are subject to study methods, types of procedures, and the precautions of the individuals involved; consequently, the stated risk of transmission with a single exposure may be greater than initially suspected. Factors that have been identified to alter the rate of conversion are a deep injury contact, injury by a device visibly contaminated with a patient's blood, or injury by a device placed in the artery or vein. These factors are associated with a higher titer of viral exposure; consequently, the rate of conversion is greater than the rate of 0.5% noted previously.[416] The risk of transmission is also greater with exposure to a larger quantity of blood or an HIV-infected person with a terminal illness.[414] Rates of conversion in surgical settings are known to vary widely.[417] The specific occupational risk of bloodborne infections in the health care setting primarily depends on three factors: (1) prevalence of infected patients within the patient population; (2) probability of acquiring a specific infection after a single occupational exposure; and (3) frequency of at-risk exposures.[412] Recently in a study examining the risk of transmission of HIV by surgical subspecialties and occupation, cardiothoracic surgery had the highest rate. The rate of mucocutaneous contamination by blood splashing during surgery has been estimated to be higher, approximately 50% for cardiothoracic surgery. It appears that almost 60% of exposures in cardiac surgery occur in the surgical unit, with suturing representing one third of the contacts. However, HIV infection accounts for only 5% of these exposures, compared with 78% for hepatitis C. Blood-to-hand contacts represent many of the exposures in the cardiac surgical setting.[417] Contact of blood with the body increases the risk of infection dramatically as blood loss exceeds 500 mL.

The best way to prevent occupation-related HIV infection is to prevent exposure to HIV-contaminated bodily fluids, most notably blood. Greene and colleagues[418] using data confined to anesthesia personnel and obtained in 1991 to 1993, found that the majority of percutaneous injuries were from contaminated needles, usually hollow bore and preventable. Hollow-bore needles that have been used in venous or arterial puncture appear to have a higher incidence of HIV transmission than solid needles. Needleless or protected-needle infusion devices and revised anesthesia practice protocols have lowered the incidence of percutaneous injuries.[419] All anesthesia personnel should routinely wear face shields or eye protection and gloves to prevent cutaneous and mucous membrane contamination.

The safety of blood transfusion regarding infection has been confirmed.[420] All donated blood undergoes HIV-antibody screening, but a *window period* of approximately 22 days exists when antigen may exist in a donor's blood without antibody. As of 1995, only 29 documented cases of AIDS have been attributed to receiving HIV-seronegative blood, although the actual number may be higher. Lackritz and associates[421] evaluated the American National Red Cross blood system and estimated that one blood donation in 360,000 occurred during the window period. Furthermore, 15% to 42% of this blood was discarded on account of other laboratory abnormalities. They also estimated that 1 in 2,600,000 donations was HIV positive, but it was missed because of laboratory error. The American Red Cross defined the risk for the administration of HIV-infected blood as 1 in 450,000 to 660,000 donations. Extrapolating their data nationwide to all 12 million annual donations, approximately 18 to 27 HIV-infected donations are available for transfusion. Schreiber and colleagues[422] estimated that one in 493,000 donated units of blood would result in HIV transmission. They also estimated the risks of transmitting human T-cell lymphotropic virus, hepatitis C virus, and hepatitis B virus to be 1 in 641,000; 1 in 103,000; and 1 in 63,000, respectively. Despite the appropriate concern about HIV transmission during blood transfusion, similar attention should also be directed toward the transmission of hepatitis B and C viruses.

The effectiveness of postexposure prophylaxis has been difficult to prove in view of the small number of exposures that prevent an adequate statistical analysis of the rate of seroconversion after contact. In case-controlled trials, zidovudine is the only drug that has been shown to reduce the rate of seroconversion.[423,424] Table 24.11 displays the antiretroviral drugs available in 2009. Table 24.12 outlines the recommendations of the US public health service and from the Centers for Disease Control and Prevention for postexposure prophylaxis. Postexposure chemoprophylaxis with two drugs is indicated when health care workers are at risk for acquiring HIV via percutaneous exposure. The two-drug combination of nucleoside reverse transcriptase inhibitor agents is recommended if significant exposure occurs over a 4-week course. Possible combinations include zidovudine-lamivudine, lamivudine-stavudine, or didanosine-lamivudine.[414] A third drug is recommended if the risk is believed to be even higher

TABLE 24.11 Antiretrovirals Available in 2009

NRTIs	*NNRTIs*	*Protease Inhibitors*	*New Classes*
Abacavir	Delavirdine	Atazanavir	Fusion inhibitors (eg, enfurvitide)
Didanosine	Efavirenz	Darunavir	CCR5 inhibitors (eg, maraviroc)
Emtricitabine	Nevirapine	Fosamprenavir	Integrase inhibitors (eg, raltegravir)
Lamivudine	Etravirine	Indinavir	
Stavudine		Lopinavir	
Tenofovir		Nelfinavir	
Zidovudine		Ritonavir	
		Saquinavir	
		Tipranavir	

CCR5, C-C chemokine receptor type 5; *NRTIs*, nucleoside reverse transcriptase inhibitors; *NNRTIs*, nonnucleoside reverse transcriptase inhibitors.

TABLE 24.12 Provisional Public Health Service Recommendations for Chemoprophylaxis After Occupational Exposure to Human Immunodeficiency Virus

Type of Exposure	*Source Material*[a]	*Antiretroviral Prophylaxis*[b]	*Antiretroviral Regimen*[c]
Percutaneous	Blood[d]		
	Highest risk	Recommend	ZDV plus 3TC plus IDV
	Increased risk	Recommend	ZDV plus 3TC ± IDV[e]
	No increased risk	Offer	ZDV plus 3TC
	Fluid containing visible blood, other potentially infectious fluid,[f] or tissue	Offer	ZDV plus 3TC
	Other body fluid (eg, urine)	Not offered	
Mucous membrane	Blood	Offer	ZDV plus 3TC ± ID[e]
	Fluid containing visible blood, other potentially infectious fluid,[f] or tissue	Offer	ZDV ± 3TC
	Other body fluid (eg, urine)	Not offered	
Skin	Blood	Offer	ZDV plus 3TC ± IDV[e]
Increased risk[g]	Fluid containing visible blood, other potentially infectious fluid,[f] or tissue	Offer	ZDV ± 3TC
	Other body fluid (eg, urine)	Not offered	

[a]Any exposure to concentrated human immunodeficiency virus (HIV; eg, in a research laboratory or production facility) is treated as percutaneous exposure to blood with the highest risk.

[b]Recommend—Postexposure prophylaxis (PEP) should be recommended to the exposed worker with counseling. Offer—PEP should be offered to the exposed worker with counseling. Not offered—PEP should not be offered because these are not occupational exposures to HIV.

[c]Regimens: zidovudine (ZDV), 200 mg three times a day; lamivudine (3TC), 150 mg twice daily; indinavir (IDV), 800 mg three times a day. (If IDV is not available, then saquinavir may be used, 600 mg three times a day). Prophylaxis is administered for 4 weeks. For full-prescribing information, see package inserts.

[d]Highest risk—Both larger volume of blood (eg, deep injury with large diameter hollow needle previously in source patient's vein or artery, especially involving an injection of source patient's blood) and blood containing high titer of HIV (eg, source patient with acute retroviral illness or end-stage AIDS; viral load measurement may be considered, but its use in relation to PEP has not been evaluated). Increased risk—Either exposure to larger volume of blood or blood with high titer of HIV. No increased risk—No exposure to larger volume of blood or to blood with high titer of HIV (eg, solid suture needle injury from source patient with asymptomatic HIV infection).

[e]Possible toxicity of additional drug may not be warranted.

[f]Includes semen; vaginal secretions; or cerebrospinal, synovial, pleural, peritoneal, pericardial, and amniotic fluids.

[g]For skin, risk is increased for exposures involving high titer of HIV; prolonged contact, extensive area, or an area in which skin integrity is visibly compromised. For skin exposures without increased risk, the risk of drug toxicity outweighs the benefit of PEP.

Risks and prevention strategies. *Infect Dis Clin North Am.* 1997;11:341, and from the Centers for Disease Control and Prevention (CDC). Update: provisional Public Health Service recommendations for chemoprophylaxis after occupational exposure to HIV. *MMWR Morb Mortal Wkly Rep.* 1996;45:468,199.)

or the HIV titer is higher in the exposure. Therapy should be initiated as soon as possible, because there is a *window* before the systemic infection occurs. Early exposure to the antiretroviral therapy permits a better chance to preserve immune function and alter the course of the disease. Current recommendations suggest at least 1 to 2 hours from the time of exposure for the initiation of prophylaxis to be successful, but this has not been proven. In some cases, prophylaxis has been successfully administered 36 hours after exposure.[419] It has been shown that those who are exposed to HIV through occupation and who do not seroconvert may still develop markers of T-cell mediated response to the virus. However, the risk of this is lower if the exposed person has received antiretroviral prophylaxis.[419]

All patients at any stage of infection with HIV, even during the "window of opportunity" are at risk for transmission.[425] To date, only 22 patients have HIV seroconversion after prophylaxis, with 6 of those patients receiving combination therapy. Follow-up for the occurrence of side effects should start after 4 weeks and continue for at least 6 months after exposure.[419] Serologic testing for conversion should occur 6 weeks, 3 months, and 6 months from the time of exposure. If hepatitis C was confirmed, then testing for seroconversion should continue for another 12 months because of the effect of hepatitis C to delay HIV seroconversion. Zidovudine has potential complications; therefore its administration should be carefully considered since most exposures to HIV do not result in seroconversion. Additionally, zidovudine has been associated with several failures and complications.[417]

Prophylaxis therapy for occupational exposure should involve investigation into the source of the exposure with the recent rise of resistant strains to carefully design the optimal regimen. Determining the HIV serologic nature of the source for infection as soon as possible is critical to minimize any exposure to prophylaxis if the source is found to be HIV negative. Prophylaxis is not indicated if the patient is negative for HIV. If testing the infecting source is delayed, then at least one dose of prophylactic agents should be administered.[411] The viral load for prophylaxis differs greatly if the donor is chronically infected, and the postexposure prophylaxis will be influenced by it. The proper prophylaxis is important because incremental toxicity increases as the number of antiretroviral agents is increased.

Because new therapies for HIV have become more widespread,[426] patients undergoing cardiac surgery may be receiving these newer medications (see Table 24.11). Triple drug therapy is now the standard of care. The complexity of medications that these patients may receive certainly increases the possibility of drug interactions. The nucleoside analog reverse transcriptase inhibitors are primarily secreted by the kidneys, therefore fewer drug interactions are possible. However, the nonnucleoside analog reverse transcriptase inhibitors and protease inhibitors are metabolized by the liver with the cytochrome P450 mechanism so that many drug interactions are possible, especially with anesthetic agents. Ritonavir, a potent protease inhibitor, can increase the blood concentration levels of amiodarone, midazolam, diazepam, and meperidine, to name a few. Drug interactions should be considered if a patient is taking these medications and requires cardiac surgery.

Renal Insufficiency and Cardiac Surgery

Chronic kidney disease is increasingly common, having a global prevalence of greater than 10%.[427] In recent years, the number of individuals with chronic renal failure (CRF) undergoing cardiac surgery has increased between 2% and 3% of the cardiac surgical population.[428] Patients with CRF may not necessarily be dialysis dependent before surgery but are more likely to develop worsening renal function after CPB than those with normal preoperative renal function.[429] Acute kidney injury occurs frequently (28%) and is associated with increased mortality.[430,431] Morbidity and mortality are especially high in patients on long-term dialysis who are undergoing cardiac surgery and CPB, ranging from 17% to 77% and 8% to 31%, respectively.[432] Because CRF accelerates the development of atherosclerosis, many of these patients will eventually require myocardial revascularization. Irrespective of whether the CRF patient is dialysis dependent, he or she is an anesthetic challenge, especially in regards to fluid management, electrolyte status, and hemostasis. The ability to avoid dialysis in the nondialysis-dependent CRF patient is very important to hospital lengths of stay and long-term mortality. A collaborative effort by the cardiac surgeon, anesthesiologist, nephrologist, and cardiologist is instrumental in the

care of these patients. Unfortunately, long-term survival is still appreciably diminished, even with minimal perioperative morbidity.

Patients with CRF are more prone to fluid overload, hyponatremia, hyperkalemia, and metabolic acidosis. Optimal hemodynamic and fluid status before surgery is important. Hemodialysis should be strongly considered the day before surgery, especially in those who are strictly dialysis dependent. Chronic dialysis patients tend to arrive for surgery with worsened left ventricular function, possibly from an inefficient waste and toxin removal. CHF can occur as a result of hypervolemia and poor left ventricular function, manifesting as pulmonary edema and respiratory distress. Dialysis and medical therapy directed at improving cardiac function may be required to optimize the patient preoperatively. Chronic medications should be carefully reviewed to ensure that certain medications, such as antihypertensive agents, are given. The importance of preoperative preparation for patients with CRF is evident by the significantly high mortality rate associated with urgent surgery.[428]

Perioperative mortality of patients with CRF undergoing cardiac surgery is associated with several risk factors. A preoperative creatinine of 2.5 mg/dL is associated with greater mortality even in those patients with nondialysis-dependent CRF.[432] Late mortality may range from 8.3% to 55% if dialysis is ongoing for longer than 60 months.[428] Pulmonary dysfunction also increases the perioperative mortality of CRF patients.

Patients with CRF differ from those with normal renal function in a variety of ways, which influence anesthesia management. A normochromic, normocytic anemia is common primarily because of decreased or absent erythropoietin secretion for which the kidney is the predominant source. Anemia is now treated with recombinant human erythropoietin therapy instead of blood. The cardiovascular benefits are especially noticeable with the correction of anemia. However, treatment is costly and requires multiple injections weeks before surgery, which may not always be possible.

Efforts to find renoprotective agents for patients that are either at high-risk for renal failure or those with CRF have been unsuccessful. Randomized double-blind prospective trials looking at the use of *N*-acetylcysteine for patients undergoing CPB with CRF have found mixed results.[433–435] *N*-acetylcysteine is an antioxidant and vasodilator with the ability to increase cyclic guanosine monophosphate (cGMP) and nitric oxide, which has shown promise in contrast-related renal failure. Fenoldopam, a dopamine-1 receptor agonist, was studied in patients undergoing CPB with preoperative creatinine levels above 1.5 mg/dL.[436] Patients were given a renal dose of dopamine or fenoldopam perioperatively. Postoperative parameters were only improved in those receiving fenoldopam, suggesting a renal protective effect, but additional studies are needed. Mannitol and Lasix may also prevent early oliguric renal failure.[437]

Anesthesia Considerations

CRF affects dosing of medications that have a large volume of distribution. Decreased serum protein concentration diminishes plasma binding, leading to higher levels of free drug to bind with receptors. Many patients with CRF have hypoalbuminemia. In general, anesthetic induction agents and benzodiazepines are safe to use in patients with CRF. A common induction agent, thiopental, is highly protein bound, therefore the dose should be reduced accordingly. Medications that rely totally on renal excretion have a limited role. Fentanyl and sufentanil may be more effective for pain management because excretion is not renally dependent as morphine sulfate. Currently used volatile anesthetic agents rarely incur any additional renal dysfunction, even with underlying CRF unless severely prolonged duration of anesthesia occurs. Muscle relaxants and agents for antagonism of muscle paralysis have varying degrees of renal excretion (Table 24.13).

A rapid-sequence induction is recommended in those with CRF in response to the likelihood of delayed gastric emptying. Significant extracellular volume contraction may also be present before the induction of anesthesia as a result of the 6- to 8-hour fast before surgery and dialysis within 24 hours of surgery that may lead to hypotension on induction. Because fluid requirements are usually high with CPB, a PAC is especially useful to manage fluid administration. TEE may complement fluid management by assessment of left ventricular volume and function. Before the initiation of CPB, fluid administration should be limited, especially if the patient is dialysis dependent. In the nondialysis-dependent patient, fluid should be given to maintain adequate urine output but to also avoid excessive cardiovascular filling pressures that incite pulmonary edema. Fluids should not be too aggressively restricted, because doing so may cause acute renal failure superimposed on CRF. Low-dose dopamine has been recommended for patients with CRF, but its value is indeterminate.

TABLE 24.13 Commonly Used Muscle Relaxants and Renal Failure

Relaxant	*Acceptable*	*Renal Excretion*
Atracurium	Yes	<5%
Curare	Yes, with caution	60%
Cis-atracurium	Yes	<10%
Doxacurium	Yes, with caution	70%
Gallamine	No	100%
Metocurine	Yes	50%
Pancuronium	Yes, with caution	70%
Pipecuronium	Yes, with caution	70%
Vecuronium	Yes	30%
Rocuronium	Yes	9%[b]
Mivacurium	Yes	7%[c]
Succinylcholine	Yes, with normokalemia	0%

In general, CRF will worsen after CPB in part because of a combination of nonpulsatile flow, low renal perfusion, and hypothermia.[432] Studies remain mixed regarding the ability of pulsatile flow during CPB to preserve renal function, compared with nonpulsatile CPB.[438] Renal perfusion is lowered as CPB is initiated, increasing the chance for ischemia of the renal cortex. Mean arterial pressure should be kept above 80 mm Hg. The stress of surgery and hypothermia may impair autoregulation so that renal vasoconstriction reduces renal blood flow. The fluid required to initiate CPB may significantly reduce the hemoglobin and oxygen-carrying capacity in view of the preexisting anemia of CRF without the addition of red blood cells (RBCs) to the priming volume or immediately upon initiation of CPB. A hematocrit of 25% should be maintained during CPB.[432] Washed RBCs are recommended for RBC transfusion to lessen excessive potassium and glucose levels intraoperatively. Potassium plasma levels should be checked periodically. Patients with CRF often have glucose intolerance from an abnormal insulin response; therefore more frequent determination of serum glucose levels is advisable.

The anephric patient poorly tolerates post-CPB hypervolemia associated with prolonged duration of CPB. Dialysis can be performed during CPB and is technically easy and effective because small molecules (uremic solutes, electrolytes) are removed.[439] Instead of dialysis during CPB, hemofiltration (ultrafiltration) is more frequently performed effectively, clearing excess water without the hemodynamic instability of dialysis. Circulating blood passes through the hollow fibers of the hemoconcentrators, which have a smaller pore size than albumin (55,000 daltons) that remove water and solutes. These midsize (inflammatory) molecules are small enough to pass through the pores to concentrate the blood. Potassium is eliminated, thereby helping reduce excessive potassium concentration commonly associated with

cardioplegia administration. Hemofiltration during CPB may not achieve a net reduction in the overall total fluid balance of the patient in part because a minimum volume of fluid must be maintained in the venous reservoir of the extracorporeal circuit but may be associated with earlier extubation after CPB.[440]

Excessive bleeding after CPB is not uncommon in those with CRF in part because of preoperative platelet dysfunction. Antifibrinolytic medications are pharmacologic measures used to successfully reduce excessive bleeding and transfusion requirements associated with cardiac surgery.[79] Tranexamic acid, an inexpensive, synthetic antifibrinolytic, is excreted primarily through the kidneys; consequently, a dose reduction will be required, based on the preoperative creatinine level. A newer dosing regimen has been developed, based on levels of tranexamic acid.[441] The drug, aprotinin, a serine protease inhibitor with antiinflammatory and antifibrinolytic properties, is concentrated in the proximal renal tubules. Recently, aprotinin was found to triple the risk of renal failure with dialysis, compared with tranexamic acid and aminocaproic acid in patients undergoing CABG surgery in an observational study involving over 4000 patients.[442] This study was followed by a randomized double-blinded trial of patients undergoing cardiac surgery with aprotinin, aminocaproic acid, or tranexamic acid that was halted before the completion of enrollment as a result of the increase in mortality with aprotinin, compared with the other lysine analog antifibrinolytic agents.[443] Although this trial did not find a statistically significant increase in renal failure or the need for renal replacement therapy, there was an increase in the number of patients who had their creatinine dose doubled. Ultimately, the US Food and Drug Administration (FDA) has removed aprotinin from clinical use.

Postoperatively, if dialysis is required in patients with end-stage renal disease, then the risk of dialysis dependence is greatly increased.[437] If the patient is dialysis-dependent preoperatively, dialysis is usually resumed within 24 to 48 hours of surgery and then according to the patient's preoperative routine to optimize fluid, electrolyte, and metabolic status. Dialysis may be needed soon after return from the surgical unit if mobilization of fluids into the intravascular space causes CHF. Hemodialysis primarily corrects electrolyte imbalances and removes organic acids to correct metabolic acidosis. Dialysis may lessen the platelet dysfunction associated with uremia to minimize hemostatic abnormalities and excessive hemorrhage. Peritoneal dialysis may be preferable if the postoperative hemodynamic status of the patient is unstable. Peritoneal dialysis, compared with hemodialysis, is more convenient to administer and does not require the immediate support of a nephrologist. However, continuous renal replacement therapy can be instituted intraoperatively and postoperatively to manage acute renal failure with volume overload and metabolic instability with great results in cardiac patients after CPB.[444] Continuous renal replacement therapy has become very popular in cardiac surgical patients in the last 10 years because the bedside nurse can direct the degree of fluid pull in response to the patient's changing hemodynamic status. Between 0.7% and 1.4% of patients undergoing cardiac surgery may require this transient form of therapy for renal failure.

Patients with CRF are at high risk for morbidity and mortality with cardiac surgery involving CPB. Attention to the following steps may improve outcome: (1) assessment of conditions associated with CRF that lead to complications such as platelet function, lung function, and anemia; (2) adequate RBC mass; (3) fluid and electrolyte care, particularly after CPB; (4) hemofiltration; (5) blood conservation techniques and treatment of coagulopathy; (6) judicious use of dialysis; and (7) scrutiny for infections that patients with CRF are more susceptible to develop.

Hematologic Problems in Patients Undergoing Cardiac Surgery

Anesthetic concerns for patients with hematologic problems who undergo cardiac surgery are further complicated by the stress CPB places on coagulation and oxygen-carrying systems. Hemophilia, cold agglutinins (CAs), sickle cell disease (SCD), antithrombin (AT) deficiency, and von Willebrand disease (vWD) are a few of the hematologic disorders that may require special consideration if CPB is used. In general, a multidisciplinary approach, including individuals with expertise in these areas, is helpful in providing optimal care with such rare conditions.

Hemophilia

In the 1940s and 1950s, the coagulation factors that separated hemophilia A (factor VIII [FVIII] deficiency) from hemophilia B (factor IX [FIX] deficiency) were identified. Before that discovery, hemophilia was a debilitating disease with a life expectancy of less than 20 years. Subsequently, improvements in FVIII therapy has prolonged life, but the early factor concentrates were not virally safe; consequently, 60% to 95% of individuals with hemophilia beyond 8 years of age were infected with hepatitis C virus,[445] and eventually two thirds of individuals with hemophilia became infected with HIV.[446] Although life expectancy temporarily fell below 40 years of age,[447] new FVIII replacement therapy such as recombinant FVIII (rFVIII) greatly reduced viral transmission. The result was more autonomy for patients with hemophilia, prolonging their life beyond 50 years, and ensuring that they will more likely experience age-related disorders such as coronary artery disease.

Hemophilia A is the third most common X-linked disorder, occurring in 1 in 5000 male births.[445] Hemophilia B, also known as *Christmas disease*, is also an X-linked disorder with one fourth the incidence of hemophilia A. FVIII is instrumental for a normally functioning clotting cascade. With a half-life of only 8 to 12 hours, FVIII and FIXa accelerate activation of factor X. Hemophilia is characterized by spontaneous bleeding in the joints and muscles in its severe form. Hemophilia A or B are very similar in presentation, course, and treatment. Treatment of hemophilia A and B primarily depends on replacement of FVIII or FIX, respectively. Preparations of rFVIII, developed in the 1990s, effectively control 80% of bleeding episodes with a single dose. Viral contamination has been essentially eliminated; therefore the incidence of inhibitors is no more likely than plasma-derived factors. Cardiac surgeries require more intense hemostasis than most other surgical and nonsurgical situations. This requirement is exacerbated by the stress on the coagulation system and increased risk of excessive bleeding associated with cardiac surgery.[448]

Specific challenges are involved in undergoing cardiac surgery and CPB with hemophilia. Management is derived from case reports and series without randomized, prospective trials. Relatively few institutions have experience in performing cardiac surgery in those with hemophilia; systematic information regarding optimal perioperative care is limited. However, a recent study indicated similar outcomes in patients undergoing CPB with or without hemophilia.[449]

Preoperative assessment of the cardiac surgical patient with hemophilia must determine the severity of the patient's hemophilia by history and laboratory tests, because perioperative bleeding is related to the degree of factor deficiency. Mild hemophilia has factor levels between 6% and 30% with occasional symptoms and represent 30% to 40% of hemophilia cases.[450] Moderate hemophilia has factor levels between 1% and 5% and represent 10% of hemophilia cases. Severe hemophilia has factor levels below 1% with easy bleeding that could become severe during surgery if factor activity remains at 1%. Severe hemophilia occurs in approximately 50% of hemophilia cases. Most patients arrive for surgery with an FVIII or FIX activity less than 5%. Although a factor level near 50% of normal is regarded as adequate to achieve noncardiac surgical hemostasis, hemostatic demand and associated coagulation abnormalities[448] with cardiac surgery and CPB will require a higher FVIII level.

Preoperatively, FVIII activity should be 80% to 100% for cardiac surgery. The amount of factor replacement is estimated from the total fluid volume of the extracorporeal circuit (priming volume), plasma volume, and the desired factor activity. If the preoperative FVIII or FIX level is recent (morning of surgery), then this value may be acceptable

for the determination of FVIII and FIX replacement for the initiation of CPB. Otherwise, FVIII and FIX levels should be obtained before initiation of CPB. Replacement of FVIII or FIX during CPB may be achieved by intermittent bolus or continuous infusions, but the optimal factor activity for CPB has not been established. Based on hemodilution that typically occurs during CPB, 30% to 50% FVIII or FIX levels would be consistent with other coagulation factors during this period, but FVIII levels are difficult to obtain during CPB, secondary to the high heparin dosing required. Consequently, a bolus of FVIII or FIX before the initiation of CPB is a consideration.

The disadvantage of bolus administration of factor replacement is the resulting high peak levels, but it ensures that trough levels will be adequate for hemostasis. Continuous infusions may preserve FVIII levels at a constant and "safe" level to minimize bleeding.[451] Currently, only a few forms of rFVIII can be used for continuous infusions because of product instability. Depending on the bolus dose of rFVIII (50 IU/kg), a continuous infusion of 4 IU/k per hour may infuse for 72 hours to maintain FVIII activity greater than 100%.[452] Obtaining FVIII or FIX levels after heparin neutralization is still important to guide factor replacement in combination with attempts to obtain hemostasis after CPB. FVIII levels after heparin neutralization and postoperatively should approach 100% to reduce the risk of excessive bleeding. FVIII levels are helpful every other day for a period of 1 to 2 weeks while the chest tubes remain.[453] FVIII levels will vary tremendously because no treatment provides a sustained FVIII level with the diverse individual requirements and consumption of FVIII among cardiac surgical patients. A platelet antagonist such as aspirin may be recommended to prevent thrombosis because of the excessive levels of FVIII that may occur during bolus dosing.[449]

Antifibrinolytic therapy has been used in patients with hemophilia to inhibit the normal clot lysing process. A recent study has demonstrated a hemostatic benefit with tranexamic acid for cardiac surgery and CPB.[449] Antifibrinolytic agents, tranexamic acid, and epsilon-aminocaproic acid are used prophylactically to reduce blood loss and transfusion requirements in cardiac surgery involving CPB.[79] Another antifibrinolytic, aprotinin, has been removed from clinical use as a result of increased risk of death, compared with the other lysine analog antifibrinolytic agents.[442,443] Antifibrinolytic agents are routinely stopped 2 hours after arrival in the ICU, but some benefit has been seen by extending the duration of administration.[449] Serial thromboelastographies (TEGs) are useful if antifibrinolytic agents are going to be administered an extended duration with close inspection for hypercoagulable changes in the TEG shape. Additional methods and techniques for blood conservation should be considered to reduce the risk of bleeding and transfusion with hemophilia.

1-Desamino-8-D-arginine vasopressin (DDAVP), a vasopressin analog, has been used successfully in mild-to-moderate hemophilia A to decrease intraoperative transfusion requirements.[445,454,455] A rapid increase in all components of FVIII occurs after DDAVP administration, but FVIII level will fall by 50% 10 hours after administration. The response of DDAVP depends on the resting FVIII level and hemostatic demand. If the patient with hemophilia possesses 5% to 20% procoagulant activity, then he or she is more likely to respond to DDAVP, in contrast to those with severe FVIII deficiencies who will not respond to DDAVP.[455] The peak effect occurs 1 hour after an intravenous dose of 0.3 μg/kg is given. DDAVP may be given at 12- to 24-hour intervals, but tachyphylaxis is possible after multiple doses.

Therapy for hemophilia B has changed significantly with the availability of a concentrated purified recombinant FIX (rFIX). rFIX is not exposed to human or animal protein. Previously, individuals with hemophilia B were treated with plasma-derived products called *prothrombin-complex concentrates* that contain factors IX, X, II, and VII. These active complexes have resulted in fatal thrombotic reactions because these complexes are not normally generated or regulated by the coagulation pathway. Circulating FIX levels will not increase as much as FVIII after transfusion because FIX is distributed in both intravascular and extravascular spaces, unlike FVIII; consequently, the calculated dose has to be doubled.[456] FIX activity of approximately 50% is adequate to achieve hemostasis yet minimize the risk of thrombotic complications[457]; however, others have recommended higher dosing to achieve 100% activity.[456,458] Recently, FIX product has been successfully used for continuous infusion for replacement therapy during CPB and cardiac surgery.[458] Typically, rFIX is given as bolus once daily for surgery. Continuous infusion of rFIX has been shown recently to be effective in providing conditions for optimal hemostasis for cardiac surgery with CPB, as well as reducing the overall amount of concentrate administered.[458] Furthermore, the occurrence of inhibitors with rFIX is rare but must be evaluated before treatment. rFIX concentrate is not licensed yet in the United States for continuous infusion. Recommended levels for perioperative FIX levels have not been established for cardiac surgical patients, despite multiple case reports of it effective and safe use in this cardiac population. More information dosing of rFIX is available.[458] A review of the publications of cardiac surgery and hemophilia patients, 30 adults and 3 children, concluded that "routine cardiac surgery can be performed safely in patients with hemophia."[459]

Antibodies to FVIII or FIX may occur in patients with hemophilia who have received replacement therapy. The incidence of FVIII or FIX inhibitors is 18% to 52% and 2% to 16% of the hemophilia population, respectively.[460,461] Inhibitors occur more often in patients receiving the purest replacement factors, which is a major concern for future replacement therapy with purer products.[462] The strength of the immune response is instrumental in the development of inhibitors. For example, HIV-positive patients with hemophilia do not develop FVIII inhibitors. The inhibitor titer will characterize the patients as mild or high responders. High responders are at great risk because the anamnestic response may generate very high antibody titers that can render factor replacement therapy totally ineffective hemostatically.[463] The problem with patients who develop inhibitors and require surgery is the inability to predict hemostasis at any point of the hospitalization.

Cardiac surgery has been successfully performed in patients with FVIII inhibitors.[464] Patients with low antibody titers often tolerate conventional concentrate infusion but require higher and more frequent doses for efficacy. The defect in the intrinsic coagulation pathway must be bypassed and prothrombin-complex concentrates that contain activated forms of factors VII, IX, and X must be administered, which have been largely successful in achieving hemostasis in the presence of FVIII and FIX inhibitors.[446] Recently, a new recombinant FVIIa has become available.[465] FVIIa appears to bind to tissue factor on the surface of the activated platelet to form complexes at the site of injury. This activates other coagulation intrinsic and extrinsic factors and platelets. It causes the generation of thrombin and fibrin to create hemostasis. It is infused as a bolus 90 to 120 μg/kg and repeated at 3-hour intervals for a maximum of four times. In over 1900 surgical and nonsurgical bleeding episodes in more than 400 patients with hemophilia A or B, FVIIa has been shown to be safe with over 103 major surgical procedures with excellent results in 80% of cases.[466] A randomized controlled trial in cardiac surgery with FVIIa has been performed in adults without hemophilia that showed reductions in allogeneic transfusions.[467] Caution should be taken when using FVIIa because two metaanalysis studies of FVIIa safety have shown an increased risk of arterial thromboembolism.[468,469]

Particular caution must be taken in managing the airway in patients with hemophilia to avoid any trauma-induced bleeding. Nonsteroidal pain medications may be counterproductive in these patients because of their effect on platelet function. Strict asepsis must be maintained because the immune system of these patients may be very weak and extremely susceptible to bacterial and viral infections.

von Willebrand Disease

vWD is the most commonly inherited hemostatic abnormality, with prevalence in the general population of 0.8%.[470] vWD is an autosomal dominant bleeding disorder caused by a deficiency and/or abnormality of von Willebrand factor (vWF). An acquired form of vWD is associated with various disease states and medications.[471] The nomenclature

TABLE 24.14 Classification of von Willebrand Disease

New[a]	*Old*[a]	*Characteristics*
1	I platelet normal, I platelet low, 1A, I-1, I-2, I-3	Partial quantitative deficiency of vWF
2A		Qualitative variants with decreased platelet-dependent function that is associated with the absence of high–molecular-weight vWF multimers
2B		Qualitative variants with increased affinity for platelet GPIb
2M		Qualitative variants with decreased platelet-dependent function that is not caused by the absence of high–molecular-weight vWF multimers
2N		Qualitative variants with significantly decreased affinity for factor VIII
3		Virtually a complete deficiency of vWF

of vWF and FVIII complex have been standardized to resolve past confusion (Box 24.9).

vWF is a large, adhesive glycoprotein that is produced by vascular endothelial cells and megakaryocytes. It is found in platelet α-granules, plasma, and subendothelium. It circulates in blood as an array of multimers of various sizes. Large multimers have more binding sites for platelets and therefore augment platelet adhesion and aggregation. Each vWF subunit has a site for a platelet receptor to bind and the extracellular matrix component of the vessel wall to attach.[472] vWF has two major hemostatic functions: (1) a carrier protein and stabilizer for FVIII and (2) mediation of platelet adhesion to injured sites.[473] It plays a crucial role in mediating platelet adhesion, platelet aggregation, and clotting during high shear conditions.[474] Patients with vWD have an abnormality of both vWF and FVIII. vWD is classified into three major types and four subtypes (Table 24.14).[475] Individuals with type 1 and type 2 make up 70% and 20% of people with vWD, respectively.[476] Type 3 vWD represents only 10% of individuals and is autosomal recessive. Type 3 vWD individuals are severely affected and whose presentation is similar to individuals with hemophilia who have a very low FVIII activity (1% to 4%).

Erik von Willebrand first identified the abnormal bleeding time (BT) that characterized vWD. The laboratory diagnosis of vWD is complex because of the broad phenotypes that exist. No single laboratory test is diagnostic for vWD. The BT is sensitive for vWD, but it is prolonged in only 50% of individuals with type 1 vWD. It is significantly prolonged in type 3 vWD. The activated partial thromboplastin time (aPTT) is usually prolonged but not a good screening test for vWD because FVIII activity, which affects the aPTT, varies greatly in

vWD. The ristocetin cofactor assay vWF:ristocetin cofactor (RCo), also known as the *vWF activity*, is the most sensitive and specific test for vWD and the single best test to identify vWD (Table 24.15).[476] It measures the ability of vWF to bind to glycoprotein Ib platelet receptors. The vWF antigen test measures the quantity of vWF protein, not functional activity. vWF multimers can be visualized by electrophoresis and establish the type of vWD by their presence or absence. FVIII activity is frequently low in vWD. In mild cases of vWD, the aPTT, FVIII, and BT may be normal with only a slight decrease in the RCo and vWF antigen.[477] Factors such as age, estrogen levels, adrenergic stimulus, and inflammation can directly affect vWF levels and complicate laboratory evidence of vWD.

A complete medical history is important to complement laboratory testing. Family history is a sensitive indicator of vWD. Individuals with vWD will frequently describe bleeding that is more mucosal in origin (epistaxis), compared with people with hemophilia. Medical history is important because routine laboratory screening may fail to detect vWD. Unlike hemophilia, patients with mild vWD may go unnoticed for years with unremarkable bleeding patterns and rarely need long-term prophylaxis. Variant forms of vWD further increase the possibility of missing the diagnosis. If undiagnosed, then surgical bleeding may be severe, particularly if combined with ingestion of antiplatelet medications. Aspirin and antiinflammatory medication consumption should be identified preoperatively. Questioning the patient individually to determine the severity of bleeding is important, because major differences in the bleeding tendencies can be present within a family and with similar laboratory tests.[471] The severity of bleeding usually determines replacement therapy, instead of DDAVP or the use of antifibrinolytic agents.[478]

Because vWF has a dual role in hemostasis, correction of platelet vessel-wall interaction and deficiency of FVIII must be achieved with a prophylaxis regimen to undergo cardiac surgery requiring CPB. Correction of vWF deficiency may be accomplished by either facilitating vWF release from *in vivo* storage sites or administering exogenous components. Each type of vWD requires a specific therapeutic approach. Preoperative FVIII or RCo levels are recommended to optimize hemostatic capability for surgery. FVIII levels should be obtained intraoperatively and then once per day after surgery. Both FVIII and vWF levels will decrease on initiation of CPB, but vWF will subsequently increase as it is released from storage pools.[474] BT is rarely used anymore to guide therapy because its correlation with surgical hemostasis is poor.[478] FVIII level and vWF should be normalized intraoperatively and 7 days to 10 days after surgery to reach effective hemostasis.[479] The reliability of guides to dosing with vWD is poor, and the achievement of hemostasis should be the catalyst for additional therapy.

DDAVP is a synthetic analog of the natural hormone vasopressin without the pressor effect and is the first choice for treatment in vWD; however, not all types of vWD respond to it. DDAVP is effective in type 1 vWD[480] but ill-advised in type 2B vWD because thrombocytopenia may result. It is useless in type 3 vWD because there are no stores of vWF to release.[481] DDAVP does not directly cause the release of FVIII/vWF from the endothelial cell but stimulates monocytes to produce

a substance that releases vWF. A response to DDAVP should occur in 30 minutes with a threefold to eightfold increase in FVIII and vWF that may persist for 8 to 10 hours.[480] Hemostasis may require one or two doses of DDAVP at least 12 hours apart. It is readily available, inexpensive, and has minimal risk for patients but may be contraindicated in those with atherosclerosis, CHF, or require diuretic therapy.[482] DDAVP is effective if given in an intravenous, intranasal, or subcutaneous manner, but the intranasal preparation lacks predictability and strength of the intravenous preparation.[476] Intravenous dosing (0.3 μg/kg) requires 20 to 30 minutes to avoid a decline in mean arterial pressure of 15% to 20%. Tachyphylaxis may occur, with a 30% decrease in the effectiveness of the second dose if DDAVP is given more than once in each 24-hour period. For a majority of patients with mild vWD, DDAVP is effective and avoids exposure to plasma products. Side effects of DDAVP include facial flushing, headache, and fluid retention with hyponatremia. Reports of increased thrombosis with DDAVP are anecdotal.

Blood products should not be administered to patients with vWD unless another treatment is ineffective or contraindicated. Plasma-derived factor concentrates are the current standard for replacement therapy if the patient is unresponsive to DDAVP.[482] Factor concentrates in the past were not always effective in vWD because VWF:RCo was low and many of the hemostatically active vWF multimers were absent; as a result, FVIII levels were adequately replenished, but platelet function was impaired. These commercially available concentrates contain large amounts of both vWF and FVIII but differ in their purification and pathogen removal and inactivation techniques. Consequently, there is broad variation in the ratio of vWF and FVIII in the products and their multimer compositions that are so important for effective hemostasis. The various types of products and their dosing have recently been reviewed.[478,479,482] In general, the dosing is 60 to 80 IU/kg for a bolus dose of the factor concentrate to maintain hemostasis. The safety of these purified plasma-derived factor concentrates regarding viral transmission has been shown to be excellent (Table 24.16). An especially good product that contains a ratio of vWF:FVIII (2.4) is Haemate P/Humate-P. Clinicians must be cautious of the ratio of vWF:FVIII in the product and the type of the vWD to correctly treat the patient. The definitive amount of vWF or FVIII that is required to control bleeding for the optimal care is indeterminate. Platelet infusions should be considered in patients with type 3 vWD if bleeding persists after administering replacement concentrates.

Antifibrinolytic agents should be considered in patients with vWD to reduce clot lysis. Tranexamic acid is the most common agent used, whereas aprotinin is no longer available.[443] As in hemophilia, inhibitors can occur in vWD, causing life-threatening bleeding. Prothrombin-complex concentrates have been used to treat bleeding, but inducing a prothrombotic state and thrombosis in cardiac patients with mechanical valves is a risk.[483]

Antithrombin

AT and protein C are two primary inhibitors of coagulation. A delicate balance exists between the procoagulant system and the inhibitors of coagulation (Table 24.17). AT is the most abundant and important of

TABLE 24.17 Balance That Normally Exists Between Prothrombotic and Antithrombotic Forces Within the Circulation

Prothrombotic Factors	*Antithrombotic Factors*

the coagulation pathway inhibitors. The impact of deficiencies of AT and advisability of restoration of normal levels continues to evolve with respect to cardiac surgery.

AT is an α_2-globulin that is produced primarily in the liver. It binds thrombin, as well as other serine proteases, factors IX, X, XI, and XII, kallikrein, and plasmin irreversibly, which neutralizes their activity. However, only inhibition of thrombin and factor Xa by AT has physiologic and clinical significance.[484] AT deficiency may occur as a congenital or acquired deficiency. Acquired deficiencies are secondary to increased AT consumption, loss of AT from the intravascular compartment (renal failure, nephrotic syndrome) or liver disease (cirrhosis). A normal AT level is 80% to 120%, with activity less than 50% considered clinically important.[485]

Congenital deficiency of AT is the prototypical, hypercoagulable state produced by an imbalance of coagulation and fibrinolytic factors (see Table 24.17). The prevalence is 1 in 2000 to 5000 persons.[486] Congenital AT deficiency is separated into four types (I–IV) and based on the quantitative and qualitative defects of the AT molecule. It is transmitted in an autosomal dominant pattern with affected individuals typically maintaining 50% AT activity. If the levels decline to less than 50% activity, then the risk of venous thrombosis is significant.[485] The only abnormal coagulation test associated with this condition is the assay for AT activity, which is diagnostic. Affected individuals may experience a thromboembolic event at an early age, but arterial thrombosis is encountered in less than 1% of individuals.[487] The advisability of long-term anticoagulation therapy is indeterminate in these individuals. Anticoagulation prophylaxis is recommended in cases in which the risk for thrombosis is temporarily increased, such as surgery.[488] The risk of thrombosis is higher in congenital forms than acquired forms of AT deficiency.[486,489]

In contrast to the rare case of congenital AT deficiency, acquired deficiencies of AT are commonly encountered in cardiac surgical patients. Anticoagulation with heparin for CPB depends on AT to inhibit clotting as heparin, alone, has no effect on coagulation. Heparin catalyzes AT inhibition of thrombin over a 1000-fold by binding to a lysine residue on AT and altering its conformation. Thrombin actually attacks AT, disabling it, but in the process attaches AT to thrombin,

forming the AT-thrombin complex. This complex has no activity and is rapidly removed. Thirty percent of AT is consumed during this process; consequently, AT levels are reduced temporarily. If AT levels are not restored, then a condition called *heparin resistance* may arise. The many causes of heparin resistance are listed in Box 24.10. Heparin resistance is defined as the failure of a specific heparin dose (300–400 u/kg) to prolong an activated clotting time beyond 480 seconds in preparation for the initiation of CPB. Failure to reach 480 seconds may be considered inadequate anticoagulation with the risk of thrombus formation during CPB.

Heparin resistance is increasingly common in cardiac surgical practice today because heparin exposure before cardiac surgery is more common. Heparin resistance has been reported to occur in 3% to 13% of cardiac surgical patients. A randomized prospective study, analyzing 2270 cardiac cases, identified only 3.7% of patients to be heparin resistant.[490] Observing a visible clot in the CPB circuit even with inadequate anticoagulation is uncommon. However, inadequate anticoagulation during CPB will systematically activate the hemostatic and inflammatory systems generating thrombin, platelet and clotting factor consumption, and excessive fibrinolysis. This combination of physiologic processes places the patient at risk for both neurologic injury and excessive bleeding.

The importance of AT deficiency in heparin resistance has been demonstrated,[491,492] but it is not the only issue. Platelets, fibrin, vascular surfaces, and plasma proteins all interact to determine the anticoagulant effect of heparin. This is evident from a randomized double-blind, placebo-controlled trial comparing treatments for heparin resistance.[491] Eleven patients remained heparin resistant despite fresh frozen plasma (FFP) and AT administration. Similarly, adequate activated coagulation time values of 480 seconds were not achieved in 30% of patients, even with 800 U/kg of heparin.[493] Typically with heparin resistance, 50% more heparin is given during CPB for anticoagulation. Unfortunately, aggressive heparin dosing in the midst of heparin resistance will further exacerbate a preoperative AT deficiency. On the initiation of CPB, AT activity decreases by 25% to 50%, secondary to dilution and elimination of the AT-thrombin complex.[486,489] Low levels of AT induce a prothrombotic environment that is conducive to thromboembolic behavior based partly on the occurrence of clotting in AT-deficient patients exposed to CPB.[494] The mean baseline AT levels of heparin-resistant patients is 56% ± 25%, which is consistent with previous studies.[490] AT levels may even decrease to less than 40% after deep hypothermic circulatory arrest and prolonged CPB, compared with the average AT level identified as 82% preoperatively in a recent trial.[495]

Heparin resistance was routinely treated with FFP for many years. However, a large disparity between AT levels after recombinant AT, compared with FFP, was noted in a prospective, randomized trial of recombinant AT or FFP for patients who were consistently defined as heparin resistant.[492] More recently, two units of FFP often failed to normalize AT levels in patients who were defined as heparin resistant.[496,497] A 75 μg/kg bolus dose of recombinant AT has effectively improved pre-CPB AT levels from 56% to 75% ± 31%.[490] The use of allogeneic blood products to treat AT deficiency should be discouraged.

In 1974, AT was isolated from human plasma and AT concentrates were discovered.[487] AT concentrate preparations are derived from human plasma pools but are subjected to fractionation procedures and heating to inactivate potential viral contaminants without reducing biologic activity.[489] Recombinant AT concentrates have been studied in cardiac surgical patients.[491,492,498] Single-dose vials of AT contain approximately 500 units and may be given over 10 to 20 minutes safely.[499] AT levels are often low preoperatively for cardiac surgical patients with a further fall attributable to CPB hemodilution and heparinization, leading to mean AT levels of 42% activity.[492] AT concentrates are beneficial in both hereditary and acquired AT deficiency.[486,487] The optimal AT level for CPB has not been defined, but a level greater than 80% is considered less likely to be associated with thrombus formation.

Inadequate anticoagulation during CPB will cause thrombin generation, leading to platelet activation and clotting factor consumption; however, definitive proof that AT supplementation will improve outcome is absent. AT supplementation has demonstrated reduced thrombin and fibrinolytic activity in patients undergoing CPB, based on statistically significant improvement in biochemical markers of hemostatic activation such as prothrombin fragment 1.2 concentrations, D-dimer concentration, and the AT-thrombin complex.[492,498,500] Unfortunately, clinical measures such as mediastinal chest tube drainage and transfusion requirements have been less consistent than biochemical measures.[489,490,492,498,500] Recently, AT supplementation was demonstrated to normalize thrombin generation with an *in vitro* preparation that used the plasma of five patients who had undergone prolonged CPB and deep hypothermic circulatory arrest to measure thrombin generation.[495] The addition of normal donor plasma or AT-deficient plasma to the test plasma resulted in excessive thrombin generation, compared with control blood. It was only the pure AT concentrate that arrested thrombin formation, with the test plasma returning it to below baseline in the control plasma (Fig. 24.83). Two studies have shown increased bleeding and transfusion requirements with AT levels less than 63%[501] and 58%.[493] However, to prove rare clinical endpoints with AT supplementation, compared with placebo in prospective trials, would be problematic.

The benefits of restoring AT levels may go beyond simple heparin responsiveness to an association with postoperative outcome. AT levels of 58% or less, obtained after cardiac surgery in a prospective, observational study, were found to be predictive of an increased incidence of surgical reexploration, adverse neurologic outcomes, thromboembolic events, and prolonged ICU duration.[493] Both duration of CPB and preoperative heparin use were also found to be associated with lower postoperative values of AT. Similarly, low preoperative AT levels were associated with lower postoperative AT levels, worse survival, and longer time to extubation, based on a retrospective analysis of cardiac surgical patients.[501] However, no conclusions can be made about AT supplementation until a prospective trial has been performed in a blinded, randomized fashion to assess the value of AT. An excellent summary of trials evaluating the value of AT concentrate for prophylaxis regarding AT-deficient patients before surgery strongly recommended AT supplementation.[486] Other indications for AT are listed in Box 24.11. Postoperatively, AT levels will continue to decline at a rate dependent on the extent of tissue disruption and hemorrhage. The nadir occurs on the third day and preoperative levels return by the fifth day; therefore supplementation is not required after this time.

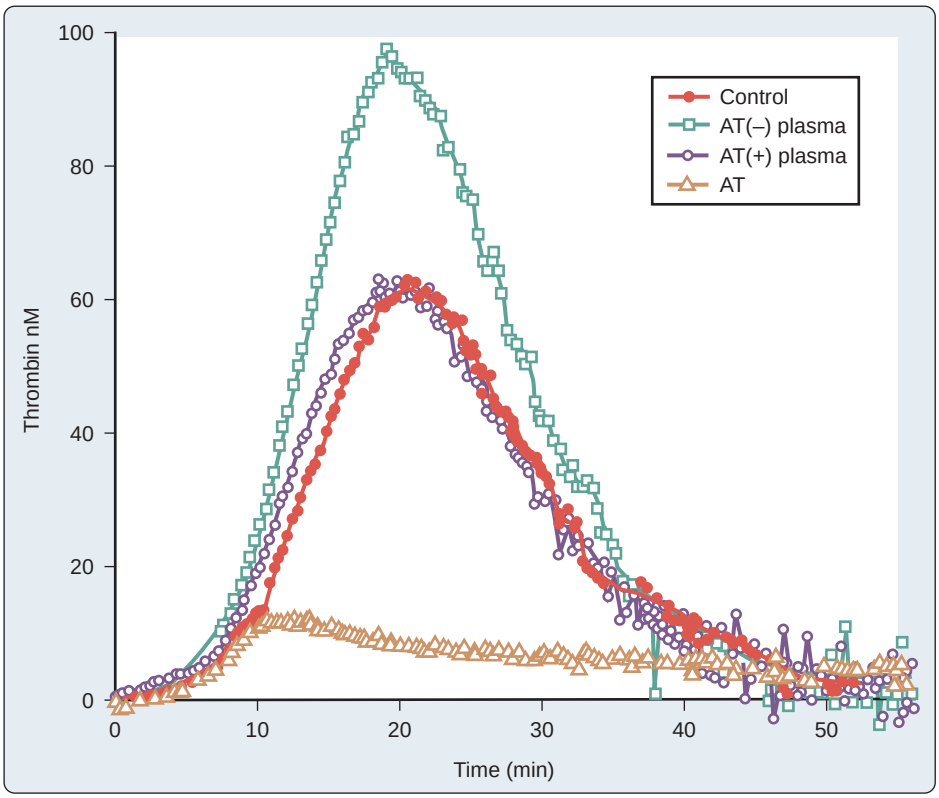

Fig. 24.83 Thrombin generation in platelet-poor plasma after cardiopulmonary bypass surgery is illustrated in representative tracings of five experiments. *Solid red circles* represent control (platelet-poor plasma only); *gold triangles* represent antithrombin (AT) (platelet-poor plasma supplemented with antithrombin concentrate); *green squares* represent AT(–) (platelet-poor plasma supplemented with antithrombin-depleted plasma). *Open purple circles* represent AT(+) (platelet-poor plasma supplemented with normal [non–AT-depleted] plasma). *(Reproduced with permission from Sniecinski R; SzlamF; Chen EP, et al. Antithrombin deficiency increases thrombin activity after prolonged cardiopulmonary bypass.* Anesth Analg. *2008;106:713–718.)*

BOX 24.11 INDICATIONS FOR ANTITHROMBIN REPLACEMENT THERAPY

Approved Indications[a]
Congenital antithrombin deficiency
Perioperative
Postsurgical prophylaxis for deep vein thrombosis
Acute thromboembolism
Pregnancy: delivery and abortion
Neonates with congenital AT deficiency

Probable Indications[b]
Neonates born to mothers with congenital antithrombin deficiency or with strong family history of thrombosis
Disseminated intravascular coagulation attributable to sepsis, trauma, and burns or associated with pregnancy
Heparin resistance associated with low antithrombin levels
Extracorporeal circulation (cardiopulmonary bypass, hemodialysis)
Hepatic artery thrombosis after orthotopic liver transplant

Possible Indications[c]
Venoocclusive disease
Orthotopic liver transplant
LeVeen peritoneovenous shunt
Chronic hepatic insufficiency

Investigational Use
Nephrotic syndrome
Antithrombin deficiency attributable to gastrointestinal loss (inflammatory bowel disease, protein-losing enteropathy)
Pregnancy: preeclampsia, gestational hypertension, and acute fatty liver of pregnancy
Neonatal respiratory distress syndrome

[a]Clinical data suggest efficacy.
[b]Clinical data suggest improvement in laboratory and clinical measures.
[c]Clinical data suggest improvement in laboratory values without proven clinical efficacy.

Cold Agglutinins

CAs are common but rarely clinically important. The incidence rate in cardiac surgical patients varies between 0.8% and 4%.[502] Often associated with lymphoreticular neoplasms, mycoplasma pneumonia, and infectious mononucleosis, they are immunoglobulin M (IgM) class autoantibodies directed against the RBC I-antigen or related antigens.[503] CAs form a complement antigen-antibody reaction on the surface of the RBC membrane that causes lysis. The degree of hemolysis is related to the circulating titer and thermal amplitude of the CAs.[504] Thermal amplitude, that is, the blood temperature below which the CAs will react, is the key information to assign clinical relevance. The titer and thermal amplitude are determined at a range of temperatures in the serum by an indirect hemagglutination test. Most individuals have cold autoantibodies that react at 4°C but in very low titers. Accelerated destruction of RBCs occurs if the thermal amplitude is above 30°C. The more pathologic CAs have a higher thermal amplitude and higher titers at 30°C. From a pathologic standpoint, thermal amplitude is more important than titer. Pathologic CAs cause RBC clumping and vascular occlusion that injures the myocardium, liver, and kidney.[505] Microscopic RBC clumping may erroneously be attributed to other possibilities during hypothermic CPB unless agglutination is observed. Some have reported visible agglutination in the cardioplegic line.[506] Increasing the temperature will rapidly inactivate CAs.[507]

Blood banks routinely screen for the presence of autoantibodies at 37°C, but cold antibodies, only reactive at lower temperatures, are not detected. The significance of CAs is determined by evaluating agglutination of RBC in 20°C saline and 30°C albumin. If there is no agglutination, then significant hemolysis is unlikely.[508] Before the initiation of CPB, the titer and thermal amplitude of CAs must be determined to avoid a temperature during CPB that would cause hemolysis. Intraoperatively, low-thermal amplitude CAs can be determined by mixing cold cardioplegia with some of the patient's blood to check for a separation of cells. If there is concern about CAs after routine testing, then the sample can also be diluted to simulate CPB, cooled, and inspected for RBC agglutination. The occurrence of hemodilution commonly associated with CPB may weaken agglutination and hemolysis in a patient with high reactivity and titer of CAs exposed to hypothermia.

Clinical suspicion is necessary to detect CAs because many other explanations for hemolysis during CPB exist. Consequently, if CAs are suspected or identified preoperatively, then the avoidance of hypothermia is the safest course. Despite normothermic CPB, cold cardioplegia may cause RBC agglutination in small myocardial vessels.[506] Evidence of CAs may also be seen as incomplete cardioplegic delivery or high pressures in the CPB circuit.[509] Hypothermic myocardial protection has been successfully used in some patients with CAs. A review of 832 patients scheduled to undergo surgery and CPB identified only 7 cases of CAs who were strongly positive at 4°C.[507] They concluded that asymptomatic patients with nonspecific, low-titer and low-thermal amplitude CAs might undergo hypothermia and CPB without serious detectable sequelae. However, the possibility of subtle end-organ damage exists.

If hypothermic CPB is necessary, despite the presence of CAs, then the choices are preoperative plasmapheresis, hemodilution, and maintenance of CPB temperature above the CAs thermal amplitude (Fig. 24.84).[504,510] Cold cardioplegia may be used without first undergoing plasmapheresis if normothermic CPB is used and 37°C cardioplegic solution is injected before administering 4°C cardioplegic solution,

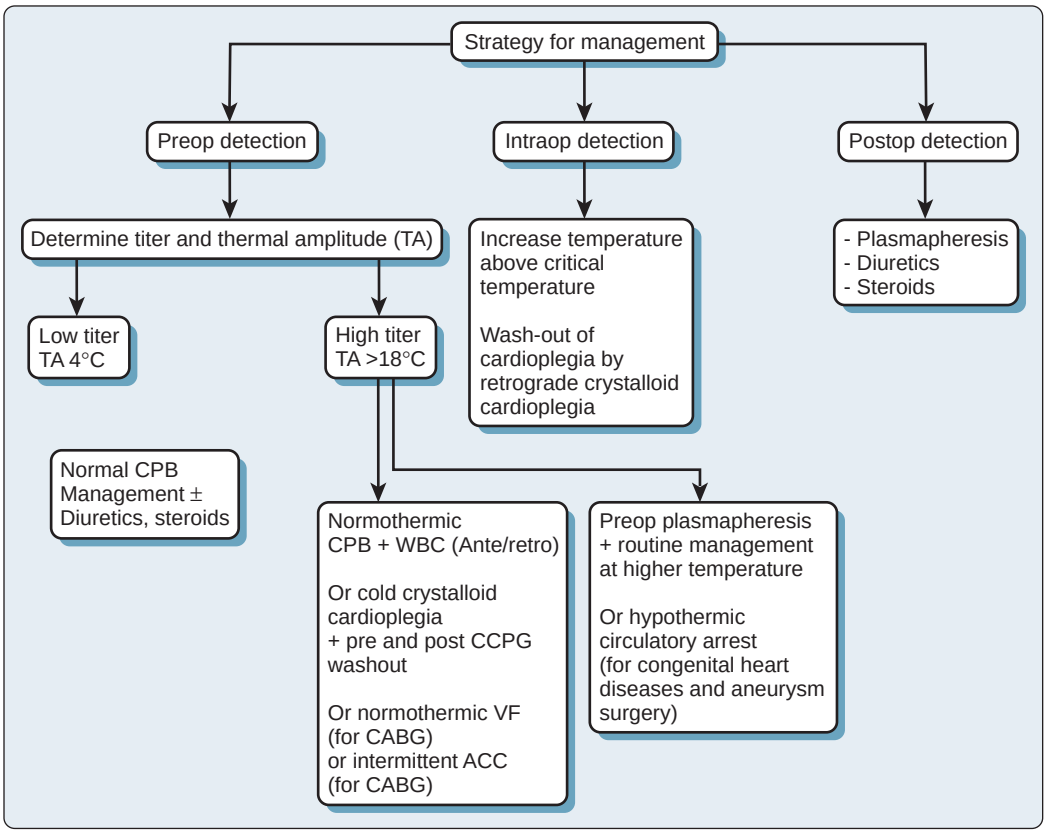

Fig. 24.84 Algorithm illustrates the strategy for the management of cold agglutinin (CA). *ACC*, Aortic cross-clamp; *CABG*, coronary artery bypass grafting; *CCPG*, cold crystalloid cardioplegia; *CPB*, cardiopulmonary bypass; *Intraop*, intraoperative; *Postop*, postoperative; *Preop*, preoperative; *VF*, ventricular fibrillation; *WBC*, warm blood cardioplegia. *(Reproduced with permission from Agarwal SK, Ghosh PK, Gupta D. Cardiac surgery and cold-reactive proteins.* Ann Thorac Surg. *1995;60:1143.)*

clearing all potentially reactive cells. The risk of hemolysis is still high in patients with high-thermal amplitude CAs. If CAs are particularly malignant, then all of the patient's blood from the venous reservoir is drained and discarded. It is replaced entirely by donor blood,[511] unfortunately exposing the patient to the risks of allogeneic blood products. Normothermic CPB and antegrade or retrograde warm blood cardioplegia may be the best option.[512] If CAs should go undetected, then postoperative end-organ damage or low CO may occur. Subsequently, plasma exchange, steroids, elevated urine output, and maintenance of a good CO are recommended.[502] In a case series of 16 patients with CAs who underwent 19 procedures requiring CPB, no patient demonstrated evidence of permanent myocardial dysfunction, had a neurologic event, required dialysis, or died within 30 days.[513] Another case series identified 47 patients out of 14,900 cardiac surgery patients. No difference in composite mortality or severe morbidity was revealed between patients with CAs and those without.[514]

All participants in the care of a patient with CAs should be acutely aware of the potential risk to the patient of hypothermia. Anesthetic gases, intravenous fluids, blood, and plasma should be heated before administration to these individuals. Surgical unit temperature should be warm. Washed RBCs may also be useful if transfusions of fresh components are necessary.[505]

Sickle Cell Disease

SCD is a heterogeneous group of inherited disorders involving the sickle ß-globin gene and was first reported in 1910 by Herrick.[515] Survival in SCD has greatly improved as a result of early diagnosis, antibiotics, and supportive care; however, it remains an important health threat, particularly if major surgery is contemplated.[516,517] Median life expectancy for male and female African Americans with SCD is 42 years and 48 years, respectively. Preparation and meticulous intraoperative care are imperative for the best results.

The ß-globin gene has worldwide distribution but is found most often in West Central Africa. HbA and HbS genes have codominant expression, which allows both genes to be represented in the Hb molecule. One in 10 American blacks are a heterozygous carrier of the ß-globin gene, referred to as sickle cell trait (AS), whereas the homozygous state, sickle cell anemia (SS), occurs in 1 of 400 blacks. The prevalence of SCD in American blacks is 0.2%. HbC disease (SC) occurs in approximately 2% of American blacks; SS accounts for 60% to 70% of SCD in the United States.

The ß-globin gene has a mutation in the DNA that results in a substitution of the amino acid, valine, for glutamic acid in the ß-globin chain that is responsible for normal Hb polymerization upon deoxygenation. The mutated Hb molecule is less negatively charged than the normal Hb, therefore as oxygen saturation approaches 85%, Hb tends to polymerize.[518] As the HbS comes out of solution and gels intracellularly, the RBC sickles (Fig. 24.85). Sickling is a reversible change in the RBC shape. Desaturation is the primary stimulus for sickling. In addition to desaturation, the risk of sickling is related to the amount of HbS in the RBCs. AS individuals do not sickle until the oxygen saturation is less than 40% because their ratio of HbS to total Hb is low. Since SS and SC patients have significantly more HbS, they sickle at an oxygen saturation of 85%, typically, the venous saturation. HbS is responsible for the major hallmarks of SCD: sickling, hemolytic anemia, and vasoocclusive events.[517,519,520] Vasoocclusive events are more likely because sickled RBCs have an increased affinity for the endothelial surface of blood vessels that significantly increases blood viscosity, leading to stasis.[518,521] During a vasoocclusive episode, the endothelium will produce activators such as endothelin that alter the endothelial surface and cause vasoconstriction and injury.

The clinical severity of SS, SC, and AS varies as a function of both inherited (thalassemia or fetal Hb) and acquired factors.[521] Patients with AS are asymptomatic unless they become profoundly hypoxic, acidotic, or hypothermic.[522] On the contrary, individuals with either SS or SC are chronically ill with a life-threatening illness. However, survival for individuals with SS is 95% at 20 years and even longer with

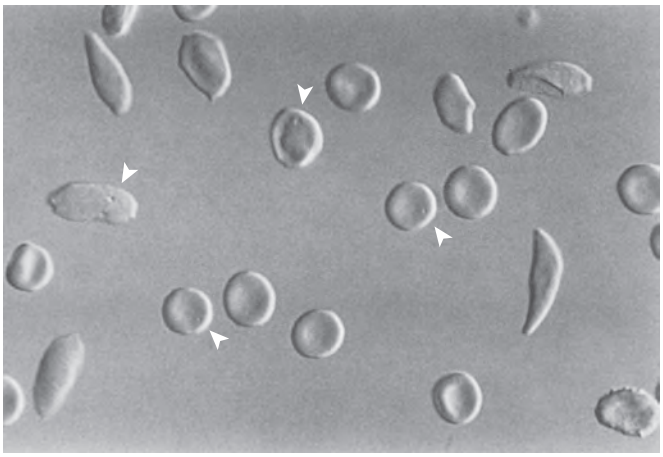

Fig. 24.85 The red cell pit count is used to assess splenic reticuloendothelial function. Erythrocytes from a child with sickle cell anemia were fixed in isotonic buffered glutaraldehyde and viewed by Normarski differential interference contrast microscopy. The increased percentage of red cells with large endocytic vacuoles *(pitted or pocked cells, arrowheads)* indicates functional asplenia. *(Reproduced with permission from Lane PA. Sickle cell disease.* Pediatr Clin North Am. *1996;43[3]:639.)*

SCD.[523] Individuals with SS are usually undersized, skeletally deformed as a result of bone marrow hyperplasia, and may be slightly jaundiced. They are chronically anemic with an Hb concentration often below 8 g/dl. The individual's RBCs are more fragile with a RBC viability of 10% of normal, which accounts for the chronic anemia. As a major site of sickling, the spleen eventually becomes nonfunctional; consequently, individuals with SS are extremely susceptible to infections, especially bacterial infections. Strict asepsis is important.

Three critical conditions may occur in those with SCD: painful crisis, aplastic crisis, and crisis affecting major organs. The painful crisis (sickle cell crisis) is a vasoocclusive, infarctive process, resulting in tissue anoxia exemplified by pulmonary infarctions. Diagnosis is often one of exclusion. Vasoocclusive crises primarily affect male patients 15 to 25 years of age. They are initiated by exertion, infection, dehydration, cold, acidosis, hypoxia, or vascular stasis.[524] The rheologic properties of the sickle RBCs combine with the tendency for adherence to the vessel wall to cause poor microvascular perfusion. Hydration with dextrose and water is important during a crisis, enabling free water to enter the cells and thus lower the Hb concentration; but in this situation, blood transfusion is not helpful.[518] Aplastic crisis is significantly less common than painful crisis but is the most feared hematologic complication of SS. It is characterized by a precipitous fall in Hb, secondary to hemolysis, without the normal bone marrow response. In contrast to vasoocclusive crisis, transfusion is not only helpful, but it is also essential. Aplastic crisis will last 7 to 10 days. Finally, various major organ systems such as the lungs (acute chest syndrome), spleen (splenic infarcts), kidneys, heart (myocardial dysfunction) and the central nervous system (stroke) are poorly perfused, causing permanent injury. Coronary artery occlusions are rare. Stroke is secondary to an intimal injury and thrombosis within the artery. Stroke occurs in approximately 8% of individuals with SS, and children are more likely affected. The lifetime chance of neurologic complications in those with SCD is 25%. Two thirds will have a subsequent stroke within 36 months.

Oral long-term daily use of hydroxyurea has been shown to reduce or prevent many acute and chronic complications of SCD.[516] Hydroxyurea is a ribonucleotide reductase inhibitor and it acts by increasing fetal Hb levels. A prospective randomized trial, the Multicenter Study of Hydroxyurea in Sickle Cell Anemia, enrolled only adults with SCD who experienced more than three vasoocclusive crises during the previous year.[525] The patients who continued hydroxyurea therapy experienced improved outcomes at 2, 9, and 17 years.

Not all individuals with SCD have been identified before general anesthesia, and death has been the first manifestation of the disease.[526] Hb electrophoresis is the most accurate diagnostic test, but peripheral blood smears are not diagnostic. Hematologic consultation should be obtained in any person suspected to have SCD and who is scheduled for any type of surgery or anesthesia. Patients with SS have been considered at increased risk for surgery, general anesthesia, and postoperative complications. Results from the Cooperative Study of SCD, which included 3765 SCD patients in 23 clinical centers across the United States, determined the overall mortality rate was 0.3% with only 3 deaths related to anesthesia or surgery.[527] No deaths occurred in children younger than 14 years of age. Postoperative complications were variable and primarily related to the operative procedure. Despite many different surgical procedures and anesthetics in this large multicenter study, the mortality rate was low with few complications. Modern techniques and monitoring capabilities have enabled individuals with SCD to receive better care and outcome,[517] therefore surgery is a more viable option for consideration.

Preoperatively, complete assessment of the cardiovascular system, specifically looking for myocardial ischemia, PAH,[528] and CHF, is important in the individual anticipating cardiac surgery. Echocardiographic findings indicate that an estimated 20% to 30% of those with SCD have PAH, and its presence increases the risk of death. Problematically, autopsy series have shown that nearly one third of patients at autopsy with SCD had pathologic evidence of PAH without a diagnosis. Until recently, PAH was thought to occur from a thrombotic or embolic cause; now, however, a precapillary form of PAH is evident.[528] Renal function is also likely to be abnormal.[529] Folic acid and careful intravenous hydration in the preoperative period lessens the risk of dehydration, hyperosmolality, and low urine output.[530] An increased incidence of pulmonary dysfunction in patients with SS increases the risk of hypoxia; consequently, preoperative sedation must be carefully titrated along with careful patient observation. The value of prophylactic antibiotics is indeterminate.

The role of preoperative transfusion in the management of patients with SS has been debated for years. The recommendation for preoperative RBC transfusion in patients with SS is based on a reduction in circulating concentration of HbS in an effort to improve oxygen-carrying capacity, suppress the erythropoietic drive, and shift the P_{50} to the left; nevertheless; the possibility of sickling is not eliminated.[521] An HbS less than 30% has been traditionally regarded as necessary for individuals who undergo surgery. To verify this, a multicenter, randomized trial of 551 patients with SCD undergoing various noncardiac surgical procedures was conducted. Preoperative transfusion was designed with either a conservative or aggressive strategy to be evaluated according to the incidence of perioperative complications.[531] The percentage of HbS in the patients managed conservatively was 60%, compared with 30% for the aggressive strategy. The conservative strategy was associated with one half as many transfusion-associated complications. This study supports other work that found maintaining HbS at 50% instead of 30% was as effective in reducing the risk of stroke in nonsurgical situations.[532] For noncardiac surgery, growing evidence suggests that dilution of sickle cells with transfusions should be limited[527] and intraoperative transfusion should reflect standard transfusion guidelines.[517]

For the initiation of CPB, 5% HbS is often recommended,[533] although an HbS of 30% appears suitable.[534] Currently, alternatives to allogeneic transfusion are few for CPB and cardiac surgery. Exchange transfusion has been used successfully to correct anemia preoperatively with less risk of volume overload than simple transfusion.[535] It is important with the exchange transfusion for cardiac surgery to preserve the patient's platelets and plasma to be given after separation from CPB.[536] RBC transfusion, alone, increases blood viscosity more than exchange transfusion because a significant amount of HbS remains. There is concern that increased viscosity may temporarily negate an improvement in oxygen delivery that corresponds to the presence of additional RBCs.[537] The lower blood viscosity and increased oxygen delivery to the tissues derived from the exchange transfusion is probably more efficient. Exchange transfusion has become routine before major surgery, but no prospective trials of exchange transfusion have been conducted to establish its value.

Anesthetic management of individuals with SCD has been reviewed.[522,530] The availability of blood must be established before any surgery because of the possibility of alloimmunization. The incidence of antibodies may approach 50% with more than two thirds being Kell or Rh in SCD.[537] Antibodies may delay the availability of blood and increase the chance of a delayed hemolytic transfusion reaction that can mimic a painful crisis. Therefore any donor blood must be typed to ensure compatibility for ABO, Rh, and Kell antigens. Blood for transfusion should be less than 7 days old and warmed. Before induction of anesthesia, preoxygenation is essential. Maintenance of oxygenation throughout the procedure is critical but in no way guarantees an uncomplicated course. Volatile agents are associated with less sickling.[521] Maintenance of perfusion to the major organs and peripherally is very important to maintain normal acid-base status. The occurrence of hypotension is best treated initially with fluid administration to optimize volume status and to avoid vasopressors. Renal dysfunction causes SCD patients to concentrate urine poorly; therefore volume status is very dynamic. Efforts should be made to maintain the patient's normal body temperature. Intraoperative sickle crisis will sometimes occur, despite the best care, but poses a problem to diagnose during anesthesia. Signs of an intraoperative crisis include seizure, change in respiratory pattern, hypotension, or hematuria but are unfortunately nonspecific and unreliable. Laboratory tests are not helpful either. Nothing pharmacologically, such as alkalinization of the blood or administration of urea, can reduce the tendency to sickle.[521]

CPB has been associated with significant morbidity and mortality in adults and children with SCD.[538] CPB imposes severe physiologic stresses such as low-flow states, circulatory arrest, aortic cross-clamping, mechanical destruction of blood elements, and protein denaturation that predispose the individual to a sickling crisis. No evidence-based guidelines are available for body temperature, cardioplegia, priming solution, and transfusion practice during CPB.[539] The effect and safety of systemic and regional hypothermia (cardioplegia) in patients with SCD is indeterminate. *In vitro*, the solubility of deoxygenated HbS increases as the body temperature is decreased, which reduces sickling. However, decreased temperature increases blood viscosity. Viscosity increases by 30% when the body temperature declines to 30°C.[530] The harmful effects of hypothermia may be primarily related to vasoconstriction and vascular stasis; therefore hypothermia may be tolerated if peripheral perfusion and oxygenation are good. Currently, many patients undergo normothermic instead of hypothermic CPB because of advantages related to postoperative myocardial function.[540] Patients with either AS or SS have been cooled to 26°C or less without a sickling crisis, but partial or total exchange transfusion with a final HbS of 10% was performed in some of the patients.[539] Because oxygenation during CPB is excellent during moderate hypothermia, speculation suggests that sickling may be less common even without partial or full exchange transfusion.[520]

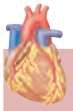
A reduction of HbS has been recommended before initiating CPB, which can be accomplished by dilution with a nonsanguineous priming solution, a blood priming solution, cardioplegia, intravenous fluid, and simple transfusion or blood component sequestration. These measures decrease the percentage of HbS, but a significant number of RBCs remain at risk for sickling. Only a form of exchange transfusion removes sickled cells. Exchange transfusions are advisable if deliberate hypothermia is planned.[539] Automated RBC exchange can be performed in the surgical unit or in the preoperative area. Intraoperative exchange can be performed more safely with the benefit of intraoperative monitoring to guide the transfusion and avoid volume overload and possible cardiac decompensation in patients with serious cardiac conditions. In addition, with CPB, draining blood from the CPB circuit is possible. Another novel approach involves partial RBC removal with the autotransfusion device before CPB to decrease the percentage of HbS, followed by an acute one-volume whole blood exchange during the initiation of CPB. The advantage is the procurement of a platelet-pheresed product with both techniques.[534] Another option is to use

primarily allogeneic blood in the priming volume in which, on the initiation of CPB, venous blood is diverted to other reservoirs and the warmed blood in the priming volume reaches the patient, resulting in an HbS concentration less than 5%. The diverted blood may have the RBCs separated from the plasma and platelets and discarded while the remaining non-RBC components are subsequently infused. This process decreases blood product exposure and allows the transfusion of normal donor blood. These techniques of blood component sequestration may eliminate the need for a hemapheresis procedure. It can also be used in patients with severe SCD who have a history of sickle crisis. Not everyone subscribes to the need for these measures with SCD. Métras and associates[541] described 15 patients with SCD (13 with AS) who underwent cardiac surgery. None of the patients received preoperative exchange transfusions, despite the use of moderate hypothermia, aortic cross-clamping, and cold cardioplegia. There was no evidence of sickling or increased postoperative complications. The authors concluded that as long as hypoxia, acidosis, and dehydration are avoided, preoperative exchange transfusions or blood transfusions are not mandatory; however, they did not study the most severe cases of SCD.

The advisability of cell salvage techniques in SCD is questionable. Intraoperative autotransfusion has been condemned by those who claim an adverse effect on sickling, but is supported by others.[542] The patient's percentage of HbS may influence how well intraoperative autotransfusion is tolerated. If intraoperative autotransfusion is used, then the recommendations are an exchange or a transfusion to an HbS less than 40%, increased hematocrit to greater than 30%, and heparinization until harvesting. Solutions need a physiologic pH.[521]

Individuals with SCD are known to be at risk for a variety of thromboembolic complications such as stroke, MI, pulmonary embolism, and deep vein thrombosis. This considerations may be important in terms of providing anticoagulation in patients for CPB. All aspects of hemostasis, including platelet function, procoagulant proteins, anticoagulant proteins, and fibrinolytic systems, are altered in the direction of procoagulation.[543] Chronic depletion of nitric oxide and arginine may also contribute to the hypercoagulable states in SCD. Evidence suggests that tissue factor expression on circulating endothelial cells may be abnormal with a more procoagulant activity, compared with individuals without SCD. There is also evidence of increased thrombin formation, based on biochemical markers in SCD. Finally, some of the anticoagulant proteins such as protein S and C are below normal levels. The impact on attempts to provide anticoagulation are not known, but carefully assessing the procoagulant state of the patient frequently during treatment of excessive bleeding is important to avoid increasing the risk of thrombotic complications postoperatively. Empirical transfusion may lead to excess blood products after CPB, which may result in a procoagulant state; therefore algorithm-directed transfusion is advantageous.[544] The thromboelastogram is especially useful after CPB to determine whether the patient has developed a hypercoagulable state that may be detrimental to those with SCD.

Larger doses of fentanyl have been reported in children undergoing CPB with SS to attenuate stress during the surgery, especially intubation.[545] Additionally, nearly one third of patients with SS will have PAH, and a high dose of fentanyl will also attenuate pulmonary vascular responses.[528] Early extubation after CABG surgery has minimal risk (Box 24.12). However, reviewing the patient's history regarding analgesia is important, because narcotic intolerance is common; as a result, he or she may require more aggressive perioperative pain therapy.[546] Patients who return from surgery for any reason may be at increased risk for postoperative pneumonia. Acute chest syndrome may appear as pneumonia or mask true pneumonia. Acute chest syndrome has resulted in fatalities. Patients with AS are not at increased risk for postoperative complications.



BOX 24.12 PROPOSED GUIDELINES FOR PERIOPERATIVE MANAGEMENT OF PATIENTS WITH SICKLE CELL DISORDERS UNDERGOING CORONARY ARTERY BYPASS GRAFTING SURGERY

Preoperative Period
Hemoglobin (Hb) electrophoretic studies
Correction of any coexisting infection
Partial or complete exchange transfusions for patients with Hb SS
Light benzodiazepine premedication
Supplemental oxygen to avoid a decrease in oxygen saturation

Intraoperative Period
Preoxygenation for 3 to 5 minutes in all cases
Small dose of opioid and hypnotic induction
Inhaled or intravenous (IV) maintenance of anesthesia
Tepid or warm cardiopulmonary bypass
Mean pump flow >50 mL × kg^{-1} × min^{-1}, perfusion pressure ≥60 mm Hg
Blood transfusion if hematocrit is <20%
Retransfusion of pump blood is not advisable

Postoperative Period
Early extubation within 2 to 6 hours
Maintenance of intravascular volume and body temperature
Avoidance of vasopressors is desirable
Early incentive spirometry
Multimodal approach to pain relief (opioids, nonsteriodal antiinflammatory drugs, acetaminophen)
Warming blankets to maintain temperature ≥37°C
Shivering: meperidine, 10 to 25 mg IV
Routine antibiotic coverage for 2 days
Blood transfusion: Hb <7.5 g/dL for those ≤70 years old; Hb <8.5 g/dL for those >70 years old
Close monitoring of oxygenation, perfusion, and acid-base indices for 12 to 24 hours

Acknowledgments

This chapter is dedicated to the memory of Dwight C. Legler, MD, who first authored this chapter. He is still sadly missed by all members of the Cardiovascular Division of the Department of Anesthesiology at the Mayo Clinic. Many thanks to Maria A. de Castro, MD, Robert A. Strickland, MD, and William J. Mauermann, MD, for their previous excellent contributions to this chapter.

Anesthesia for Heart, Lung, and Heart-Lung Transplantation

ANDREW W. MURRAY, MBChB | JOSEPH J. QUINLAN, MD | BRIAN BLASIOLE, MD, PhD | PHILLIP ADAMS, DO

KEY POINTS

1. Cardiac denervation is an unavoidable consequence of heart transplantation, and reinnervation is at best partial and incomplete.
2. Drugs acting directly on the heart are the drugs of choice for altering cardiac physiology after heart transplantation.
3. Allograft coronary vasculopathy remains the greatest threat to long-term survival after heart transplantation.
4. Broadening of donor criteria has decreased time to lung transplantation.
5. Air trapping in patients with severe obstructive lung disease may impair hemodynamics and require deliberate hypoventilation.
6. Newly transplanted lungs should be ventilated with a low tidal volume and inspiratory pressure and as low an inspired oxygen concentration as can be tolerated.
7. Reperfusion injury is the most common cause of perioperative death.
8. The frequency of heart-lung transplantation has decreased as the frequency of lung transplantations has increased.

Heart Transplantation

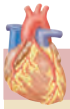
The history of heart transplantation spans almost a century. Canine heterotopic cardiac transplantation was first reported in 1905,[1] but such efforts were doomed by ignorance of the workings of the immune system (Box 25.1). Further research in the late 1950s and early 1960s set the stage for the first human cardiac transplant by Barnard in 1966.[2] However, there were few long-term survivors in this era because of continued deficiency in understanding and modulating the human immune system, and the procedure fell into general disfavor. Continued research at selected centers (such as Stanford University) and lessons learned from renal transplantation led to greater understanding of the technical issues and immunology required, and by the early 1980s, cardiac transplantation gained widespread acceptance as a realistic option for patients with end-stage cardiomyopathy.

Heart transplantation experienced explosive growth in the mid-to-late 1980s, but the annual number of heart transplants worldwide plateaued by the early 1990s at approximately 3500 per year.[3] The factor limiting continued growth has been a shortage of suitable donors. As of February 2015, there were slightly more than 4000 patients on the United Network for Organ Sharing (UNOS) cardiac transplant waiting list (includes all U.S. candidates), an increase of 25% compared with 2004. During that same time period the frequency of heart transplantation also increased (by approximately 17%) but failed to keep pace with the increase in the size of the waiting list. Only 2431 heart transplants were performed in the United States during the 2014 calendar year, slightly above the average of 2290 heart transplants per year over the preceding decade.[4] The median waiting time for a cardiac graft varies widely according to blood type (approximately 52 days for type AB recipients in contrast with 241 days for type O recipients listed for the period 2003–2004, based on OPTN data as of February 1, 2015). Of those patients listed for heart transplantation in 2009, 27.5% had spent more than a year waiting for a transplant. Adult patients on the heart transplant waiting list are assigned a status of 1A, 1B, or 2. Status 1A patients require mechanical circulatory support, mechanical ventilation, high-dose or multiple inotropes, with continuous monitoring of left ventricular filling pressure. Status 1B patients require mechanical circulatory support beyond 30 days or inotropic support without continuous monitoring of left ventricular filling pressure. All other patients are classified as Status 2. The most frequent recipient indications for adult heart transplantation remain either idiopathic or ischemic cardiomyopathy. Other less common diagnoses include viral cardiomyopathy, systemic diseases such as amyloidosis, and complex congenital heart disease (CHD).

The 1-year survival rate after heart transplantation has been reported to be 79%, with a subsequent mortality rate of approximately 4%/year.[3] There has been only slight improvement in the survival statistics over the past decade; the Organ Procurement and Transplant Network reports that the 1- and 3-year survival rates after heart transplantation for those transplanted in the United States during the period 1997 to 2004 were approximately 87% and 78%, respectively.[4] One-year survival rate after repeat heart transplantation more than 6 months after the original procedure is slightly lower (63%) but substantially worse if performed within 6 months of the original grafting (39%).[3] Risk factors for increased mortality have been associated with recipient factors (prior transplantation, poor human leukocyte antigen matching, ventilator dependence, age, and race), medical center factors (volume of heart transplants performed, ischemic time), and donor factors (race, sex, age), and have remained relatively unchanged over the past two decades.[5] Early deaths most frequently are due to graft failure, whereas intermediate-term deaths are caused by acute rejection or infection. Late deaths after heart transplantation most frequently are due to allograft vasculopathy, posttransplant lymphoproliferative disease or other malignancy, and chronic rejection (see Box 25.1).

Recipient Selection

Potential candidates for heart transplantation generally undergo a multidisciplinary evaluation including a complete history and physical examination, routine hematology, chemistries (to assess renal and hepatic function), viral serology, electrocardiography, chest radiography, pulmonary function tests, and right- and left-heart catheterization.



BOX 25.1 HEART TRANSPLANTATION

- Frequency of transplantation remains limited by donor supply.
- Pathophysiology before transplantation is primarily that of end-stage ventricular failure.
- Pathophysiology after transplantation reflects the effects of denervation.
- Allograft coronary vasculopathy is a frequent long-term complication.

Ambulatory electrocardiography, echocardiography, and nuclear gated scans are performed if necessary. The goals of this evaluation are to confirm a diagnosis of end-stage heart disease that is not amenable to other therapies and that will likely lead to death within 1 to 2 years, as well as to exclude extracardiac organ dysfunction that could lead to death soon after heart transplantation. Patients typically have New York Heart Association (NYHA) class IV symptoms and a left ventricular ejection fraction less than 20%. Although most centers eschew a strict age cutoff, the candidate should have a physiologic age younger than 60. Detecting pulmonary hypertension and determining whether it is due to fixed elevation of pulmonary vascular resistance (PVR) is crucial; early mortality because of graft failure is threefold greater in patients with increased PVR (transpulmonary gradient >15 mm Hg or PVR >5 dynes•sec•cm^{-5}).[6] If increased PVR is detected, a larger donor heart, a heterotopic heart transplant, or a heart-lung transplant (HLT) may be more appropriate. Active infection and recent pulmonary thromboembolism with pulmonary infarction are additional contraindications to heart transplantation. The results of this extensive evaluation should be tabulated and available to the anesthesia team at all times because heart transplantation is an emergency procedure.

Donor Selection and Graft Harvest

Once a brain-dead donor has been identified, the accepting transplant center must further evaluate the suitability of the allograft. Centers generally prefer donors to be free of previous cardiac illness and younger than 35 years because the incidence of coronary artery disease markedly increases at older ages. However, the relative shortage of suitable cardiac donors has forced many transplant centers to consider older donors without risk factors and symptoms of coronary artery disease. If it is necessary and the services are available at the donor hospital, the heart can be further evaluated by echocardiography (for regional wall motion abnormalities) or coronary angiography, to complement standard palpation of the coronaries in the operating room. The absence of sepsis, prolonged cardiac arrest, severe chest trauma, and a high inotrope requirement also are important. The donor is matched to the prospective recipient for ABO blood-type compatibility and size (within 20%, especially if the recipient has high PVR); a crossmatch is performed only if the recipient's preformed antibody screen is positive.

Donors can exhibit major hemodynamic and metabolic derangements that can adversely affect organ retrieval.[7] Most brain-dead donors will be hemodynamically unstable.[8] Reasons for such instability include hypovolemia (secondary to diuretics or diabetes insipidus), myocardial injury (possibly a result of catecholamine storm during periods of increased intracranial pressure), and inadequate sympathetic tone because of brainstem infarction. Donors often also have abnormalities of neuroendocrine function such as low T_3 and T_4 levels. Administration of T_3 to brain-dead animals improves ventricular function after transplantation[9]; T_3 administration has enabled decreases in inotropic support in some[10,11] but not all human studies.[12] Donor volume status should be assiduously monitored, and inotropic and vasopressor therapy should be guided by data from invasive monitors.

Donor cardiectomy is performed through a median sternotomy, usually simultaneously with recovery of other organs such as lungs, kidneys, and liver. Just before cardiac harvesting, the donor is heparinized and an intravenous cannula is placed in the ascending aorta for administration of conventional cardioplegia. The superior vena cava (SVC) is ligated and the inferior vena cava (IVC) transected to decompress the heart, simultaneous with the administration of cold hyperkalemic cardioplegia into the aortic root. The aorta is cross-clamped when the heart ceases to eject. The heart also is topically cooled with ice-cold saline. After arrest has been achieved, the pulmonary veins are severed, the SVC is transected, the ascending aorta is divided just proximal to the innominate artery, and the pulmonary artery (PA) is transected at its bifurcation. The heart is then prepared for transport by placing it in a sterile plastic bag that is placed, in turn, in another bag filled with ice-cold saline, all of which are carried in an ice chest. Of all the regimens tested, conventional cardioplegia has proved most effective in maintaining cardiac performance.[13] The upper time limit for ex vivo storage of human hearts appears to be approximately 6 hours.[14]

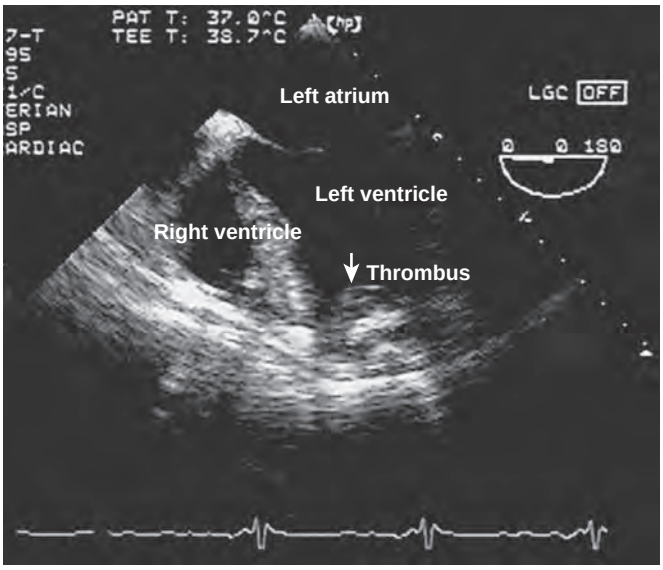


Fig. 25.1 Transesophageal echocardiographic image of laminated intraventricular thrombus in the native left ventricular apex. If intracavitary thrombus is found, great caution is warranted during dissection before cardiopulmonary bypass to avoid systemic embolization.

Surgical Procedures

Orthotopic Heart Transplantation

Orthotopic heart transplantation is carried out via a median sternotomy, and the general approach is similar to that used for coronary revascularization or valve replacement. Frequently, patients will have undergone a prior median sternotomy; repeat sternotomy is cautiously performed using an oscillating saw. The groin should be prepped and draped to provide a rapid route for cannulation for cardiopulmonary bypass (CPB) if necessary. After the pericardium is opened, the aorta is cannulated as distally as possible and the IVC and SVC are individually cannulated via the high right atrium. Manipulation of the heart before institution of CPB is limited if thrombus is detected in the heart with transesophageal echocardiography (TEE; Fig. 25.1). After initiation of CPB and cross-clamping of the aorta, the heart is arrested and excised (Fig. 25.2). The aorta and PA are separated and divided just above the level of their respective valves, and the atria are transected at their grooves. A variant of this classic approach totally excises both atria, mandating bicaval anastomoses. This technique may reduce the incidence of atrial arrhythmias, better preserve atrial function by avoiding tricuspid regurgitation, and enhance cardiac output (CO) after transplantation.[15,16]

The donor graft then is implanted with every effort to maintain a cold tissue temperature, beginning with the left atrial (LA)

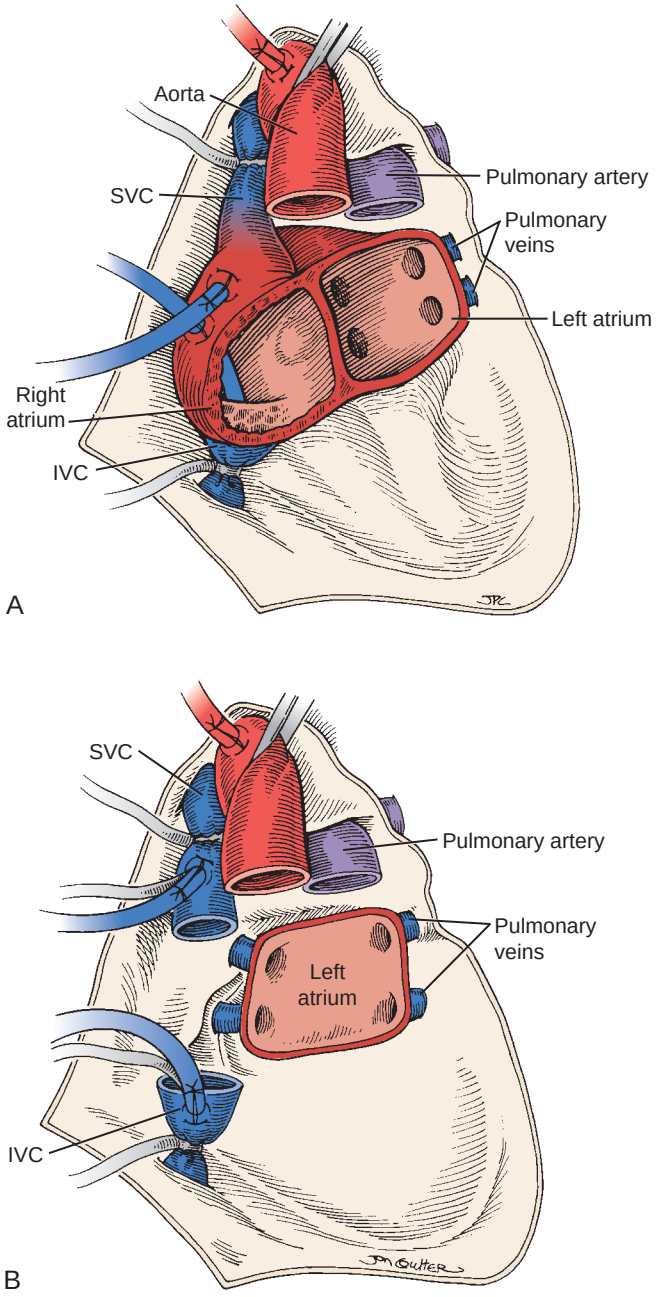

Fig. 25.2 Mediastinum after excision of the heart but before allograft placement. Venous cannulas are present in the superior *(SVC)* and inferior vena cava *(IVC)*, and the arterial cannula is present in the ascending aorta. (A) Classic orthotopic technique. (B) Bicaval anastomotic technique.

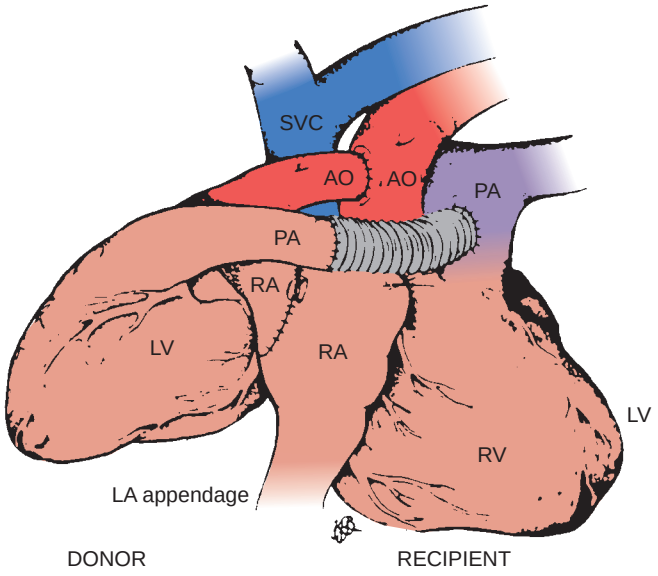

Fig. 25.3 Placement of heterotopic graft in the right chest, with anastomoses to the corresponding native left *(LA)* and right atria *(RA)*, ascending aorta *(AO)*, and an interposition graft to the native pulmonary artery *(PA)*. *LV*, left ventricle; *RV*, right ventricle; *SVC*, superior vena cava. *(From Cooper DKC, Lanza LP.* Heart Transplantation: The Present Status of Orthotopic and Heterotopic Heart Transplantation. *Lancaster, United Kingdom: MTP Press; 1984.)*

anastomosis. If the foramen ovale is patent, it is sutured closed. The donor right atrium is opened by incising it from the IVC to the base of the right atrial (RA) appendage (to preserve the donor sinoatrial node), and the RA anastomosis is constructed. Alternatively, if the bicaval technique is used, individual IVC and SVC anastomoses are sewn. The donor and recipient pulmonary arteries are then brought together in an end-to-end manner, followed by the anastomosis of the donor to the recipient aorta. After removal of the aortic cross-clamp, the heart is de-aired via a vent in the ascending aorta. Just before weaning from CPB, one of the venous cannulae is withdrawn into the right atrium and the other removed. The patient is then weaned from CPB in the usual manner. After hemostasis is achieved, mediastinal tubes are placed for drainage, the pericardium is left open, and the wound is closed in the standard fashion.

Heterotopic Heart Transplantation

Although orthotopic placement of the cardiac graft is optimal for most patients, certain recipients are not candidates for the orthotopic operation, and instead the graft is placed in the right chest and connected to the circulation in parallel with the recipient heart. The two primary indications for heterotopic placement are significant irreversible pulmonary hypertension and gross size mismatch between the donor and recipient. Heterotopic placement may avoid the development of acute right ventricular (RV) failure in the unconditioned donor heart in the face of acutely increased RV afterload.

Donor harvesting for heterotopic placement is performed in the previously described manner, except that the azygos vein is ligated and divided to increase the length of the donor SVC; the PA is extensively dissected to provide the longest possible main and right PA; and the donor IVC and right pulmonary veins are oversewn, with the left pulmonary veins incised to create a single large orifice. The operation is performed via a median sternotomy in the recipient, but the right pleura is entered and excised. The recipient SVC is cannulated via the RA appendage, and the IVC via the lower right atrium. After arresting the recipient heart, the LA anastomosis is constructed by incising the recipient left atrium near the right superior pulmonary vein and extending this incision inferiorly and then anastomosing the respective left atria. The recipient RA-SVC is then incised and anastomosed to the donor RA-SVC, after which the donor aorta is joined to the recipient aorta in an end-to-side manner. Finally, the donor PA is anastomosed to the recipient main PA in an end-to-side manner if it is sufficiently long; otherwise, they are joined via an interposed vascular graft (Fig. 25.3).

Special Situations

Mechanical ventricular assist devices (see Chapters 28 and 36) have been used successfully to bridge patients who would otherwise die of acute heart failure awaiting transplantation.[17] Although ventricular assist devices may improve the survival of patients awaiting transplantation,[18] complications associated with their use may negatively impact

survival after transplantation.[19] The technique of transplantation is virtually identical in such patients to that for ordinary orthotopic transplantation. However, repeat sternotomy is obligatory, and repeat sternotomy is associated with higher morbidity and mortality, as well as higher intraoperative blood use, postoperative length of ICU and hospital stays, and frequency of reoperation for bleeding after subsequent heart transplantation.[20] Placement of large-bore intravenous access is prudent because excessive hemorrhage can occur during or after the transplant procedure.

Rarely, patients will present for cardiac transplantation combined with transplantation of the liver.[21,22] The cardiac allograft usually is implanted first to better enable the patient to survive potential hemodynamic instability associated with reperfusion of the hepatic allograft. Large-bore intravenous access is mandatory. Conventional full heparinization protocols or low-dose heparin with heparin-bonded circuits may be used. A venous cannula can be left in the right atrium at the completion of the heart transplant procedure to serve as a return site for subsequent venovenous bypass during liver transplantation.

Pathophysiology Before Transplantation

The pathophysiology of heart transplant candidates is predominantly end-stage cardiomyopathy. Normally, such patients will have both systolic dysfunction (characterized by decreased stroke volume and increased end-diastolic volume) and diastolic dysfunction, characterized by an increased intracardiac diastolic pressure. As compensatory mechanisms to maintain CO fail, the increased LV pressures lead to increases in pulmonary venous pressures and development of pulmonary vascular congestion and edema. A similar process occurs if RV failure also occurs. Autonomic sympathetic tone is increased in patients with heart failure, leading to generalized vasoconstriction, as well as salt and water retention. Vasoconstriction and ventricular dilation combine to substantially increase myocardial wall tension. Over time, the high levels of catecholamines lead to a decrease in the sensitivity of the heart and vasculature to these agents via a decrease in receptor density (ie, downregulation) and a decrease in myocardial norepinephrine stores.[23]

Therapy of heart failure seeks to reverse or antagonize these processes (see Chapters 11, 36, and 38). Almost all candidates will be maintained on diuretics; hypokalemia and hypomagnesemia secondary to urinary losses are likely, and the anesthesiologist must be alert to the possibility that a patient is hypovolemic from excessive diuresis. Another mainstay of therapy is vasodilators (such as nitrates, hydralazine, and angiotensin-converting enzyme inhibitors), which decrease the impedance to LV emptying and improve cardiac function and survival in patients with end-stage heart failure.[24,25] Paradoxically, slow incremental β-blockade with agents such as the β_1-antagonist metoprolol also can improve hemodynamics and exercise tolerance in some patients awaiting heart transplantation.[26] Patients who are symptomatic despite these measures often will require inotropic therapy. Digoxin is an effective but weak inotrope, and its use is limited by toxic side effects. Phosphodiesterase inhibitors such as amrinone, milrinone, and enoximone are efficacious, but chronic therapy is restricted by concerns about increased mortality in those receiving these agents.[27,28] Therefore inotrope-dependent patients often are treated with intravenous infusions of β-adrenergic agonists such as dopamine or dobutamine. Patients refractory to even these measures may be supported with intraaortic balloon counterpulsation, but its use is fraught with significant vascular complications and essentially immobilizes the patient. Many patients with low CO are maintained on anticoagulants such as warfarin to prevent pulmonary or systemic embolization, especially if they have atrial fibrillation.

Pathophysiology After Transplantation

The physiology of patients after heart transplantation is of interest not only to anesthesiologists in cardiac transplant centers but to the anesthesiology community at large because a substantial portion of these patients return for subsequent surgical procedures (see Chapter 45).[29,30]

Cardiac denervation is an unavoidable consequence of heart transplantation. Many long-term studies indicate that reinnervation is absent,[31,32] or at best partial or incomplete,[33] in humans. Denervation does not significantly change baseline cardiac function,[34,35] but it does substantially alter the cardiac response to demands for increased CO. Normally, increases in heart rate can rapidly increase CO, but this mechanism is not available to the transplanted heart. Heart rate increases only gradually with exercise, and this effect is mediated by circulating catecholamines.[31] Increases in CO in response to exercise are instead mostly mediated via an increase in stroke volume.[36] Therefore maintenance of adequate preload in cardiac transplant recipients is crucial. Lack of parasympathetic innervation probably is responsible for the gradual decrease in heart rate after exercise seen in transplant recipients, rather than the usual sharp decline.

Denervation has important implications in the choice of pharmacologic agents used after cardiac transplantation. Drugs that act indirectly on the heart via either the sympathetic (ephedrine) or parasympathetic (atropine, pancuronium, edrophonium) nervous systems generally will be ineffective. Drugs with a mixture of direct and indirect effects will exhibit only their direct effects (leading to the absence of the normal increase in refractory period of the atrioventricular node with digoxin,[37] tachycardia with norepinephrine infusion, and bradycardia with neostigmine).[38] Thus agents with direct cardiac effects (such as epinephrine or isoproterenol) are the drugs of choice for altering cardiac physiology after transplantation. However, the chronically high catecholamine levels found in cardiac transplant recipients may blunt the effect of α-adrenergic agents, as opposed to normal responses to β-adrenergic agents.[39]

Allograft coronary vasculopathy remains the greatest threat to long-term survival after heart transplantation. Allografts are prone to the accelerated development of an unusual form of coronary atherosclerosis that is characterized by circumferential, diffuse involvement of entire coronary arterial segments, as opposed to the conventional form of coronary atherosclerosis with focal plaques often found in eccentric positions in proximal coronary arteries.[40] The pathophysiologic basis of this process remains elusive, but it is likely due to an immune cell–mediated activation of vascular endothelial cells to upregulate the production of smooth muscle cell growth factors.[41] More than half of all heart transplant recipients have evidence of concentric atherosclerosis 3 years after transplant, and more than 80% at 5 years.[42] Because afferent cardiac reinnervation is rare, a substantial portion of recipients with accelerated vasculopathy will have silent ischemia.[43] Noninvasive methods of detecting coronary atherosclerosis are insensitive for detecting allograft vasculopathy.[44] Furthermore, coronary angiography often underestimates the severity of allograft atherosclerosis[45]; other diagnostic regimens such as intravascular ultrasound and dobutamine stress echocardiography may detect morphologic abnormalities or functional ischemia, respectively, in the absence of angiographically significant lesions.[40,45,46] Therefore the anesthesiologist should assume that there is a substantial risk for coronary vasculopathy in any heart transplant recipient beyond the first 2 years, regardless of symptoms, the results of noninvasive testing, and even angiography.

Anesthetic Management

Preoperative Evaluation and Preparation

The preoperative period often is marked by severe time constraints because of the impending arrival of the donor heart. Nevertheless, a rapid history should screen for last oral intake, recent anticoagulant use, intercurrent deterioration of ventricular function, or change in anginal pattern; a physical examination should evaluate present volume status, and a laboratory review (if available) and a chest radiograph should detect the presence of renal, hepatic, or pulmonary dysfunction. Many hospitalized patients will be supported with inotropic infusions and/or an intraaortic balloon pump, and the infusion rates and timing of the latter should be reviewed.

Equipment and drugs similar to those usually used for routine cases requiring CPB should be prepared. A β-agonist such as epinephrine should be readily available both in bolus form and as an infusion to rapidly treat ventricular failure; and an α-agonist such as phenylephrine or norepinephrine is useful to compensate for the vasodilatory effects of anesthetics because even small decreases in preload and afterload can lead to catastrophic changes in CO and coronary perfusion in these patients.

Placement of invasive monitoring before induction will facilitate rapid and accurate response to hemodynamic events during induction. In addition to standard noninvasive monitoring, an arterial catheter and a PA catheter (with a long sterile sheath to allow partial removal during graft implantation) are placed after judicious use of sedation and local anesthetics. Placing the arterial catheter in a central site rather than the radial artery will avoid the discrepancy between radial and central arterial pressure often seen after CPB, but it also may be necessary to cannulate a femoral artery for arterial inflow for CPB if there has been a prior sternotomy. Floating the PA catheter into correct position may be difficult because of cardiac chamber dilation and severe tricuspid regurgitation. Large-bore intravenous access is mandatory, especially if a sternotomy has been previously performed, in which case external defibrillator/pacing patches also may be useful. The overall hemodynamic picture should be evaluated and optimized insofar as possible just before induction. If the hemodynamics seem tenuous, then starting or increasing an inotrope infusion may be advisable.

Induction

Most patients presenting for heart transplantation will not be in a fasting state and should be considered to have a full stomach. Therefore the induction technique should aim to rapidly achieve control of the airway to prevent aspiration while avoiding myocardial depression. A regimen combining a short-acting hypnotic with minimal myocardial depression (etomidate, 0.3 mg/kg), a moderate dose of narcotic to blunt the tachycardic response to laryngoscopy and intubation (fentanyl, 10 μg/kg), and succinylcholine (1.5 mg/kg) is popular[47]; high-dose narcotic techniques with or without benzodiazepines also have been advocated.[48,49] Vasodilation should be countered with an α-agonist. Anesthesia can be maintained with additional narcotic and sedatives (benzodiazepines or scopolamine).[49,50]

Intraoperative Management

After induction, the stomach can be decompressed with an orogastric tube and a TEE probe introduced while the bladder is catheterized. A complete TEE examination often will reveal useful information not immediately available from other sources, such as the presence of cardiac thrombi (see Fig. 25.1), ventricular volume and contractility, and atherosclerosis of the ascending aorta and aortic arch. Crossmatched blood should be immediately available once surgery commences, especially if the patient has had a previous sternotomy; patients not previously exposed to cytomegalovirus should receive blood from donors who are likewise cytomegalovirus negative. Sternotomy and cannulation for CPB are performed as indicated earlier. The period before CPB often is uneventful, apart from arrhythmias and slow recovery of coronary perfusion because of manipulation of the heart during dissection and cannulation. The PA catheter should be withdrawn from the right heart before completion of bicaval cannulation.

Once CPB is initiated, ventilation is discontinued and the absence of a thrill in the carotid arteries is documented. Most patients will have an excess of intravascular volume, and administration of a diuretic and/or the use of hemofiltration via the pump may be beneficial by increasing the hemoglobin concentration. A dose of glucocorticoid (methylprednisolone, 500 mg) is administered as the last anastomosis is being completed before release of the aortic cross-clamp to attenuate any hyperacute immune response. During the period of reperfusion an infusion of an inotrope is begun for both inotropy and chronotropy. TEE is used to monitor whether the cardiac chambers are adequately de-aired before weaning from CPB.

Weaning from bypass begins after ventilation is resumed and the cannula in the SVC is removed. The donor heart should be paced if bradycardia is present despite the inotropic infusion. Once the patient is separated from CPB, the PA catheter can be advanced into position. Patients with increased PVR are at risk for acute RV failure and may benefit from a pulmonary vasodilator such as prostaglandin E_1 (0.05–0.15 μg/kg/min).[51] Rarely, such patients will require support with a RV assist device.[52] TEE often will provide additional useful information about right- and left-heart function and volume, and document normal flow dynamics through the anastomoses. Unless a bicaval anastomosis was created, a ridge of redundant tissue will be evident in the left atrium and should not cause alarm (see Videos 25.1 and25.2).

Protamine then is given to reverse heparin's effect after satisfactory weaning from CPB. Continued coagulopathy despite adequate protamine is common after heart transplantation, especially if there has been a prior sternotomy. Treatment is similar to that used for other postbypass coagulopathies: meticulous attention to surgical hemostasis, empiric administration of platelets, and subsequent addition of fresh-frozen plasma and cryoprecipitate guided by subsequent coagulation studies (see Chapters 19, 34, and 35). After adequate hemostasis is achieved, the wound is closed in standard fashion and the patient transported to the intensive care unit (ICU).

Postoperative Management and Complications

Management in the ICU after the conclusion of the procedure essentially is a continuation of the anesthetic management after CPB.[53] The electrocardiogram; arterial, central venous, and/or PA pressures; and arterial oxygen saturation are monitored continuously. Cardiac recipients will continue to require β-adrenergic infusions for chronotropy and inotropy for up to 3 to 4 days. Vasodilators may be necessary to control arterial hypertension and decrease impedance to LV ejection. Patients can be weaned from ventilatory support and extubated when the hemodynamics are stable and hemorrhage has ceased. The immunosuppressive regimen of choice (typically consisting of cyclosporine, azathioprine, and prednisone, or tacrolimus and prednisone) should be started after arrival in the ICU. Invasive monitoring can be withdrawn as the inotropic support is weaned, and mediastinal tubes removed after drainage subsides (usually after 24 hours). Patients usually can be discharged from the ICU after 2 or 3 days (see Chapters 37–39).

Early complications after heart transplantation include acute and hyperacute rejection, cardiac failure, systemic and pulmonary hypertension, cardiac arrhythmias, renal failure, and infection. Hyperacute rejection is an extremely rare but devastating syndrome mediated by preformed recipient cytotoxic antibodies against donor heart antigens. The donor heart immediately becomes cyanotic from microvascular thrombosis and ultimately ceases to contract.[54] This syndrome is lethal unless the patient can be supported mechanically until a suitable heart is found. Acute rejection is a constant threat in the early postoperative period and may present in many forms (eg, low CO, arrhythmias). Acute rejection occurs most frequently during the initial 6 months after transplantation, so its presence is monitored by serial endomyocardial biopsies, with additional biopsies to evaluate any acute changes in clinical status. Detection of rejection mandates an aggressive increase in the level of immunosuppression, usually including pulses of glucocorticoid or a change from cyclosporine to tacrolimus. Low CO after transplantation may reflect a number of causative factors: hypovolemia, inadequate adrenergic stimulation, myocardial injury during harvesting, acute rejection, tamponade, or sepsis. Therapy should be guided by invasive monitoring, TEE, and endomyocardial biopsy. Systemic hypertension may be caused by pain, so adequate analgesia should be obtained before treating blood pressure with a vasodilator. Because fixed pulmonary hypertension will have been excluded during the recipient evaluation, pulmonary hypertension after heart transplantation usually will be transient and responsive to vasodilators such as prostaglandin E_1, nitrates, or hydralazine after either orthotopic or heterotopic placement.[55,56] Atrial and ventricular tachyarrhythmias are common after heart transplantation[57]; once rejection has been ruled

out as a cause, antiarrhythmics are used for conversion or control (except those acting via indirect mechanisms such as digoxin, or those with negative inotropic properties such as β-blockers and calcium channel blockers). Almost all recipients will require either β-adrenergic agonists or pacing to increase heart rate in the immediate perioperative period, but 10% to 25% of recipients also will require permanent pacing.[58,59] Renal function often improves immediately after transplantation, but immunosuppressives such as cyclosporine and tacrolimus may impair renal function.[60,61] Finally, infection is a constant threat to immunosuppressed recipients. Bacterial pneumonia is frequent early in the postoperative period, with opportunistic viral and fungal infections becoming more common after the first several weeks (see Chapter 41).

Pediatric Considerations

In the pediatric population, cardiomyopathy, complex CHD, and repeat transplant are the primary indications for heart transplantation. Cardiomyopathy is the most common indication for pediatric heart transplantation and has been an increasing indication over the past 30 years.[62,63] The ages and indications of patients with CHD undergoing heart transplant is changing as surgical management of CHD continues to advance. The most common indication in the CHD population for transplant is failed single-ventricle palliation.[63] Repeat heart transplant is rare in pediatrics and is associated with worse outcomes compared with the original transplant.

A 2007 scientific statement from the American Heart Association presented recommended indications for pediatric heart transplant mostly based on expert consensus.[64] A class I indication for pediatric heart transplant was class D heart failure defined as symptomatic heart failure at rest requiring continuous inotropic support, mechanical ventilation, or mechanical device support. Pediatric patients with class C heart failure (current or past history of symptomatic heart failure) who were at risk of sudden death or development of pulmonary hypertension should also be listed for heart transplant. The biggest challenge for pediatric transplant programs is to determine which CHD patients are symptomatic, at risk for sudden death, or at risk of developing pulmonary hypertension. In general, transplantation is recommended in patients who have decompensated heart failure refractory to medical treatment and CHD patients that are not candidates for reparative surgery or palliation.

Overall survival has improved in children undergoing heart transplantation. Enhanced preservation of the donor heart, improved selection of recipients and donors, and refinements in surgical techniques and immunosuppressive therapy have contributed to this trend.[62,65] Unfortunately, the number of potential recipients will always exceed the supply of organ donors. Strategies to decrease the waiting list include limiting transplantation to patients with CHD to those with ventricular dysfunction, severe valvular dysfunction, or severe coronary anomalies. ABO-incompatible transplantation is also now permitted under UNOS guidelines in children younger than 1 year of age with any isohemagglutinin titer and for children between 1 and 2 years of age with isohemagglutinin titers of 1:4 or lower. Despite strategies to shorten the waiting time, wait list mortality is 17% for pediatric heart transplant candidates with infants currently having the longest waiting time.[66,67]

The preoperative assessment for heart transplantation in the patient with complex CHD can be quite extensive depending on the heart defect and previous corrective or palliative procedures. Similar to the child with dilated cardiomyopathy, assessment of the indexed pulmonary vascular resistance (PVRI) is essential.[59] Transplantation with an increased PVRI is potentially contraindicated because it is associated with acute right ventricular failure and mortality. In adults, a PVRI greater than 5 units and a transpulmonary gradient greater than 15 mm Hg are generally contraindications for transplantation.[6] The upper limit of PVR associated with successful cardiac transplantation has not been established in children. Acceptable PVRI is less than 10 units in children, but it is not unusual for a pediatric heart transplant candidate to have a PVRI greater than 10 units. However, even in the 6 to 10 unit range, the child is at risk for acute RV failure because the donor's right ventricle is thin walled and the myocardium has been ischemic. If the PVRI decreases significantly in the catheterization laboratory, with a trial of vasodilator testing, hyperventilation, administering 100% fraction of inspired oxygen, and nitric oxide, the candidate is deemed acceptable for transplant. If the PVRI remains borderline, the candidate is admitted to the hospital for a 1- or 2-week trial with milrinone and dobutamine. If the PVRI then falls, transplantation is offered with the thought that these patients might benefit from pulmonary vasodilation therapy during weaning from CPB and in the ICU after transplantation.

Another aspect to be emphasized in the pretransplant evaluation of these patients with complex CHD is the need for a detailed anatomic evaluation. It is not uncommon for this group of patients to have branch pulmonary artery stenosis, discontinuous pulmonary arteries, abnormal pulmonary venous return, hypoplastic aortic arch, and coarctation of the aorta. Anomalies of systemic and pulmonary veins are associated with atrial isomerism, and different surgical techniques are needed to address these issues during transplantation. The most common indication for cardiac transplantation in CHD patients is for the so-called failed Fontan for physiologic repair of cardiac defects with single ventricle.[63] They present with protein-losing enteropathy, chronic liver disease, and pulmonary arteriovenous malformations. The existence of large aortopulmonary collaterals can lead to high-output failure or moderate-to-severe hypoxemia that may lead to primary graft failure. Small malformations may regress with time. Although the donor ischemic time, ICU days, and total hospital days are prolonged in CHD patients, the outcome is comparable to the patient with dilated cardiomyopathy after heart transplantation.

In some recipients, the circulation is supported by extracorporeal membrane oxygenation (ECMO) or a ventricular assist device as a bridge to transplantation. Prolonged support is associated with bleeding, sepsis, and multiorgan dysfunction. It is not uncommon to list an infant who is on ECMO for heart transplant after a failed Norwood procedure. The need for ECMO is associated with increased waitlist mortality.[66–68]

Besides determining the blood type (ABO), it is important to assess for the presence of antibodies against human histocompatibility leukocyte antigen (HLA). Anti-HLA antibodies are uncommon in in patients with cardiomyopathy, but may have developed in the recipient who was exposed to blood products during palliation for complex CHD. Transplantation in the setting of elevated panel reactive antibody greater than 10% or allosensitization carries an increased risk of mortality.[69] Techniques to decrease the circulating anti-HLA antibodies (desensitization) include administering IVIG, cyclophosphamide, mycophenolate mofetil or plasmapheresis.[70,71]

Children are naturally anxious before surgery and premedication is provided with benzodiazepines. Preoperative placement of invasive monitors is typically not feasible in children prior to induction; however, noninvasive monitoring should be in place before induction. A peripheral IV or other long-term intravenous access will already be in place, permitting an intravenous induction. Full-stomach precautions are generally recommended; however, children typically do not tolerate prolonged periods of apnea. In addition, hypoxia and hypercarbia will aggravate PVR, necessitating expert airway management. Induction of anesthesia can be accomplished with any sedative-hypnotic agent, including propofol, etomidate, or high-dose narcotic (fentanyl), a benzodiazepine, and a nondepolarizing muscle relaxant. Titration to vital signs is important. Arterial and central venous access is obtained, and large-bore venous access is also recommended because postoperative bleeding is common in patients with CHD owing to extensive scarring and adhesions from previous palliative procedures.

Anesthesia is maintained with an inhalation agent, additional opioid, benzodiazepine, and nondepolarizing muscle relaxants. Frequently, the groin vessels are exposed for urgent cannulation before sternotomy, and during this procedure fewer narcotics are required. A PA catheter can be used in the older child, but direct measurement of

RV pressures in the grafted organ can be transduced by the surgeon if there are concerns about pulmonary hypertension.

Acute RV dysfunction is a major postbypass problem. with acute RV failure occurring in an estimated 15% to 40% of pediatric heart transplants.[72] In pediatric procedures, the donor-recipient heart size matching (by weight) ranges between 80% and 160%; however, the upper limit can be increased for neonates and in cases in which there is concern for pulmonary hypertension. Measures to preserve donor RV function posttransplant include keeping PVR normal by suctioning the endotracheal tube, maintaining adequate oxygenation and moderate hyperventilation, and ensuring adequate anesthesia and analgesia to decrease circulating catecholamines. Milrinone is used for providing inotropy and decreasing PVR, whereas nitric oxide is a useful adjunct. Patients may occasionally need to be placed on ECMO to allow for pulmonary artery pressure normalization and recovery of RV function.

Lung Transplantation

History and Epidemiology

Although the first human lung transplant was performed in 1963, surgical technical problems and inadequate preservation and immunosuppression regimens prevented widespread acceptance of this procedure until the mid-1980s (Box 25.2). Advances in these areas have since made lung transplantation a viable option for many patients with end-stage lung disease. According to data collected by UNOS between 2000 and 2002, the annual frequency of lung transplantation has remained stagnant, with the total number still averaging in the vicinity of 1000. Further growth in lung transplantation was feared to be constrained by a shortage of donor organs, with demand for organs still vastly exceeding supply. This was expected to be potentially exacerbated by data that were published in 2009, revealing that double-lung transplant afforded fewer hospitalizations and potentially better long-term survival.[73] Despite these data, since 2003 the number of double-lung transplants has increased significantly in the United States, whereas the number of single-lung transplants remained stagnant. The greatest growth in double-lung transplant occurred in the population with chronic obstructive pulmonary disease without alpha-1 antitrypsin deficiency and interstitial lung disease.

According to the most recent data available for the Registry of the International Society of Heart and Lung Transplantation for the period January 1, 1985, to June 30, 2013, a total of 47,647 lung transplants were reported.[3] This total was made up of 45,697 first transplants and 1950 retransplantations. Retransplants have consistently remained at about 5% of the total number of transplants in the United States, whereas European data suggested 3.6%. Younger and female patients represented the greatest chance of retransplant. The year 2011 saw the highest number of transplants; there was a decrease in the number of low-volume centers (defined as fewer than 10 transplants per year) with a commensurate increase in the number of high-volume centers performing more procedures. Between 2008 and 2013, 156 centers reported doing lung transplant procedures. Of these, 44 centers accounted for 65% of all lung transplants and 14 centers reported volumes of greater than 50 transplants per year.[74]

It is estimated that more than one million individuals with end-stage lung disease are potential recipients of lung transplants.[75] The Organ Procurement and Transplantation Network has 1643 patients listed as candidates for lung transplantation in the United States. This number does not accurately reflect the number of organs required because some patients will require bilateral lung transplantation. Average time to transplant increased to as high as 451 days in 1999; however, most recently, that time has declined to 325 days for those waiting for 1 to 2 years. After stagnating from 2001 to 2003 at slightly more than 1000 transplants annually, the number of transplants in the United States has grown steadily since 2010 to between 1700 and 1900 annually. Currently, about one-fourth of patients undergo transplant within 251 days. Most of this improvement has been seen with recipients who are 50 years and older. One explanation for this may be increasing leniency in organ-selection criteria. The use of expanded criteria does not appear to have been associated with an increase in mortality. Mortality for patients on the waiting list also has continued to decline, from a 2001 high of about 500 to approximately 198 in 2014.[74] Although some of this improvement may be ascribed to better medical management of patients on the waiting list, it is also likely due to broadened criteria for acceptance for transplantation and the corresponding increase in the number of transplants performed per year.

Data from 1990 to 2012 have shown a median survival of about 5.7 years, with 88% surviving 3 months, 80% surviving 1 year, 65% at 3 years, 53% at 5 years, and 32% at 10 years. Improvement has continued over time; this is reinforced by the increase in 3-month survival from 83% to 91% and by 1-year survival improvement from 72% to 83% over the entire reporting period. Double-lung transplant recipients did better than single-lung transplants, with median survival being 7.0 years as compared for 4.5 years for single-lung transplants.[74]

Younger and female recipients showed improved survival over older and male recipients (Fig. 25.4). Patients who received lungs from CMV-negative donors had better survival over lungs received from CMV-positive donors.

Even better survival data have been reported from centers with extensive experience with these procedures (1-year survival rates of 82% for double-lung recipients and 90% for single-lung recipients).[76] Infection is the most frequent cause of death in the first year after transplant, but this is superseded in later years by bronchiolitis obliterans.[3] Additional causes for mortality are primary graft, failure, technical problems with the procedure, and cardiovascular causes. In patients who have longer survival, the causes shift more toward bronchiolitis obliterans (BO), chronic rejection, and malignancy. Notable is that 21% of all lung transplants were performed at 21 centers around the world averaging 50 procedures per year.[3]

Some of the most challenging patients are those with cystic fibrosis (Fig. 25.5). The 1-year survival rate of 79% and 5-year survival rate of 57% after lung transplantation have shown that despite the high incidence of poor nutrition and the almost ubiquitous colonization by multidrug-resistant organisms, these patients can still successfully undergo lung transplantation with acceptable outcomes data.[77]

It is a sign of the maturity of lung transplantation procedures that survival data for redo lung transplantation also are becoming available. Retransplantation has very high early mortality and a median survival rate of only 2.5 years.[74]

Infection and multiorgan failure before repeat transplant are associated with an almost uniformly fatal outcome. Subsequent data from

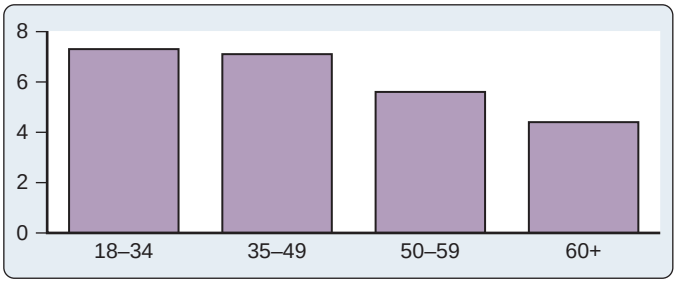

Fig. 25.4 Median survival in years by recipient age.

BOX 25.2 LUNG TRANSPLANTATION

- Broader donor criteria have decreased the time from listing to transplantation.
- Nitric oxide minimizes reperfusion injury.
- Donor lungs should be ventilated with a protective strategy (low inspired oxygen, low tidal volume/inspired pressure) after transplantation.

BOX 25.3 RISK FACTORS FOR INCREASED MORTALITY

- Smaller transplant center: 30 transplants per year
- Greater donor-to-recipient height mismatch
- Older recipient: older than 55
- Higher bilirubin
- Higher supplemental oxygen therapy
- Lower cardiac output
- Lower FVC
- Higher creatinine

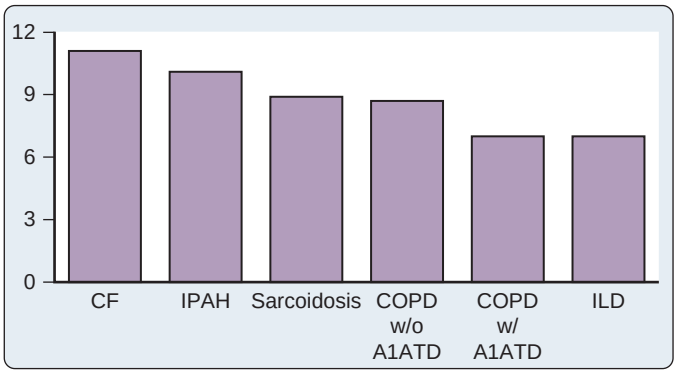

Fig. 25.5 Median survival in 1-year survivors by indication. *A1ATD,* alpha-1 antitrypsin deficiency; *CF,* cystic fibrosis; *COPD,* chronic obstructive pulmonary disease; *ILD,* interstitial lung disease.

UNOS, however, have shown an improvement, with the 1-year survival rate at 66.3% in the retransplant patients as compared with 83.8% in the primary transplant population. This is, however, significantly worse at 3 years, with repeat survival rate at 38.8% compared with 63.2% (Box 25.3).

Recipient Selection

Because donor lungs are scarce, it is important to select those most likely to benefit from lung transplantation as recipients. In general, candidates should be terminally ill with end-stage lung disease (NYHA class III or IV, with a life expectancy of approximately 2 years), be psychologically stable, and be devoid of serious medical illness (especially extrapulmonary infection) compromising other organ systems. Patients already requiring mechanical ventilation are poor candidates, although lung transplantation can be successful in such a setting. Other factors such as advanced age, previous thoracic surgery or deformity, and steroid dependence may be regarded as relative contraindications by individual transplant centers. Hepatic disease solely caused by right-heart dysfunction should not preclude candidacy (Boxes 25.4 and 25.5).

Potential recipients undergo a multidisciplinary assessment of their suitability, including pulmonary spirometry, radiography (plain film and chest CT scan), and echocardiography or multigated image acquisition scan. Patients older than 40 years and those with pulmonary hypertension usually undergo left-heart catheterization to exclude significant coronary atherosclerosis or an intracardiac shunt. TEE may yield data (eg, unanticipated atrial septal defect) that will alter subsequent surgical approach in approximately one-quarter of patients with severe pulmonary hypertension.[78] Candidates who are accepted often are placed on a physical conditioning regimen to reverse muscle atrophy and debilitation and kept within 20% of their ideal body weight. Because lung transplantation is an emergency procedure (limited by a lung preservation time of 6–8 hours),[79] results of this

BOX 25.4 ABSOLUTE CONTRAINDICATIONS FOR LUNG TRANSPLANTATION

- Malignancy within 2 years (preferably 5 years)
- Untreatable significant disease in another organ system
- Atherosclerotic disease not corrected
- Acute medical instability: hepatic failure
- Bleeding diathesis that is not correctable
- Mycobacterium tuberculosis infection
- Highly virulent or resistant microbial infections
- Chest wall deformity
- Obesity
- Medical noncompliance
- Psychiatric disease leading to noncooperation in management plan
- Absent social support system
- Substance abuse/addition
- Severely impaired functional status

BOX 25.5 RELATIVE CONTRAINDICATIONS FOR LUNG TRANSPLANTATION

- Age >65 years with limited functional reserve
- Obesity
- Malnutrition
- Severe osteoporosis
- Prior lung resection surgery
- Mechanical ventilation or ECLS
- Highly resistant bacterial colonization
- Hepatitis B and C
- HIV infection with detectable viral load
- *Burkholderia* and *Mycobacterium abscessus* infection in which good control is not expected

comprehensive evaluation should be readily available to the anesthesiology team at all times. Ideally, the transplant recipient should also see the anesthesiology team at the time of evaluation to determine whether the patient has any specific anesthetic challenges. This will allow for the team taking care of the patient to rapidly assess the patient before transplantation. Weiss[80] published data in 2009 that supported the cautious transplantation of patients older than 60 years but recommended against transplantation of patients older than 70. Data from the same authors suggested that race-matching also provided a survival benefit that manifested itself in the first 2 years after transplant.[81]

Mechanical bridging therapy is now available as a way to provide longer support of the recipient until a suitable organ can be located. Mechanical ventilation is the most commonly used mechanism and often used to support the patient between exacerbations of their underlying disease but is not without risk of develop ventilator-associated infection or injury. Extracorporeal life support (ECLS) has been thought of for a long time but initial survival data were discouraging. The ideal candidate is young with no multiorgan dysfunction and in appropriate medical condition to allow rehabilitation. The outcomes have improved to the degree that post-ECLS transplanted patients have similar outcomes as those without the need for ECLS. The UNOS database has shown improved 1-year survival from 30% in 2005 to an impressive 75% in 2010 for those using ECLS. Despite this promise there are still significant risks of complication related to coagulopathy, infection, and complications arising at sites of vascular access.[82] Fuehner and colleagues described the use of ECLS in awake patients who were allowed to ambulate and receive therapy to maintain their conditioning.[83]

Donor Selection and Graft Harvest

The ongoing shortage of suitable donor organs has led to a liberalization of selection criteria. Prospective lung donors who were cigarette smokers are no longer rejected simply based on a pack-year history. Computed tomography has been used to assess the structural integrity of the lung, particularly in donors who have suffered traumatic chest injury. Lungs that have contusion limited to less than 30% of a single lobe can be considered adequate.[84] Greater use also has been made of organs from older but otherwise healthy donors (55 to 60 years old), especially when the ischemic period will be short.[85] A clear chest radiograph, normal blood gas results, unremarkable findings on bronchoscopy, sputum stain, and direct intraoperative bronchoscopic and gross evaluation confirm satisfactory lung condition. The lungs are matched to the recipient for ABO blood type and size (oversized lungs can result in severe atelectasis and compromise of venous return in the recipient, especially after double-lung transplantation). Donor serology and tracheal cultures will guide subsequent antibacterial and antiviral therapy in the recipient.

Most lung grafts are recovered during a multivisceral donor harvest procedure. The heart is removed as described for heart transplantation, using inflow occlusion and cardioplegic arrest, with division of the IVC and SVC, the aorta, and the main PA. Immediately after cross-clamping, the pulmonary vasculature is flushed with ice-cold extracellular preservative solution, which often contains prostaglandin E_1. This is believed to promote pulmonary vasodilation, which aids homogenous distribution of the preserving solution. Other additives that have been included are nitroglycerin and low-potassium 5% dextran. The left atrium is divided to leave an adequate LA cuff for both the heart graft and lung graft(s) with the pulmonary veins. After explantation, the lung also may be flushed to clear all pulmonary veins of any clots. After the lung is inflated, the trachea (or bronchus for an isolated lung) is clamped, divided, and stapled closed. Inflating the lung has been shown to increase cold ischemia tolerance of the donor organ. The lung graft is removed, bagged, and immersed in ice-cold saline for transport. The use of extracellular preservation fluid has been shown to be beneficial in protecting the lungs from ischemia/reperfusion injury. However, the most important factor to consider when determining resistance to ischemia/reperfusion is the duration of the ischemia itself. When the ischemia time exceeds 330 minutes, the risk of mortality rapidly increases.[86]

Recipients who have donor-specific antibodies (DSA) tend to worse short- and long-term outcomes. These patients may need to be considered for an aggressive desensitization protocol that entails plasma exchange and is carried out immediately after anesthetic induction and terminated before the perfusion of the first donor allograft. In addition to this, patients will receive rabbit antithymocyte globulin (ATG) after the final plasma exchange and mycophenylate in the postoperative period. With this protocol, patients who were sensitized were able to have outcomes similar to those who were not sensitized.[87]

Induction of immunosuppression is becoming more commonplace but has remained controversial. The goal is to decrease the degree of calcineurin inhibitor use and its attendant side effects. Whitson and associates showed in a review of the UNOS database that the use of induction with agents such as alemtuzumab and basiliximab improved outcomes.[88]

Surgical Procedures

Because of the relative shortage of lung donors and the finding that recipients can gain significant exercise tolerance even with only one transplanted lung,[89] single-lung transplantation used to be the procedure of choice for all lung transplant candidates. Subsequently, however, the published data have indicated better outcomes for those patients receiving double-lung transplant. Certain situations exist in which it is, practically speaking, better to transplant both lungs. For example, the presence of lung disease associated with chronic infection (cystic fibrosis and severe bronchiectasis) mandates double-lung transplantation to prevent the recipient lung from acting as a reservoir of infection and subsequently cross-contaminating the allograft. Patients with severe air trapping may require double-lung transplantation if uncontrollable ventilation/perfusion mismatching will be likely after transplantation. Lobar transplantation into children and young adults from living related donors is discussed separately later in this chapter.

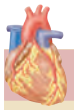
Single-Lung Transplant

The choice of which lung to transplant is usually based on multiple factors, including avoidance of a prior operative site, preference for removing the native lung with the worst ventilation/perfusion ratio, and donor lung availability. The recipient is positioned for a posterolateral thoracotomy, with the ipsilateral groin prepped and exposed in case CPB becomes necessary. With the lung isolated, a pneumonectomy is performed, with special care to preserve as long a PA segment as possible. After removal of the diseased native lung, the allograft is positioned in the chest with particular attention taken to maintaining its cold tissue temperature. The bronchial anastomosis is performed first. A telescoping anastomosis is used if there is significant discrepancy in size between the donor and the recipient. The object of the technique is to minimize the chance of dehiscence. Although it was once common to wrap bronchial anastomoses with omentum, wrapping produces no added benefit when a telescoping anastomosis is performed. The PA is anastomosed next, and finally, the left atrial cuff on the allograft containing the pulmonary venous orifices is anastomosed to the native left atrium. The pulmonary circuit is then flushed with blood and de-aired. The initial flush solution is usually cold (4°C) but is followed by a warm (37°C) flush. The warm flush usually is performed during final completion of the vascular anastomoses. The administration of pulmonoplegia aims to achieve a controlled reperfusion.[90] The contents of this solution are listed in Box 25.6.

After glucocorticoid administration, the vascular clamps are removed and reperfusion is begun. The vascular anastomoses are inspected for any areas of hemorrhage, and then the lung is reinflated with a series of ventilations to full functional residual capacity. After achieving adequate hemostasis and satisfactory blood gases, chest tubes are placed, the wound is closed, and the patient is transported to the ICU.

Double-Lung Transplant

Early attempts at double-lung transplantation using an en bloc technique via a median sternotomy were plagued by frequent postoperative airway dehiscence because of poor vascular supply of the tracheal anastomosis, by hemorrhage caused by extensive mediastinal dissection (which also resulted in cardiac denervation), by the requirement for complete CPB and cardioplegic arrest (to facilitate pulmonary arterial and venous anastomoses), and by poor access to the posterior mediastinum. The subsequent development of the bilateral sequential lung transplant technique via a "clamshell" thoracosternotomy (essentially, two single-lung transplants performed in sequence) has avoided many of the problems inherent in the en bloc technique.[91,92] An alternative to using a clamshell incision in slender patients is an approach



BOX 25.6 WARM PULMONOPLEGIA

- Insulin

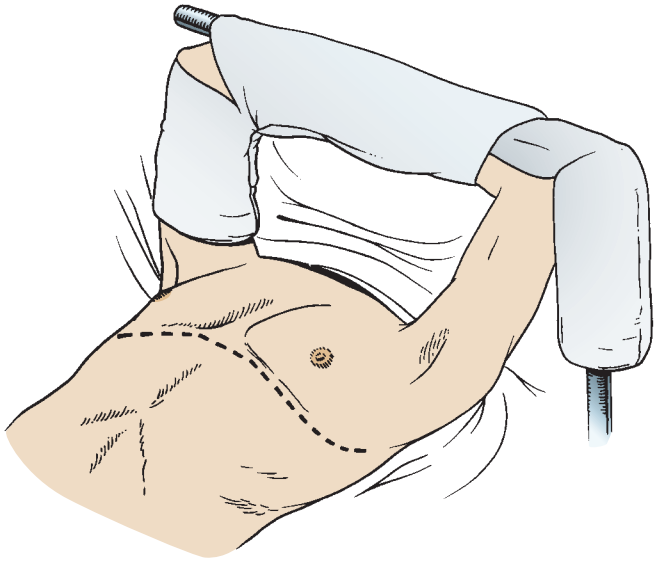

Fig. 25.6 Patient positioning for clamshell thoracosternotomy. The arms are padded and suspended from an ether screen above the head of the patient. Path of surgical incision is shown with *dotted line*. *(From Firestone LL, Firestone S. Organ transplantation. In: Miller RD, ed.* Anesthesia. *4th ed. New York: Churchill Livingstone; 1994, p 1981.)*

through two individual anterolateral thoracotomies. This can result in a particularly pleasing cosmetic result in female patients because the scar can be hidden in the breast crease. Use of CPB is optional, but it does result in better exposure of the posterior mediastinum, thus improving hemostasis, and cardiac denervation usually can be avoided. Pleural scarring usually is extensive in patients with cystic fibrosis, and postoperative hemorrhage and coagulopathy are common and potentially exacerbated if CPB is required. Transplantation of both lungs is performed in the supine position. The groin is prepped and exposed in case CPB is required. If a clamshell incision is used, the arms are padded and suspended over the head on an ether screen (Fig. 25.6). In the slender patient whose anteroposterior chest dimensions are normal, the arms may be tucked at the patient's sides. Recipient pneumonectomy and implantation of the donor lung are performed sequentially on both sides in essentially the same manner as described earlier for a single-lung transplant. The native lung with the worst function should be transplanted first. In patients whose indication for transplantation is suppurative disease, the pleural cavity is pulse-lavaged with antibiotic-containing solution that has been tailored to that patient's antimicrobial sensitivity profile, although it is unclear if this has any effect on subsequent infection. In addition to this, the anesthesiologist irrigates the trachea and bronchi with diluted iodophor solution before the donor lung is brought onto the surgical field.

Pathophysiology Before Transplantation

Patients with highly compliant lungs and obstruction of expiratory airflow cannot completely exhale the delivered tidal volume, resulting in positive intrapleural pressure throughout the respiratory cycle (auto-PEEP [positive end-expiratory pressure] or intrinsic PEEP), which decreases venous return and causes hypotension.[93] The presence of auto-PEEP is highly negatively correlated with forced expiratory volume in 1 second (FEV_1; percentage predicted) and highly positively correlated with pulmonary flow resistance and resting hypercarbia.[94] Hyperinflation is a frequent complication of single-lung ventilation during lung transplantation in patients with obstructive lung disease. Hyperinflation-induced hemodynamic instability can be confirmed by disconnecting the patient from the ventilator for 30 seconds and opening the breathing circuit to the atmosphere. If the blood pressure returns to its baseline value, hyperinflation is most likely the underlying cause. Hyperinflation can be ameliorated with deliberate hypoventilation (decreasing both the tidal volume and rate).[95] Although this may result in profound hypercarbia, high carbon dioxide tensions are often well tolerated in the absence of hypoxemia. PEEP also may decrease air trapping because it decreases expiratory resistance during controlled mechanical ventilation.[96] However, the application of PEEP requires close monitoring because if the level of extrinsic PEEP applied exceeds the level of auto-PEEP, further air trapping may result.

BOX 25.7 TREATMENT OF INTRAOPERATIVE RIGHT VENTRICULAR FAILURE

- Avoid large increases in intrathoracic pressure from:
  - Positive end-expiratory pressure (PEEP)
  - Large tidal volumes
  - Inadequate expiratory time
- Intravascular volume
  - Increase preload if pulmonary vascular resistance is normal
  - Rely on inotropes (dobutamine) if pulmonary vascular resistance is increased
- Maintain right ventricular coronary perfusion pressure with α-adrenergic agonists
- Cautious administration of pulmonary vasodilators (avoid systemic and gas exchange effects)
  - Prostaglandin E_1 (0.05–0.15 μg/kg per min)
  - Inhaled nitric oxide (20–40 ppm)

RV failure frequently is encountered in lung-transplant recipients with pulmonary hypertension because of chronically increased RV afterload. The response of the right ventricle to a chronic increase in afterload is to hypertrophy, but eventually this adaptive response is insufficient. As a result, RV stroke volume decreases and chamber dilation results. The combination of increasing afterload for the RV coupled with decreased stroke volume (and subsequent decrease in the LV stroke volume) creates an unfavorable supply-and-demand situation that makes the RV more prone for failure. The following should be kept in mind when caring for patients with severe dysfunction (Box 25.7). First, increases in intrathoracic pressure may markedly increase PVR,[97] leading to frank RV failure in patients with chronic RV dysfunction. Changes in RV function may occur immediately after adding PEEP, increasing tidal volume or decreasing expiratory time, and can have devastating consequences. In addition, although intravascular volume expansion in the presence of normal PVR increases CO, overzealous infusion in patients with increased PVR will increase RV end-diastolic pressure and RV wall stress, decreasing CO.[98] Inotropes with vasodilating properties (such as dobutamine or milrinone) often are a better choice than volume for augmenting CO in the setting of increased PVR. Furthermore, the right ventricle has a greater metabolic demand yet a lower coronary perfusion pressure than normal. RV performance can be augmented by improving RV coronary perfusion pressure with α-adrenergic agents, provided these vasoconstrictors do not disproportionately increase PVR. Vasopressin is a good choice to achieve this result. This can sometimes be a better choice than augmenting the perfusion pressure with β-adrenergic agents because the oxygen supply is increased without a large increase in oxygen demand. Additionally, the use of norepinephrine has also been shown to improve the ratio of systemic to pulmonary pressures[99] Finally, vasodilators such as nitroprusside or prostaglandin E_1 may be effective in decreasing PVR and improving RV dysfunction early in the disease process, when only mild-to-moderate pulmonary hypertension is present. However, they are of notably limited value in the presence of severe, end-stage pulmonary hypertension. Systemic vasodilation and exacerbation of shunting often limit their use. Inhaled nitric oxide activates the guanylate cyclase and raises the level of cyclic guanosine monophosphate that results in local vasodilation; it has shown promise as a means of acutely decreasing PVR without altering

systemic hemodynamics before and during the explantation phase, as well as after lung transplantation[100-102] Nitric oxide decreases both PA pressure and intrapulmonary shunting. Further, the combination of inhaled nitric oxide and aerosolized prostacyclin had a synergistic effect, without causing deleterious effects on the systemic perfusion pressure. The use of nitric oxide with or without inhaled prostacyclin may be helpful in avoiding CPB in patients having lung transplantation (see Chapters 11, 26, and 38). In addition to the medications just mentioned, patients with pulmonary hypertension may also have been started on phosphodiesterase-5 inhibitors, soluble guanylate cyclase, and endothelin receptor antagonists. Patients may also be on a prostaglandin infusion preoperatively, which should be kept running during the transplant procedure.

Pathophysiology After Lung Transplantation

The implantation of the donor lung(s) causes marked alterations in recipient respiratory physiology. In single-lung recipients, the pattern of ventilation/perfusion matching depends on the original disease process. For example, with pulmonary fibrosis, blood flow and ventilation gradually divert to the transplanted lung, whereas in patients transplanted for diseases associated with pulmonary hypertension, blood flow is almost exclusively diverted to the transplanted lung, which still receives only half of the total ventilation.[103] In such patients the native lung represents mostly dead-pace ventilation. Transplantation results in obligatory sympathetic and parasympathetic denervation of the donor lung and therefore alters the physiologic responses of airway smooth muscle. Exaggerated bronchoconstrictive responses to the muscarinic agonist methacholine have been noted in some (but not all) studies of denervated lung recipients.[104,105] The mechanism of hyperresponsiveness may involve cholinergic synapses, inasmuch as they are the main mediators of bronchoconstriction. For example, electrical stimulation of transplanted bronchi (which activates cholinergic nerves) produces a hypercontractile response.[106] This suggests either enhanced release of acetylcholine from cholinergic nerve endings because of an increased responsiveness of parasympathetic nerves or else a loss of inhibitory innervation. Such effects are unlikely to be postsynaptic in origin because the number and affinity of muscarinic cholinergic receptors on transplanted human bronchi are similar to controls.[107] Reinnervation during subsequent weeks to months has been demonstrated in several animal models,[108,109] but there was no definitive evidence concerning reinnervation of transplanted human lungs until a small study was published in 2008 that showed return of cough reflex to noxious stimuli (distal to the anastomosis) within 12 months. The presence of nerve cells in the anastomoses of deceased patients also was noted.[110] Mucociliary function is transiently severely impaired after lung transplantation and remains depressed for up to a year after the procedure.[111] Thus transplant recipients require particularly aggressive endotracheal suctioning to remove airway secretions.

Lung transplantation also profoundly alters the vascular system. The ischemia and reperfusion that are an obligatory part of the transplantation process damages endothelium. Cold ischemia alone decreases β-adrenergic cyclic adenosine monophosphate–mediated vascular relaxation by approximately 40%, and subsequent reperfusion produces even greater decreases in both cyclic guanosine monophosphate–mediated and β-adrenergic cyclic adenosine monophosphate–mediated pulmonary vascular smooth muscle relaxation.[112] Endothelial damage in the pulmonary allograft also results in leaky alveolar capillaries and the development of pulmonary edema. Pulmonary endothelial permeability is approximately three times greater in donor lungs than in healthy volunteers.[113] Regulation of pulmonary vasomotor tone solely by circulating humoral factors is another side effect of denervation. Changes in either the levels of circulating mediators or in the responsiveness of the pulmonary vasculature to such mediators may result in dramatic effects on the pulmonary vasculature. An example of the former is the finding that the potent vasoconstrictor endothelin is present at markedly increased levels (two to three times normal) immediately after transplantation and remains increased for up to a week thereafter.[114] Alterations in the response of denervated pulmonary vasculature to α_1-adrenergic agents[115] and prostaglandin E_1,[116] as well as a reduction in nitric oxide activity, also have been demonstrated in acutely denervated lung.[115] Dysfunctional responses to mediators may be exaggerated if CPB is required.[115] PVR can be substantially decreased with the administration of inhaled nitric oxide after reperfusion. It remains unclear whether nitric oxide also ameliorates reperfusion injury. Several studies suggest that nitric oxide prevents or modulates reperfusion injury as measured by decreased lung water, lipid peroxidase activity, neutrophil aggregation in the graft, and decreased IL-6, IL-8, and IL-10.[117–120] However, a number of studies suggest that although nitric oxide has an effect on pulmonary hemodynamics, it does not ameliorate reperfusion injury.[121–123]

Aerosolized inhaled prostacyclin also decreases PVR after reperfusion and improves oxygenation without the added theoretic risk for worsening reperfusion injury.[124] Inhaled prostacyclin has approximately the same effectiveness as nitric oxide in treating lungs damaged by reperfusion injury and offers the added benefit of being less expensive.[125]

A number of other agents have shown promise in decreasing postreperfusion injury in animal studies. Tetrahydrobiopterin, an essential cofactor in the nitric oxide synthase pathway, decreased the intracellular water, myeloperoxidase activity, and lipid peroxidation and increased cyclic guanosine monophosphate levels when given during reperfusion.[126] The administration of surfactant into the donor lung before harvest also appeared to ameliorate ischemia/reperfusion injury in pigs. There was a decrease in the PVR, less inflammatory cellular infiltrate, and an increase in nitric oxide levels in the group that received surfactant.[127]

Given these pathophysiologic derangements, it is not surprising that PVR increases in the transplanted lung.[128,129] However, what the clinician observes in the lung-transplant patient will depend on the severity of pulmonary vascular dysfunction present before surgery. PA pressures decrease dramatically during lung transplantation in patients who had pulmonary hypertension before transplantation,[130] and pressures remain decreased for weeks to months thereafter.[130,117] Concomitant with the decrease in PA pressure, there is an immediate decrease in RV size after lung transplantation in those patients with preexisting pulmonary hypertension, as well as a return to a more normal geometry of the interventricular septum.[111] Both of these effects are sustained over several weeks to months.[130–136] Although echocardiographic indices of RV function (RV fractional area change) have not shown a consistent improvement in the immediate posttransplant period,[130] several other studies have documented improvement in RV function during the first several months after lung transplantation.[130,131,133–136] One striking finding was that persistent depression of RV function (defined as baseline RV fractional area change of less than 30% with failure to increase after transplant by either at least 5% or by 20% of baseline) was statistically associated with death in the immediate perioperative period.[130]

Anesthetic Management

Preoperative Evaluation and Preparation

Immediate pretransplant reevaluation pertinent to intraoperative management includes a history and physical examination to screen for intercurrent deterioration or additional abnormalities that affect anesthetic management. Particular attention should be given to recent physical status, especially when the transplant evaluation was performed more than 9 to 12 months previously. A decrease in the maximal level of physical activity from that at the time of initial evaluation can be a sign of progressive pulmonary disease or worsening RV function. Most patients are maintained on supplemental nasal oxygen yet are mildly hypoxemic. Patients who are bedridden or those who must pause between phrases or words while speaking possess little functional reserve and are likely to exhibit hemodynamic instability during induction. The time and nature of the last oral intake should be determined to aid in deciding the appropriate method of securing

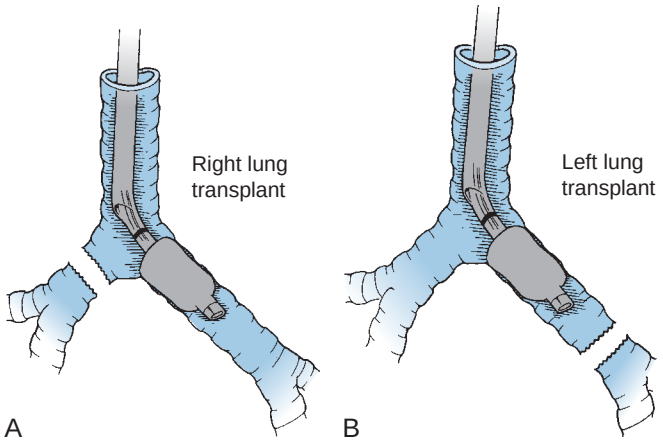

Fig. 25.7 Left endobronchial tube during (A) right- and (B) left-lung transplantation. When the endobronchial tube is correctly positioned, either bronchus may be opened for anastomosis of the donor lung without compromising the surgical field or interfering with isolated lung ventilation.

the airway. The physical examination should focus on evaluation of the airway for ease of laryngoscopy and intubation, on the presence of any reversible pulmonary dysfunction such as bronchospasm, and on signs of cardiac failure. Patients with scleroderma can present difficulty in that they often have a small mouth opening, and in some cases, they can have restricted cervical range of motion. New laboratory data often are not available before the beginning of anesthesia care, but special attention should be directed to evaluation of the chest radiograph for signs of pneumothorax, effusion, or hyperinflation because they may affect subsequent management.

Equipment necessary for this procedure is analogous to that used in any procedure in which CPB and cardiac arrest are real possibilities. Special mandatory pieces of equipment include some method to isolate the ventilation to each lung; although bronchial blockers have their advocates, double-lumen endobronchial tubes offer the advantages of easy switching of the ventilated lung, suctioning of the nonventilated lung, and facile independent lung ventilation after surgery. A left-sided double-lumen endobronchial tube is suitable for virtually all lung transplant cases (even left-lung transplants; Fig. 25.7). Regardless of whether a bronchial blocker or double-lumen tube is used, a fiberoptic bronchoscope is absolutely required to rapidly and unambiguously verify correct tube positioning, evaluate bronchial anastomoses, and clear airway secretions. An adult-sized bronchoscope offers better field of vision and superior suctioning capability but can be used only with 41 or 39 French double-lumen tubes. A ventilator with low internal compliance is necessary to adequately ventilate the noncompliant lungs of recipients with restrictive lung disease or donor lungs suffering from reperfusion injury. The added capability of the ventilator to deliver pressure-controlled ventilation also is important, especially for the patients who have pulmonary fibrotic disease or reperfusion injury. Single-lung recipients with highly compliant lungs may require independent lung ventilation with a second ventilator after transplantation (discussed in detail later). A PA catheter capable of estimating right ventricular ejection fraction (RVEF) can be useful in diagnosing RV failure and its response to inotropes and vasodilators, as well as the response of the right ventricle to clamping of the PA. However, RVEF catheters are not accurate in the presence of significant tricuspid regurgitation or when malpositioned. Continuous mixed venous oximetry is beneficial in evaluating tissue oxygen delivery in patients subject to sudden, severe cardiac decompensation in the course of the operation, as well as the responses to therapy. A rapid-infusion system can be lifesaving in cases in which major hemorrhage occurs because of anastomotic leaks, inadequate surgical ligation of mediastinal collateral vessels, chest wall adhesions, or coagulopathy after CPB.

Induction of Anesthesia

Patients presenting for lung transplantation frequently arrive in the operating room area without premedication. Indeed, many will be admitted directly to the operating room from home. Because of the nature of the procedure planned, and many months on the transplant waiting list, these patients are often extremely anxious. Considering the risk for respiratory depression from sedatives in patients who are chronically hypoxic or hypercapnic, or both, only the most judicious use of intravenous benzodiazepines or narcotics is warranted. Assiduous administration of adequate local anesthesia during placement of invasive monitoring will also considerably improve conditions for both the patient and anesthesiologist. The standard noninvasive monitoring typical of cardiovascular procedures is used (ie, two electrocardiogram leads, including a precordial lead, blood pressure cuff, pulse oximetry, capnography, and temperature measurement). Intravenous access sufficient to rapidly administer large volumes of fluid is required. Generally, two large-bore (16- or, preferably, 14-gauge catheters, or a 9 French introducer sheath) intravenous catheters are placed. Patients for bilateral sequential lung transplantation who will receive a clamshell thoracosternotomy (see Fig. 25.6) should have intravenous catheters placed in the internal or external jugular veins, because peripherally placed intravenous catheters often are unreliable when the arms are bent at the elbow and suspended from the ether screen. An intraarterial catheter is an absolute requirement for blood pressure monitoring and for obtaining specimens for arterial blood gases. Continuous monitoring via a fiberoptic electrode placed in the arterial catheter occasionally may be useful if this technology is available. One femoral artery should be left free of vascular access to allow for cannulation access for CPB or ECMO. Although the radial or brachial artery may be used in single-lung transplantation patients, these sites are not optimal in those who will require CPB (eg, en bloc double-lung transplants or patients with severe pulmonary hypertension) because the transduced pressure may inaccurately reflect central aortic pressure during and after CPB, as well as in patients undergoing a clamshell thoracosternotomy, because of the positioning of the arms. In the authors' institution, the majority of patients now have bilateral limited thoracotomies instead of the thoracosternotomy. An axillary arterial catheter may also be useful in the latter situations because it provides a more accurate measure of central aortic pressure and allows sampling blood closer to that perfusing the brain. This may be important if partial CPB with a femoral arterial cannula is used because differential perfusion of the upper and lower half of the body may result. A PA catheter is inserted via the internal or external jugular veins. A TEE probe is placed after the airway is secured. PA pressure monitoring is most useful in patients who have preexisting pulmonary hypertension, especially during induction and during initial one-lung ventilation (OLV) and PA clamping. Position of the PA catheter must be verified by TEE to ensure that it is residing in the main PA.

If the procedure is planned without CPB, care should be taken to ensure that the patient is kept at ideal physiologic temperature to minimize coagulopathy and increases in the MVO_2. This can be achieved with a warming blanket on the bed, on the patient's head and arms, and on the legs below the knees. A fluid warmer is also useful in this regard.

Three main principles should guide the formulation of a plan for induction: (1) protection of the airway; (2) avoidance of myocardial depression and increases in RV afterload in patients with RV dysfunction; and (3) avoidance and recognition of lung hyperinflation in patients with increased lung compliance and expiratory airflow obstruction (Box 25.8). All lung transplants are done on an emergency basis, and the majority of patients will have recently had oral intake and must be considered to have full stomachs. Because aspiration during induction would be catastrophic, every measure must be taken to protect the airway. Patients with known or suspected abnormalities of airway anatomy should be intubated awake after topical anesthesia is applied to the airway. Although a conventional rapid-sequence intravenous induction with a short-acting hypnotic (such as etomidate, 0.2–0.3 mg/kg), a small amount of narcotic (eg, up to 10 μg/kg of fentanyl) and succinylcholine usually will be tolerated, patients

BOX 25.8 KEY PRINCIPLES OF ANESTHETIC INDUCTION FOR LUNG TRANSPLANTATION

- Secure the airway.
- Intravenous rapid sequence induction versus gradual narcotic induction with continuous cricoid pressure
- Avoid myocardial depression and increases in right ventricular afterload.
- Avoid lung hyperinflation.

with severe RV dysfunction may exhibit profound hemodynamic instability in response to this induction regimen. For such patients, a more gradual induction is recommended, with greater reliance on high doses of narcotics and ventilation with continuous application of cricoid pressure. Consideration should also be given to possibly starting an inotrope or indicator before induction to allow for support of the RV. Patients with bullous disease or fibrotic lungs requiring high inflation pressures may develop a pneumothorax during initiation of positive-pressure ventilation. Acute reductions in Sa_{O_2} accompanied by difficulty in ventilating the lungs and refractory hypotension should generate strong suspicions that a tension pneumothorax has developed. RV function can be impaired during induction by drug-induced myocardial depression, increases in afterload, or by ischemia secondary to acute RV dilation. Agents that act as myocardial depressants should be avoided in such patients. Increases in RV afterload can result from inadequate anesthesia, exacerbation of chronic hypoxemia and hypercarbia and metabolic acidosis, as well as increases in intrathoracic pressure because of positive-pressure ventilation. Systemic hypotension is poorly tolerated because increased RV end-diastolic pressure will diminish net RV coronary perfusion pressure. In addition, chronic increase of RV afterload increases the metabolic requirements of RV myocardium. Once the trachea is intubated and positive-pressure ventilation initiated, the avoidance of hyperinflation in patients with increased pulmonary compliance or bullous disease is crucial. Small tidal volumes, low respiratory rates, and inspiratory/expiratory (I:E) ratios should be used even if this allows increased $etCO_2$ (permissive hypercapnia), although attention should be paid to the effect of this action on the pulmonary artery pressure. If hemodynamic instability does occur with positive-pressure ventilation, the ventilator should be disconnected from the patient. If hyperinflation is the cause of hypotension, blood pressure will increase within 10 to 30 seconds of the onset of apnea. Ventilation then can be resumed at a tidal volume and/or rate compatible with hemodynamic stability.

Anesthesia can be maintained using a variety of techniques. A moderate dose of narcotic (5–15 μg/kg of fentanyl or the equivalent), combined with low doses of a potent inhalation anesthetic, offers the advantages of stable hemodynamics, a high inspired oxygen concentration, a rapidly titratable depth of anesthesia, and the possibility of extubation in the early postoperative period. Patients with severe RV dysfunction who cannot tolerate even low concentrations of inhalation anesthetics may require a pure narcotic technique. Nitrous oxide generally is not used because of the requirement for a high inspired oxygen concentration throughout the procedure and its possible deleterious effects if gaseous emboli or an occult pneumothorax is present.

Intraoperative Management

Institution of OLV occurs before hilar dissection and may compromise hemodynamics or gas exchange, or both (Box 25.9). Patients with diminished lung compliance often can tolerate OLV with normal tidal volumes and little change in hemodynamics. In contrast, patients with increased lung compliance and airway obstruction often will exhibit marked hemodynamic instability, unless the tidal volume is decreased and the expiratory time is increased. The magnitude of hypoxemia generally peaks about 20 minutes after beginning OLV. Hypoxemia during OLV may be treated with continuous positive airway pressure

BOX 25.9 MANAGEMENT PRINCIPLES FOR ONE-LUNG VENTILATION DURING LUNG TRANSPLANTATION

- Tidal volume and respiratory rate
  - Maintain in patients with normal or decreased lung compliance (ie, primary pulmonary hypertension, fibrosis)
  - Decrease both tidal volume and rate in patients with increased compliance (eg, obstructive lung disease) to avoid hyperinflation (permissive hypercapnia)
- Maintain oxygenation by:
  - 100% inspired oxygen
  - Applying CPAP (5–10 cm H_2O) to nonventilated lung
  - Adding PEEP (5–10 cm H_2O) to ventilated lung
  - Intermittent lung reinflation if necessary
  - Surgical ligation of the pulmonary artery of the nonventilated lung
- Be alert for development of pneumothorax on nonoperative side
  - Sharp decline in oxygen saturation, end-tidal carbon dioxide
  - Sharp increase in peak airway pressures
  - Increased risk with bullous lung disease
- Therapy
  - Relieve tension
  - Resume ventilation
  - Emergency cardiopulmonary bypass

CPAP, Continuous positive airway pressure; *PEEP*, positive end-expiratory pressure.

BOX 25.10 INDICATIONS FOR CARDIOPULMONARY BYPASS DURING LUNG TRANSPLANTATION

Cardiac index	<2 L/min/m^2
S_vO_2	<60%
Mean arterial pressure	<50 to 60 mm Hg
S_aO_2	<85% to 90%
pH	<7.00

applied to the nonventilated lung,[137] PEEP to the ventilated lung, or both. Continuous positive airway pressure attempts to oxygenate the shunt fraction but may interfere with surgical exposure. PEEP attempts to minimize atelectasis in the ventilated lung, but may concomitantly increase shunt through the nonventilated lung. Definitive treatment of shunt in the nonventilated lung is provided by rapid isolation and clamping of the PA of the nonventilated lung. Pneumothorax on the nonoperative side may result during OLV if a large tidal volume is used.

PA clamping usually is well tolerated, except in the face of pulmonary hypertension with diminished RV reserve. If the degree of RV compromise is uncertain, a 5- to 10-minute trial of PA clamping is attempted; then the RV is evaluated by serial COs and RVEF measurements and inspection by TEE. A significant decrease in CO may predict patients who will require extracorporeal support.[138] Other indications for CPB in lung transplantation are listed in Box 25.10.[139]

Patients with severe pulmonary hypertension (greater than two-thirds of systemic pressure) generally will be placed on CPB before PA clamping. The intraoperative use of nitric oxide (20 to 40 parts per million [ppm]) may allow some procedures to proceed without the use of CPB.[140]

Lung transplantation usually can be performed without the aid of CPB; even during bilateral sequential lung transplantation, experienced teams use CPB for only about one-quarter of patients.[141,142]

Although CPB may provide stable hemodynamics, it is associated with an increased transfusion requirement.[95] In addition, graft function (as reflected by alveolar-arterial oxygen gradient) may be compromised,[143] endothelium-dependent cyclic guanosine monophosphate–mediated and β-adrenergic cyclic adenosine monophosphate–mediated pulmonary vascular relaxation may be impaired to a greater degree,[144] and a longer period of mechanical ventilation may be necessary.[141] Several exceptional circumstances require CPB: the presence of severe pulmonary hypertension because clamping of the PA will likely result in acute RV failure and flooding of the nonclamped lung, the repair of associated cardiac anomalies (eg, patent foramen ovale, atrial or ventricular septal defects), treatment of severe hemodynamic or gas exchange instabilities, and living-related lobar transplantation. Hypercarbia generally is well tolerated and should not be considered a requirement for CPB per se.[95] Thus the frequency of CPB will depend on recipient population factors such as prevalence of end-stage pulmonary vascular disease and associated cardiac anomalies.[145] The use of femoral venous and arterial cannulae for CPB during lung transplantation may lead to poor venous drainage and/or differential perfusion of the lower and upper body. Moreover, native pulmonary blood flow continues and may act as an intrapulmonary shunt during what will be partial CPB. In this case, the cerebral vessels receive this desaturated blood, whereas the lower body is perfused with fully oxygenated blood from the CPB circuit. This effect is detectable by blood gas analysis of samples drawn from suitable arteries or by appropriately located pulse oximeter probes. Treatment includes conventional measures to increase venous return and augment bypass flow, or placing a venous cannula in the right atrium if this is feasible. The anesthesiologist also should maximize the inspired oxygen concentration and add PEEP to decrease intrapulmonary shunt. If all other measures fail, ventricular fibrillation can be induced using alternating current, although this is exceedingly rare.[146]

ECMO also has been suggested as an alternative method of CPB during lung transplantation. It has been suggested that the use of ECMO with heparin-bonded circuits might improve the outcome of both single- and double-lung transplants by lessening the amount of pulmonary edema, especially in those patients who need CPB because of hemodynamic instability or who have primary pulmonary hypertension. An added benefit of this technique is that it clears the operative field of bypass cannulae, making left-sided transplant as unimpeded as right-sided transplant. There is no apparent increase in transfusion requirement.[147] Another added benefit of using ECMO in situ is that reperfusion of the lungs can be more easily controlled because the CO transiting the newly transplanted lung can be precisely controlled. This is especially the case for patients with advanced pulmonary hypertension.[148]

If CPB is used, weaning from circulatory support occurs when the graft anastomoses are complete. Ventilation is resumed with a lung protection strategy similar to that used in the ARDSnet (Acute Respiratory Distress Syndrome Network) trial.[85] This demonstrated that patients with decreased compliance related to acute respiratory distress syndrome had a 22% decrease in mortality rate when applying tidal volumes of 6 mL/kg and a plateau pressure less than 30 cm H_2O.[85] Minimizing the inspired fraction of O_2 may help prevent generation of oxygen free radicals and modulate reperfusion injury. FiO_2 can be decreased to the minimum necessary to maintain the SpO_2 greater than 90%. Special attention should be directed to assessing and supporting RV function during this period, inasmuch as RV failure is the most frequent reason for failure to wean. Although the right ventricle often can be seen in the surgical field, TEE is more valuable for visualizing this structure's functional properties at this juncture. TEE also allows the evaluation of PA (see Video 25.3) and pulmonary vein anastomoses. The PA diameter should be greater than 1 cm. Interrogating the pulmonary veins should demonstrate a two-dimensional diameter that is at least 0.5 cm with the presence of flow as measured by color-flow Doppler. In addition, pulse wave Doppler interrogation should yield flow rates less than 100 cm/second to indicate adequacy of anastomosis. The operator must align the Doppler beam angle with the pulmonary vein flow because misalignment may lead to underestimation of the true peak venous flow (see Video 25.4). Care should be taken to measure these flow rates with both lungs being perfused because the measurements could be erroneous if measured with one PA clamped (Fig. 25.8).[149,150] Inotropic support with dobutamine or epinephrine, as well as pulmonary vasodilation with nitroglycerin, nitroprusside, milrinone, or nitric oxide, may be necessary if RV dysfunction is evident. Milrinone has the advantage of providing both inotropic and vasodilatory effects; however, its administration can be complicated by significant systemic hypotension, necessitating the concomitant use of epinephrine or norepinephrine (see Chapters 11, 26, 28, 36, and 38).

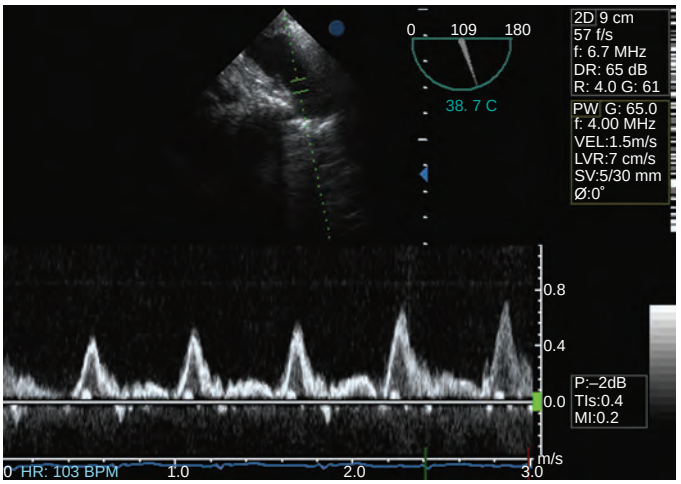

Fig. 25.8 Pulsed-wave Doppler interrogation of the left superior pulmonary vein after lung transplantation.

Coagulopathy after weaning from CPB is common. The severity of coagulopathy may be worse after double- than single-lung transplantation, probably because of the more extensive dissection, presence of collaterals and scarring, and the longer duration of CPB. Factors under the anesthesiologist's control include incomplete reversal of heparin's effects, which should be assayed by the activated coagulation time. Similarly, preexisting deliberate anticoagulation (eg, caused by warfarin) should be aggressively corrected with fresh-frozen plasma. Because platelet dysfunction is common after CPB, empiric administration is justified if coagulopathy persists. The thrombotic and fibrinolytic systems are activated during lung transplantation, especially if CPB is used, and although aprotinin can reduce this activation and perhaps reduce perioperative hemorrhage,[151–153] it has been withdrawn from production. The utility of epsilon-aminocaproic acid, tranexamic acid, and desmopressin (DDAVP) in replacing aprotinin in this setting remains unknown (see Chapter 35), although some preliminary data suggest that tranexamic acid may be similar in efficacy to aprotinin.

Reperfusion without CPB often is accompanied by a mild-to-moderate decrease in systemic blood pressure and occasionally is complicated by severe hypotension. This is usually the result of profound systemic vasodilation. The causative factor is unknown but may be caused by ionic loads such as potassium or additives such as prostaglandin E_1 in preservation solutions or by vasoactive substances generated during ischemia and reperfusion. This hypotension generally responds well to large doses of α-adrenergic agents and fortunately is short-lived. Agents of greatest use in this setting are norepinephrine and vasopressin. Ventilation is resumed with a lung protection strategy identical to that used when weaning from CPB.

Patients with preexisting increased lung compliance, as found in chronic obstructive pulmonary disease, can manifest great disparity in lung compliance after single-lung transplant. The donor lung usually will exhibit normal to decreased compliance, depending on the presence of reperfusion injury. This will result in relative hyperinflation of the native lung and underinflation with loss of functional residual

capacity in the donor lung. Hyperinflation of the native lung may cause hemodynamic instability because of mediastinal shift, especially if PEEP is applied. Therefore patients exhibiting signs of hyperinflation during OLV, which improves with deliberate hypoventilation, should be treated with independent lung ventilation after reperfusion. To accomplish this, the patient's postoperative ventilator is brought to the operating room while the donor lung is being implanted. When all anastomoses are completed, the donor lung is ventilated with a normal tidal volume (8 to 10 mL/kg) and rate, with PEEP initially applied at 10 cm H_2O. These settings can be adjusted according to blood gas analysis. Most gas exchange will take place in the transplanted lung. The native lung is ventilated with a low tidal volume (2 to 3 mL/kg) and a low rate (2 to 4/min) without PEEP. The objective is to prevent this lung from overinflating or developing a large shunt. Carbon dioxide exchange occurs predominantly in the donor lung.

Although some degree of pulmonary edema commonly is detected by chest radiograph after surgery, it is uncommon to encounter severe pulmonary edema in the operating room immediately after reperfusion of the graft. However, when it does occur, postreperfusion pulmonary edema can be dramatic and life-threatening. Copious pink frothy secretions may require almost constant suctioning to maintain a patent airway and may be accompanied by severe gas exchange and compliance abnormalities. Treatment includes high levels of PEEP using selective lung ventilation, diuresis, and volume restriction. Occasionally, patients may require support with ECMO for several days until reperfusion injury resolves; a high percentage of patients so treated ultimately survive.[154,155] Adequate analgesia is crucial for these patients to facilitate the earliest possible extubation, ambulation, and participation in spirometric exercises to enhance or preserve pulmonary function. Lumbar or thoracic epidural narcotic analgesia provides excellent analgesia while minimizing sedation. Epidural catheters can be placed before the procedure if time permits or after conclusion of the procedure. Placement of epidural catheter in cases in which a high expectation exists for the necessity of CPB remains a controversial topic. If CPB has been used or coagulopathy has developed, placement should be deferred until coagulation tests have normalized (see Chapter 42).

Fluid therapy also can impact the outcomes of lung transplantation as was demonstrated by McIlroy and associates, who showed that the greater the amount of colloid (gelatin) that was used, the greater the A-a gradient, and the greater likelihood of delayed extubation. It was unclear, though, whether this effect extended to other colloids.[156]

Postoperative Management and Complications

Routine postoperative management of the lung transplant recipient continues many of the monitoring modes and therapies begun in the operating room. Positive-pressure ventilation is continued for at least several hours; if differential lung ventilation was used intraoperatively, this is continued in the early postoperative period. Because the lung graft is prone to the development of pulmonary edema because of preservation/reperfusion and the loss of lymphatic drainage, fluid administration is minimized and diuresis encouraged when appropriate. When hemorrhage has ceased, the chest radiograph is clear, and the patient meets conventional extubation criteria, the endotracheal tube can be removed. Prophylactic antibacterial, antifungal, and antiviral therapies, as well as the immunosuppressive regimen of choice, are begun after arrival in the ICU.

Surgical technical complications are uncommon immediately after lung transplantation but may be associated with high morbidity.[157] Pulmonary venous obstruction usually presents as acute, persistent pulmonary edema of the transplanted lung.[158] Color-flow and Doppler TEE will show narrowed pulmonary venous orifices with turbulent, high-velocity flow and loss of the normal phasic waveform. PA anastomotic obstruction should be suspected if PA pressures fail to decrease after reperfusion of the lung graft. If the right PA is obstructed, this usually is evident on a TEE examination in the same way as for pulmonary venous obstruction; it is usually much more difficult to adequately inspect the left PA anastomosis with TEE, although some centers have reported a high success rate.[159] The diagnosis can be definitively made by measuring the pressure gradient across the anastomosis either by inserting needles on both sides of the anastomosis to transduce the respective pressures or by advancing the PA catheter across it. However, care should be taken not to measure this gradient while the contralateral PA is clamped, because the shunting of the entire CO through one lung will exaggerate the gradient present.[160] Angiography and perfusion scanning also are useful for making this diagnosis but are not immediately available in the operating room. Bronchial dehiscence or obstruction is extremely rare in the immediate perioperative period and can be evaluated by fiberoptic bronchoscopy.

Pneumothorax must be a constant concern for the anesthesiologist, especially involving the nonoperative side. Diagnosis of pneumothorax on the nonoperative side during a thoracotomy is extremely difficult. A sudden increase in inflation pressures with deterioration of gas exchange and possibly hypotension are characteristic. However, these same findings are possible with hyperinflation, mucous plugging, or malpositioning of the endobronchial tube. Transient cessation of ventilation and immediate fiberoptic bronchoscopy may rule out the former explanations, and the observation of an upward shift of the mediastinum in the surgical field may be observed in the presence of tension pneumothorax. If this diagnosis is strongly suspected, needle thoracostomy on the field may be lifesaving. Alternatively, the surgeon may be able to directly dissect across the mediastinum and decompress the nonoperative thorax, facilitating reinflation.

Tension pneumopericardium and postoperative hemothorax with complete ventilation/perfusion mismatch are other rare complications that have been reported after lung transplantation.[161,162] Patients with pulmonary hypertension and RV hypertrophy occasionally may develop dynamic RV outflow obstruction when transplantation acutely decreases RV afterload; the diagnosis can be confirmed using TEE.[163] Hyperacute rejection of a kind similar to that seen with heart transplantation has not been noted with lung transplantation.

The most common cause of death in the immediate perioperative period is graft dysfunction from reperfusion injury, which usually presents with hypoxemia, pulmonary infiltrates, poor lung compliance, pulmonary hypertension, and RV failure. If there are no technical reasons to account for pulmonary hypertension and RV failure, then graft dysfunction must be suspected. Unfortunately, few treatments will specifically ameliorate graft dysfunction and therapy is largely supportive. Vasodilator therapy to directly decrease PVR and, therefore, RV afterload may improve hemodynamics and, in some cases, may improve gas exchange. Both prostaglandin E_1 and nitrates can reverse severe hypoxemia and pulmonary hypertension after lung transplantation, and the latter attenuate the increase in transcription of vasoconstrictor genes (such as for endothelin and platelet-derived growth factor) induced by hypoxia.[164] Indeed, a prophylactic low-dose infusion of prostaglandin E_1 has been reported to preserve arterial oxygen tension without altering pulmonary hemodynamics in dogs after single-lung transplantation.[165] Improvement in pulmonary hemodynamics and gas exchange in patients with graft dysfunction also have been reported with the administration of nitric oxide.[101,166,167] Compared with historic control patients who developed graft dysfunction before the advent of nitric oxide, inhalation of nitric oxide decreased the duration of mechanical ventilation, frequency of airway complications, and mortality.[167] Improved hemodynamics and gas exchange may reflect the ability of nitric oxide to compensate for the decrease in endothelium-derived relaxant factor activity after transplantation. If nitric oxide has been used to control pulmonary hypertension after surgery, it should be weaned gradually to avoid any rebound pulmonary vasoconstriction.[168] Finally, ECMO may be used to support the patient until there is adequate recovery of pulmonary function.[154,155]

Infection is a constant threat in these immunosuppressed patients. Prophylactic antibiotic coverage is aimed at agents commonly causing nosocomial and aspiration pneumonias because these are common in donors. Coverage can be modified once culture results from the donor trachea are available. Patients with cystic fibrosis should receive

antibiotics targeted at bacteria found in the native lungs before transplantation. Infection should be suspected as the cause of any infiltrate found on chest radiograph, especially if fever or leukocytosis develops, but distinguishing infection from reperfusion injury and rejection may be difficult. Diagnostic bronchoscopy and bronchoalveolar lavage are useful in defining therapy and differentiating infection from rejection,[169,170] but open-lung biopsy occasionally is necessary for definitive diagnosis. Patients who are seronegative to viral agents to which the donor was seropositive (eg, cytomegalovirus) will require prophylactic antiviral therapy. Vadnerkar and colleague's[171] study showed that 43% of patients who had undetected mold infections at the time of transplant were at risk for very poor outcomes, with a mortality rate of 29%.

Rejection episodes are common and may occur as early as several days after transplantation. Rejection often presents as new infiltrates on chest radiograph in the setting of deteriorating gas exchange. Bronchoscopy with transbronchial biopsy helps to rule out other causes of deterioration and document acute changes consistent with rejection. Therapy for acute lung rejection consists of large pulses of steroids such as methylprednisolone or changing the immunosuppressive agents (cyclosporine to tacrolimus or vice versa). Expired nitric oxide has been shown to be an indicator of chronic rejection in post–lung-transplant patients. Measurements of expired nitric oxide have been shown to decrease with the switch of cyclosporine to tacrolimus, reflecting a decrease in the inflammation in the pulmonary mucosa.[172] Expired nitric oxide may be a useful tool to observe patients for the presence or change in chronic graft rejection.[173]

One of the most serious complications of lung transplantation occurs late. Bronchiolitis obliterans is a syndrome characterized by alloimmune injury leading to obstruction of small airways with fibrous scar.[174] Patients with bronchiolitis obliterans present with cough, progressive dyspnea, obstruction on flow spirometry, and interstitial infiltrates on chest radiograph. Therapy for this syndrome includes augmentation of immunosuppression,[175] cytolytic agents (which have been used with varying degrees of success),[176,177] or retransplantation in refractory cases.

Living-Related Lung Transplantation

The scarcity of suitable donor lungs has resulted in waiting times on transplant lists in excess of 2 years, during which time up to 30% of candidates succumb to their illness.[178] Living-related lung transplantation programs have developed to address the needs of lung transplant candidates with acute deterioration expected to preclude survival. Successful grafting of a single lobe for children with bronchopulmonary dysplasia or Eisenmenger syndrome, or two lobes for children and young adults with cystic fibrosis, has encouraged several centers to consider such procedures.[90,179] The anesthetic management issues related to such undertakings have been reviewed.[77] Donor candidates will have undergone a rigorous evaluation to ensure that there are no contraindications to lobe donation and that the donation is not being coerced. Donor lobectomy is performed via a standard posterolateral thoracotomy.[102] Of special note to the anesthesiologist during such procedures is the requirement for OLV to optimize surgical exposure, the continuous infusion of prostaglandin E_1 to promote pulmonary vasodilation, and the administration of heparin and steroids just before lobe harvest. Anesthetic management of the recipient is identical to that for a standard lung transplant, except that the use of CPB is mandatory for bilateral lobar transplant due the fact that sequential off-pump transplantation would warrant the entire RV output going through a single lobe of transplanted lung that would place it at higher risk of pulmonary edema and reperfusion injury.

Pediatric Considerations

Pediatric lung transplant is an attractive option for the treatment of children with end-stage lung disease. There have been nearly 2000 pediatric lung transplants reported to the International Society for Heart and Lung Transplantation since 1986, with 93 in 2012 (the last complete year of reporting) and the most reported having been 126 in 2010.[180] The number of centers performing pediatric lung transplants has also declined from 43 in 2011 to 39 in 2012, with 15 of those centers being in North America (20 in Europe). Only four lung transplants were reported for children younger than 1 year in 2012 with the majority being performed in children 11 to 17 years of age (77%).[180] Over the past 23 years, the most common indications for pediatric lung transplant were surfactant protein B deficiency and CHD in infants (<1 year old), idiopathic pulmonary artery hypertension in toddlers (ages 1–5 years), and cystic fibrosis in older children and adolescents (ages 6–10 and 11–17, respectively).[180] Absolute contraindications to lung transplantation in children are similar to those used for adults; however, relative contraindications may vary between centers.[82]

The majority of pediatric lung transplant recipients are either already inpatients, likely requiring ventilatory and/or hemodynamic support, or chronically ill outpatients who are called in when a potential donor becomes available. Outpatients are often called in on an urgent basis, and because of the sparse number of transplant centers, they may be travel long distances. Care must be coordinated to facilitate appropriate transport, intensive care availability, and an available operating room (OR), equipment, and staff.

A thorough history and physical examination are mandatory to evaluate for indication for transplant, comorbid conditions, cardiac and renal function, as well as current ventilatory and/or hemodynamic support required by the child. There are several reports of children being ambulatory and participating in physical therapy while on venovenous extracorporeal membrane oxygenation (VV-ECMO) as a bridge to lung transplant.[181–183]

Children are expectedly anxious in the preoperative timespan, and judicious premedication is appropriate while transferring to the OR. Oversedation and respiratory depression must be avoided with premedication.

The majority of patients will present to the OR with intravenous access, permitting an intravenous induction. Morbidity during induction anesthesia is increased by hypoxemia, hypercapnea, and systemic hypotension in these critically ill patients. Anesthesia is typically induced with a hypnotic agent (eg, propofol), an opioid, benzodiazepines, and nondepolarizing muscle relaxants titrated to maintain acceptable hemodynamics and expeditiously intubate the trachea. Cardiac arrest and circulatory collapse may occur after induction of anesthesia in the recipient with primary pulmonary hypertension and CHD with pulmonary hypertension.[184] In addition to standard monitors, arterial and central venous access is obtained, and large bore venous access is recommended to facilitate volume administration in the perioperative period. TEE is also useful for assessing cardiac function and volume status children, particularly because the majority of lung transplants in pediatric patients are performed with CPB. Anesthesia is maintained with an inhalation agent and additional opioid, benzodiazepine, and nondepolarizing muscle relaxants. A thickened hypertrophic right ventricle requires additional volume administration. Frequent suctioning of the endotracheal tube may be required for the recipient with cystic fibrosis intraoperatively prior to transplantation.

Unlike adult lung transplantation, CPB is nearly standard in pediatric cases because of several logistical and physiologic reasons. One limitation is the availability of double-lumen endotracheal tubes that would permit adequate one-lung ventilation in pediatric patients. In addition, the majority of pediatric lung recipients would be unlikely to be adequately oxygenated and ventilated with single lung ventilation if isolation were obtained, owing to their morbid status. CPB also allows simultaneous pneumonectomies and anastomoses with reduced risk of bacterial contamination and shortened operative times. The use of CPB is associated with coagulopathy and increased blood product transfusion, necessitating the use of an antifibrinolytic agent (eg, tranexamic acid).

Bronchoscopic evaluation of the bronchial anastomoses is performed if the endotracheal tube is large enough to accommodate a bronchoscope. TEE evaluation of pulmonary arterial and pulmonary venous blood flow is performed during weaning from CPB. Ventilation

strategies that prevent atelectasis and maintain oxygenation without alveolar overdistension, barotrauma, and volutrauma should be employed. This includes the use of PEEP, manipulation of the inspiratory to expiratory time ratio, and weaning to the lowest possible Fio_2. Epinephrine, milrinone, or other cardiovascular support may be beneficial in the perioperative period. Patients are left intubated and sedated for transfer to the intensive care unit, where postoperative management and weaning of support ensue.

Children are often maintained on two to three immunosuppressive agents, a calcineurin inhibitor such as tacrolimus, a cell-cycle inhibitor such as mycophenolate mofetil, and prednisone. Induction immunosuppression has not been shown to provide a survival benefit. Posttransplant morbidities include hypertension, diabetes mellitus, bronchiolitis obliterans syndrome, and renal dysfunction.[180] The most common cause of death within the first month after transplant is primary graft failure. A non-CMV infection is the most common cause of death from the second month after transplant through the first year. Bronchiolitis obliterans syndrome is the most common cause of death after the first year posttransplant.[180] Only 106 pediatric retransplantations have been reported in the last 20 years with survival rates far inferior to that of primary transplantation (82% and 52% for primary transplant 1- and 5-year survival rates, respectively, as compared with 57% and 33% for retransplantation.[180]

Heart-Lung Transplantation

History and Epidemiology

The diminished frequency of heart-lung transplantation since 1990 reflects that it is being supplanted by lung transplantation. The number of HLTs worldwide peaked at 241 in 1989, and there has been a continual decline in subsequent years to approximately half that number.[3] Approximately only 173 HLT candidates were registered with UNOS as of early March 2005, less than 5% of the number on the lung transplant list. The most common recipient indications remain primary pulmonary hypertension, CHD (including Eisenmenger syndrome), and cystic fibrosis.

One-year survival rate after heart-lung transplantation is 60%, significantly less than that for isolated heart or lung transplantation.[3] Mortality in subsequent years is approximately 4% per year, similar to that for heart transplantation. Risk factors for increased mortality after HLT are recipient ventilator dependence, male recipient sex, and a donor age older than 40 years.[3] Early deaths are most often due to graft failure or hemorrhage, whereas midterm and late deaths primarily are due to infection and bronchiolitis obliterans, respectively. Repeat HLT is a rare procedure and likely to remain so because the 1-year survival rate after repeat HLT is dismal (28%).[3]

Recipient Selection

Candidates undergo an evaluation similar to that for lung transplant candidates. As more patients with pulmonary hypertension and cystic fibrosis are treated with isolated lung transplantation, it is likely that the indications for heart-lung transplantation will be limited to CHD with irreversible pulmonary hypertension that is not amenable to repair during simultaneous lung transplantation or diseases with both pulmonary hypertension and concomitant severe left ventricular dysfunction.

Donor Selection and Graft Harvest

Potential heart-lung donors must meet not only the criteria for heart donors but also those for lung donation, both described earlier in this chapter. Graft harvesting is carried out in a manner similar to that previously described for heart transplantation. After mobilization of the major vessels and trachea, cardiac arrest is induced with inflow occlusion and infusion of cold cardioplegia into the aortic root. After arrest, the PA is flushed with a cold preservative solution often containing prostaglandin E_1. The ascending aorta, SVC, and trachea are transected, and the heart-lung bloc removed after it is dissected free of the esophagus. The trachea is clamped and the graft immersed in cold solution before being bagged for transport.

Surgical Procedures

The operation generally is performed through a median sternotomy, but a clamshell thoracosternotomy also is an acceptable approach. Both pleurae are incised. Any pulmonary adhesions are taken down before anticoagulation for bypass. Cannulae for CPB are placed in a manner similar to that for heart transplantation. After the aorta is cross-clamped, the heart is excised in a manner similar to that for orthotopic heart transplant. Each lung is then individually removed, including its pulmonary veins. The airways are divided at the level of the respective main bronchi for bibronchial anastomoses. For a tracheal anastomosis, the trachea is freed to the level of the carina without stripping its blood supply and an anastomosis is constructed just above the level of the carina. The atrial anastomosis is performed in a manner similar to that for orthotopic heart transplantation, and finally, the aorta is joined to the recipient aorta. After de-airing and reperfusion, the patient is weaned from CPB, hemostasis is achieved, and the wound is closed.

Pathophysiology Before Transplantation

The pathophysiology of HLT recipients combines the elements discussed earlier in this chapter. Patients usually will have end-stage biventricular failure with severe pulmonary hypertension. The cardiac anatomy may be characterized by complex congenital malformations. If obstruction of pulmonary airflow is present, there is a danger of hyperinflation after application of positive-pressure ventilation.

Pathophysiology After Transplantation

As with isolated heart recipients, HLT recipients' physiology is characterized by cardiac denervation, transient cardiac ischemic insult during graft harvest, transport, and implantation, and long-term susceptibility to accelerated allograft vasculopathy and rejection. As is the case for lung recipients, heart-lung recipients have denervated pulmonary vascular and airway smooth muscle responses, transient pulmonary ischemic insult, altered pulmonary lymphatic drainage, and impaired mucociliary clearance.

Anesthetic Management

The anesthetic management of heart-lung transplantation more closely resembles that of heart than lung transplantation because the use of CPB is mandatory. After placement of invasive and noninvasive monitoring similar to that used for heart transplantation, anesthesia can be induced with any of the techniques previously described for heart and lung transplantation. As with lung transplantation, avoidance of myocardial depression and protection and control of the airway are paramount. Although a double-lumen endotracheal tube is not mandatory, it will aid in exposure of the posterior mediastinum for hemostasis after weaning from CPB. Otherwise, anesthetic management before CPB is similar to that for heart transplantation.

A bolus of glucocorticoid (eg, methylprednisolone, 500 mg) is given when the aortic cross-clamp is removed. After a period of reperfusion, an inotrope infusion is started and the heart is inspected with TEE for adequate de-airing. Ventilation is resumed with normal tidal volume and rate, along with the addition of PEEP (5–10 cm) before weaning from CPB. After successful weaning from CPB, the PA catheter can be advanced into the PA again. Protamine then is administered to reverse heparin-induced anticoagulation. The inspired oxygen concentration often can be decreased to less toxic levels based on blood gas analysis.

Problems encountered after weaning from CPB are similar to those encountered after isolated heart or lung transplantation. Lung

reperfusion injury and dysfunction may compromise gas exchange, so administration of crystalloid should be minimized. Occasionally, postreperfusion pulmonary edema may require support with high levels of PEEP and inspired oxygen in the operating room. Ventricular failure usually responds to an increase in β-adrenergic support. Unlike isolated heart or lung transplantation, frank RV failure is uncommon immediately after heart-lung transplantation unless lung preservation was grossly inadequate. Coagulopathy often is present after HLT and should be aggressively treated with additional protamine (if indicated), platelets, and fresh-frozen plasma.

Postoperative Management and Complications

The principles of the immediate postoperative care of HLT recipients are a combination of those of isolated heart and lung recipients. Invasive and noninvasive monitoring done in the operating room is continued. Inotropic support is continued in a manner similar to that for heart transplantation. Ventilatory support is similar to that after lung transplantation; the lowest acceptable inspired oxygen concentration is used to avoid oxygen toxicity, and the patient is weaned from the ventilator after hemodynamics have been stable for several hours, hemorrhage has ceased, and satisfactory gas exchange is present. Diuresis is encouraged. Finally, the immunosuppressive regimen of choice is begun.

Infection is a more frequent and serious complication in heart-lung recipients than in isolated heart recipients. Bacterial and fungal infections are especially common in the first month after transplantation, with viral and other pathogens (*Pneumocystis carinii* and *Nocardia*) occurring in subsequent months.[185]

Similar to isolated heart or lung transplants, rejection episodes are common early after heart-lung transplantation. Rejection may occur independently in either the heart or lung.[125] Therapy is similar to that for rejection of isolated heart or lung grafts.

Heart grafts in heart-lung blocs are prone to accelerated coronary vasculopathy in a manner similar to those of isolated heart grafts. As with lung transplantation, a feared late complication of heart-lung transplantation is bronchiolitis obliterans. Clinical presentation is similar to that seen with lung transplant patients. Approximately one-third of heart-lung recipients develop this process. Anecdotal reports indicate that most affected patients also have accelerated coronary vasculopathy.

Pediatric Considerations

Pediatric HLT is an attractive option for the treatment of children with end-stage lung disease and concurrent heart failure either due to cor pulmonale or critical CHD with or without pulmonary artery or pulmonary vein abnormalities. In the 1980s and 1990s, HLT was used more frequently due to technical reasons.[186] As surgical technique and long-term outcomes for palliative procedures like the Norwood operation for hypoplastic left heart syndrome have improved, the need for concurrent HLT has decreased. Furthermore, earlier detection and intervention for CHD has led to a decline in Eisenmenger's syndrome and a subsequent decrease in HLT for this indication.[186]

From 1986 to 2011, 660 pediatric HLTs were reported to the International Society for Heart and Lung Transplantation (188 in the United States since 1988).[180,186] In 2010, only five centers reported pediatric HLTs.[180] The most common indication for pediatric HLT has been CHD in infants (<1 year old), CHD and primary pulmonary hypertension in toddlers (ages 1–5 years old), and primary pulmonary hypertension for older children and adolescents (6–10 years old and 11–17 years old, respectively).[186] Cystic fibrosis as an indication for HLT was more common in Europe than in the United States; however, cystic fibrosis as the indication for HLT has not been reported since 2007.[180,186]

Perioperative anesthetic management for children undergoing pediatric HLT is much the same as describe in the pediatric heart and pediatric lung transplant sections of this chapter.

The 5-year survival rates for HLT have increased from 45% (1997–2003) to 50% (2004–2010).[180] The limiting factor for outcomes in HLT is the lung graft, and therefore survival rates, morbidity, and mortality in HLT mirror those for lung transplantation. As with isolated lung transplantation, bronchiolitis obliterans syndrome remains the predominant cause of graft failure and patient death.[180,186]

Pulmonary Thromboendarterectomy for Chronic Thromboembolic Pulmonary Hypertension

DALIA A. BANKS, MD, FASE | WILLIAM R. AUGER, MD | MICHAEL M. MADANI, MD

KEY POINTS

1. The incidence of thromboembolic disease is difficult to estimate because of the nonspecific nature of presenting symptoms and a lack of awareness of the disorder, thus making detection difficult.
2. Chronic thromboembolic pulmonary hypertension (CTEPH) results from incomplete resolution of a pulmonary embolus (PE) or from recurrent PEs. It is an underappreciated phenomenon.
3. The cause of CTEPH after acute PE is not fully understood. Proposed mechanisms include abnormalities in fibrinolytic enzymes or resistance of the thrombus to fibrinolysis.
4. Pulmonary thromboendarterectomy (PTE) is the most effective treatment for patients with CTEPH.
5. Patients typically present with progressive exertional dyspnea and exercise intolerance because of increased pulmonary vascular resistance (PVR), decreased cardiac output, and increased minute ventilation requirements secondary to increased alveolar dead space.
6. Assessment of surgical candidacy should be performed at centers with expertise in the diagnosis and management of CTEPH. Right-sided heart catheterization defines the severity of pulmonary hypertension and the degree of cardiac dysfunction.
7. Patients with preoperative PVR greater than 1000 dynes·s·cm^{-5} have a greater operative mortality rate, but a markedly increased preoperative PVR does not contraindicate surgical treatment.
8. Complications specific to PTE make postsurgical management a challenge: reperfusion pulmonary edema and persistent pulmonary hypertension.
9. A newer surgical classification system has been developed. It describes the different levels of the resected thromboembolic specimen and corresponds to the degree of difficulty of the endarterectomy.
10. Riociguat is the first medication approved by the US Food and Drug Administration for treating certain patients with CTEPH.
11. Balloon pulmonary angioplasty is an alternative approach to PTE in patients believed to have surgically inaccessible chronic thromboembolic disease.
12. Reperfusion pulmonary edema and airway bleeding are two of the most difficult complications of PTE to manage. Anesthesiologists should be prepared to provide diagnostic and therapeutic maneuvers for these complications.

Chronic thromboembolic pulmonary hypertension (CTEPH) is a form of pulmonary hypertension (PH) that is characterized by complete or partial obstruction of the pulmonary vascular bed as a result of a recurrent or residual intraluminal organized fibrotic clot leading to increased pulmonary vascular resistance (PVR), severe PH, and eventually right-sided heart failure.[1,2]

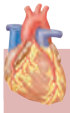
CTEPH is an underappreciated disease, and if left untreated it carries a poor prognosis. Its incidence is difficult to estimate because of the uncertainty regarding the frequency of acute pulmonary embolism (PE) and the percentage of patients in whom emboli fail to resolve. The incidence reflects a wide range, from less than 1% to as high as 9% of patients with acute PE.[3–6]

Screening for CTEPH in patients with PH or unexplained dyspnea is of paramount importance because this form of PH is potentially curable with pulmonary thromboendarterectomy (PTE), also known as pulmonary endarterectomy.[7–10] The success of the operation centers on endarterectomy of the organized fibrous thrombus in the intima and part of the medial layers of the pulmonary vascular tree. Lung transplantation is another potential option, but it is usually not a choice for patients with CTEPH because of the risk of death while on the waiting list, a shortage of organ supply, the expense, the risk of immunosuppressive agents, infection, and rejection.[11]

This chapter is based on the experience of more than 3000 PTE procedures performed at our institution, the University of California San Diego (UCSD). The chapter focuses on classification and pathogenesis of PH, pathophysiology and clinical manifestations of CTEPH, diagnostic workup, surgical approach, anesthetic management including intraoperative echocardiography, management of patients with heparin-induced thrombocytopenia and sickle cell disease (SCD) who are undergoing PTE, postoperative care, and complications such as intraoperative airway bleeding.

Classification of Pulmonary Hypertension

Classifications of PH began in 1973 at the World Health Organization (WHO) conference and have since undergone multiple revisions as the appreciation of the disease and treatment of PH has evolved. The Fourth World Symposium on Pulmonary Hypertension held in 2008



BOX 26.1 REVISED WORLD HEALTH ORGANIZATION CLASSIFICATION OF PULMONARY HYPERTENSION

Group I: Pulmonary arterial hypertension (PAH) and other subtypes of PAH
Group II: Left-sided heart disease
Group III: Respiratory disease and hypoxemia
Group IV: Chronic thromboembolic pulmonary hypertension (CTEPH)
Group V: Miscellaneous causes

Adapted from McLaughlin V, Langer A, Tan M, et al. Contemporary trends in the diagnosis and management of pulmonary arterial hypertension. *Chest.* 2013;143:324–332.

in Dana Point, California was the first international meeting to focus not only on pulmonary arterial hypertension (PAH) but also on PH resulting from left-sided heart disease, chronic lung disease, chronic venous thromboembolism, and other diseases.[12] The consensus during the Fifth World Symposium on Pulmonary Hypertension held in 2013 was to maintain the same classification of PH into five distinct subgroups of patients sharing specific features (Box 26.1).[13]

Further classification of PH by Galie and colleagues[14] and Dadfarmay and associates[15] defined the presence of precapillary (groups I, III, IV, and V) or postcapillary (group II) patterns. CTEPH is precapillary PH, as assessed by right-sided heart catheterization characterized by a mean pulmonary artery pressure (mPAP) greater than 25 mm Hg with normal pulmonary capillary wedge pressure lower than 15 mm Hg and an elevated PVR greater than 300 dynes·s·cm^{-5}. Postcapillary PH secondary to left-sided heart disease is the most frequent form of PH, and it is characterized by mPAP greater than 25 mm Hg and pulmonary capillary wedge pressure greater than 15 mm Hg with normal PVR.[16]

Differentiating PAH from pulmonary venous hypertension in group II is important given the high prevalence of left-sided heart disease (Fig. 26.1).[17] Echocardiography is an essential tool for initial screening and assessment for PH (Table 26.1).

Pathophysiology

Acute or recurrent PE is thought to be the inciting event in the development of CTEPH. Incomplete resolution of the embolus followed by thrombus organization and fibrosis leads to partial or complete vessel obstruction. In addition, vascular remodeling in the distal pulmonary arteries (pulmonary arteriopathy) also may contribute to the increased PVR,[18–20] and it is the cause of residual PH seen in some patients after otherwise successful PTE. Unresolved PE in the proximal pulmonary arterial tree causes vascular obstruction in two ways: canalization of the clot leading to multiple small endothelized channels separated by bands and webs or fibrin clot organization or absent canalization leading to dense fibrous connective tissue that completely occludes the arterial lumen[21–23] This fibrous plug is firm and adherent to the arterial wall, and the surgical challenge is to remove enough of the fibrous plug as one unit to reduce the vascular resistance without disrupting the arterial wall.

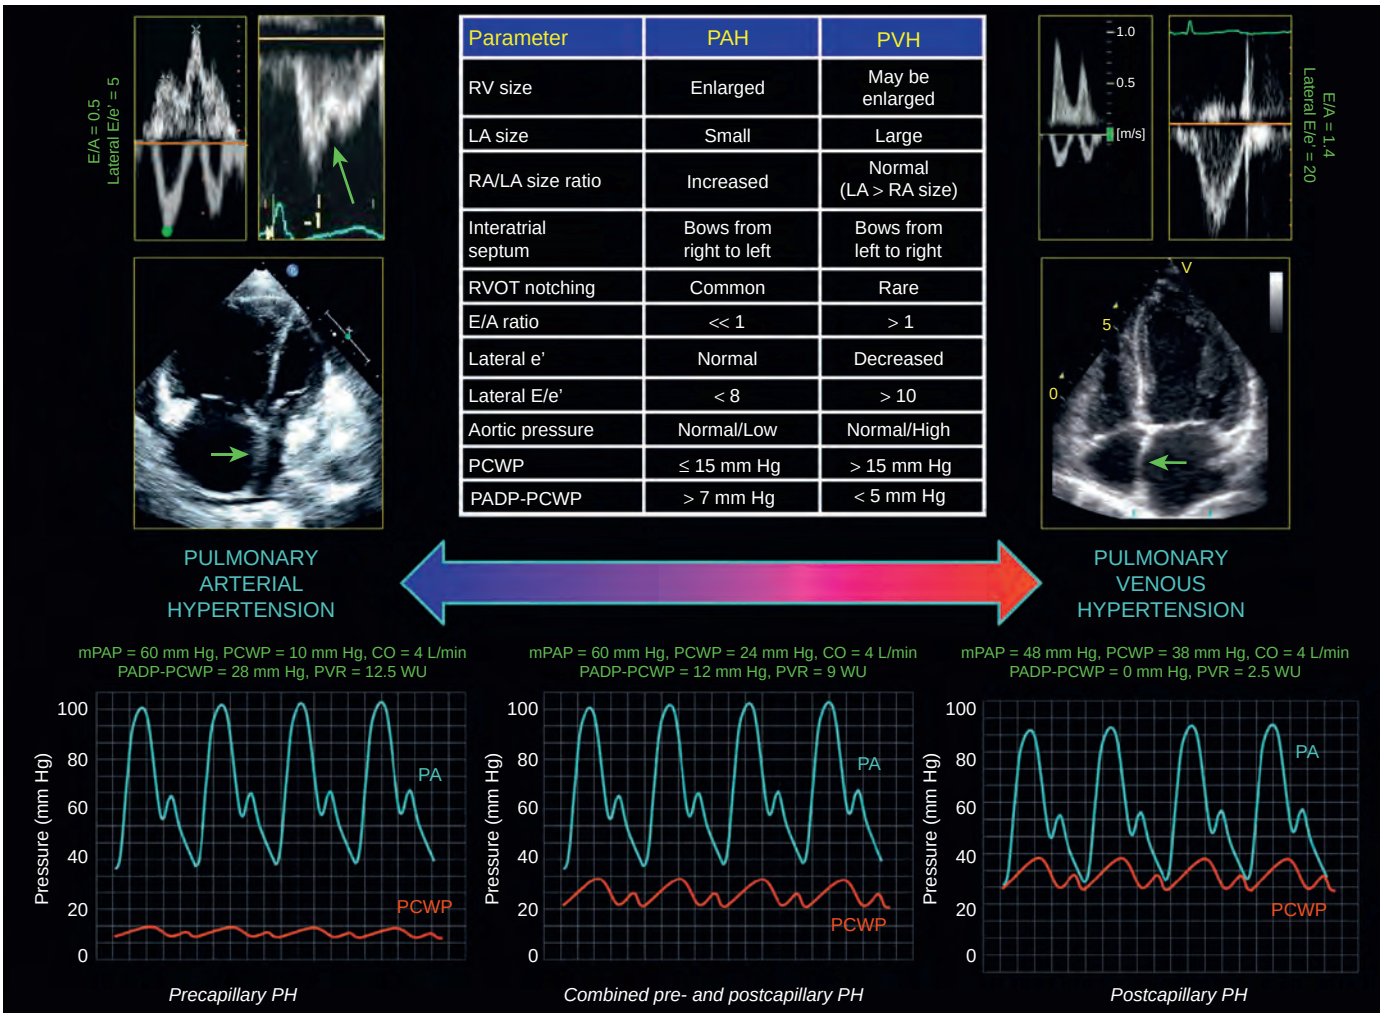
The natural history of PE in most patients is complete resolution of the thromboembolic event with restoration of normal blood flow and hemodynamics. However, in some patients embolic resolution is incomplete, resulting in the development of CTEPH. The mechanism by which thromboembolic material remains unresolved is not fully understood. A variety of factors may play a role: The volume of the embolic substance may simply overwhelm the lytic system, with total occlusion of a major arterial branch preventing the lytic material from reaching and dissolving the embolus completely. The emboli may be made of substances such as well-organized fibrous thrombus that cannot be dissolved by normal mechanisms. Some patients may have tendencies to thrombus formation, a hypercoagulable state, or abnormal lytic mechanisms. Rosenhek and colleagues[24] showed that subjects under normal physiologic conditions have greater levels of tissue plasminogen activator than plasminogen activator inhibitor 1 expression in the pulmonary artery (PA) compared with the aorta, thereby leading to improved natural fibrinolysis. However, Olman and associates[25] and Lang and colleagues[26] were unable to demonstrate a reversal in the tissue plasminogen activator–plasminogen activator inhibitor 1 relationship, thus, favoring incomplete thrombus resolution in patients with a history of CTEPH. The possibility therefore exists that patients with CTEPH either have abnormalities in their fibrinolytic enzymes or have thrombus that is resistant to fibrinolysis.

CTEPH is a common but underrecognized cause of PH. The incidence of CTEPH remains uncertain. Pengo and associates[3] observed 223 patients for a median of 94 months after an acute PE, and 3.8% of these patients developed symptomatic CTEPH. Ribeiro and colleagues[27] examined echocardiograms in 278 patients surviving acute PE for 1 year and performed clinical follow-up for 5 years. Larger perfusion defects at diagnosis, idiopathic thromboembolic disease, high PA pressure (PAP) at the time of presentation, and a history of multiple PEs were risk factors for development of CTEPH after an acute PE.[18] Five percent of patients with PE experienced clinically significant CTEPH. Dentali and associates[28] noted similar findings in 91 patients examined at 6 months after acute PE. PH associated with residual perfusion defects was identified in eight patients (8.8%), four of whom were symptomatic. Unresolved thrombi with recurrent asymptomatic PEs are likely major causes of clinically significant CTEPH.[29]

Bonderman and colleagues[30] identified the following risk factors for CTEPH in a controlled retrospective cohort study: ventriculoatrial shunts, infected pacemakers, splenectomy, previous venous thromboembolism, recurrent venous thromboembolism blood group other than O, lupus anticoagulant or antiphospholipid antibodies, thyroid replacement therapy, or a history of malignant disease. Despite being a risk factor for venous thromboembolism, the prevalence of hereditary thrombophilic states (deficiencies of antithrombin III, protein C, and protein S, and factor II and factor V Leiden mutations) is similar to that in normal control subjects or in patients with idiopathic PH.[31] In contrast, lupus anticoagulant or antiphospholipid antibodies can be found in up to 21% of patients with CTEPH,[1] and Bonderman and associates[32] demonstrated increased levels of factor VIII in 41% of patients with CTEPH. Finally, small, preliminary studies suggest the possibility of structural and functional abnormalities of fibrinogen in patients with CTEPH that perhaps confer resistance to fibrinolysis.[33,34] Morris and colleagues[33] reported relative resistance of fibrin to plasmin-mediated lysis caused by an alteration in fibrin(ogen) structure affecting accessibility to plasmin cleavage sites in patients with CTEPH.

Clinical Manifestations

A history of a previous acute thromboembolic event is not present in 25% to 30% of patients diagnosed with CTEPH.[9,30] The International CTEPH Registry published in 2011 revealed that 25.2% of enrolled patients were without a confirmed diagnosis of a previous PE; 43.9% had not experienced previous deep vein thrombosis.[35] Thus a high index of suspicion is important for the diagnosis of CTEPH in any patient presenting with exertional dyspnea and exercise intolerance, even without evidence of previous PE. Early in the disease process patients may go through a "honeymoon period" in which signs and symptoms of PH are not obvious. Symptoms appear when the right ventricle is unable to increase contractility sufficiently to augment left ventricular (LV) preload and cardiac output (CO) during exercise. Progressive exertional dyspnea is often the initial symptom of CTEPH, and, unfortunately, it is often attributed to more common medical conditions such as obstructive lung disease, obesity, or deconditioning. Exertional dyspnea results from increased PVR limiting CO and increased breathing requirements because of increased alveolar dead space.[18,20]



Parameter	PAH	PVH
RV size	Enlarged	May be enlarged
LA size	Small	Large
RA/LA size ratio	Increased	Normal (LA > RA size)
Interatrial septum	Bows from right to left	Bows from left to right
RVOT notching	Common	Rare
E/A ratio	<< 1	> 1
Lateral e'	Normal	Decreased
Lateral E/e'	< 8	> 10
Aortic pressure	Normal/Low	Normal/High
PCWP	≤ 15 mm Hg	> 15 mm Hg
PADP-PCWP	> 7 mm Hg	< 5 mm Hg

Fig. 26.1 *Left,* Prototypical echocardiographic and invasive hemodynamic findings from a patient with pulmonary arterial hypertension *(PAH).* The right atrium and right ventricle are severely enlarged, and the left ventricle and left atrium are small and underfilled. The interatrial septum bows from right to left. On mitral inflow, the E/A ratio (ratio of early to late (atrial) mitral inflow velocities) is less than 1 because of underfilling of the left atrium and decreased compliance of the left ventricle secondary to extrinsic compression from the enlarged right ventricle. The lateral e' velocity and lateral E/e' ratio (ratio of early mitral inflow velocity to early diastolic mitral annular tissue velocity) are normal (<8), suggesting normal left ventricular (LV) relaxation and filling pressures. Notching is noted in the right ventricular *(RV)* outflow tract *(RVOT)* profile on pulse-wave Doppler imaging because of increased pulmonary artery *(PA)* stiffness. The pulmonary capillary wedge pressure *(PCWP)* is normal, and the pulmonary artery diastolic pressure *(PADP)*-PCWP gradient is severely increased. *Right,* Prototypical echocardiographic and invasive hemodynamic findings from a patient with pulmonary venous hypertension *(PVH).* The left atrium is enlarged, and the interatrial septum bows from left to right. On mitral inflow, the E/A ratio is greater than 1, the lateral e' velocity is reduced, and lateral E/e' ratio is increased, suggestive of grade 2 diastolic dysfunction with impaired LV relaxation and elevated LV filling pressures. No notching is noted in the RVOT profile. The PCWP is elevated, and no gradient is present between the PADP and the PCWP. Although the right ventricle in the *right panel* is not enlarged, RV enlargement and dysfunction can be present in patients with isolated PVH. *Upper middle,* Parameters helpful for differentiating PAH from PVH on echocardiography and invasive hemodynamic testing. *Lower middle,* Invasive hemodynamic findings in a patient with combined precapillary and postcapillary pulmonary hypertension *(PH)* (elevated PCWP and PADP-PCWP gradient). The most challenging patients are in this middle zone (combined precapillary and postcapillary PH), with echocardiographic findings that lie in the middle of the prototypical examples of PAH and PVH shown here. In these patients, careful evaluation of the echocardiogram and invasive hemodynamics will be necessary for an accurate diagnosis.*CO,* Cardiac output; *LA,* left atrial; *mPAP,* mean pulmonary arterial pressure; *PVR,* pulmonary vascular resistance; *RA,* right atrial. *(Reprinted with permission from Vallerie V, McLaughlin V, Shah S, et al. Management of pumonary arterial hypertension.* J Am Coll Cardiol. *2015;65: 1976–1997.)*

TABLE 26.1 Echocardiography in the Initial Screening and Assessment for Pulmonary Hypertension

Completed?	*Action Item*	*Notes*
☐	Record estimated PASP	• Underestimated when Doppler beam alignment is poor or when TR jet is minimal • Overestimated in patients with significant anemia or in some cases of agitated saline-enhanced TR jet on continuous wave Doppler (from feathering) • Assumes absence of pulmonic stenosis • Echocardiographic PASP does not equal mean PA pressure (definition of PH per guidelines is on the basis of invasive hemodynamics: mean PA pressure ≥25 mm Hg)
☐	Evaluate RV size and function	• Signs of RV enlargement (apical four-chamber view): right ventricle shares apex with left ventricle, right ventricle larger than left ventricle, RV basal diameter >4.2 cm • RV hypertrophy (subcostal view): RV end-diastolic wall thickness >5 mm • RV systolic dysfunction: RV fractional area change <35%, TAPSE <1.6 cm, RV tissue Doppler s′ velocity <10 cm/s at base of the RV free wall (tricuspid annulus) • Septal flattening: in systole = RV pressure overload and in diastole = RV volume overload
☐	Evaluate for signs of elevated PVR	• RVOT notching on pulse-wave Doppler profile is a sign of elevated PVR • Peak TR velocity (m/s)/RVOT VTI (cm) <0.18: unlikely PVR is elevated
☐	Estimate volume status	• Use size and collapsibility of IVC (during sniff maneuver) to determine RA pressure • Hepatic vein flow: systolic flow reversal can be a sign of severe TR, RV overload, and/or increased RV stiffness • Signs of RA overload or enlargement: RA area >18 cm^2, interatrial septum bowing from right to left
☐	Evaluate severity of TR	• Features suggestive of severe TR: dense TR jet on continuous-wave Doppler, V-wave cutoff sign, and systolic flow reversal on hepatic vein pulse-wave Doppler imaging
☐	Evaluate for pericardial effusion	• In patients with PAH, the presence of a pericardial effusion = poor prognostic sign
☐	Evaluate for causes of PH (left-sided heart disease, shunt lesions)	• Left-sided heart disease: look for overt LV systolic dysfunction, grade 2 or worse diastolic dysfunction, severe aortic or mitral valvular disease, and less common abnormalities of the left side of the heart (eg, hypertrophic cardiomyopathy, cor triatriatum) • Shunt lesions: perform agitated saline bubble study
☐	Differentiate PAH from PVH	• Signs favoring PVH: LA enlargement (LA size >RA size), interatrial septum bows from left to right, E/A ratio >1.2; *E/e′* (lateral) >11; lateral e″ <8 cm/s • In patients with significantly elevated PASP at rest: grade 1 diastolic dysfunction pattern (E/A ratio <0.8) favors PAH diagnosis because of underfilled LA and decreased LV compliance secondary to RV-LV interaction (extrinsic compression of left ventricle by right ventricle) • See also Fig. 26.1

E/A ratio, Ratio of early to late (atrial) mitral inflow velocities; *IVC,* inferior vena cava; *LA,* left atrial; *LV,* left ventricular; *PA,* pulmonary artery; *PAH,* pulmonary arterial hypertension; *PASP,* pulmonary artery systolic pressure; *PH,* pulmonary hypertension; *PVH,* pulmonary vascular hypertension; *PVR,* pulmonary vascular resistance; *RA,* right atrial; *RV,* right ventricular; *RVOT,* right ventricular outflow tract; *TAPSE,* tricuspid annular-plane systolic excursion; *TR,* tricuspid regurgitation; *VTI,* velocity-time integral.

As the disease progresses and the right side of the heart fails, patients may develop ascites, early satiety, epigastric or right upper quadrant fullness, edema, chest pain, and presyncope or syncope. Other symptoms may include nonproductive cough, hemoptysis, and palpitations. Left vocal cord dysfunction and hoarseness may arise from compression of the left recurrent laryngeal nerve between the aorta and an enlarged left main PA. Early in the disease process the physical examination may be normal or may reveal an accentuated pulmonic component of the second heart sound. Pulmonary flow murmurs or bruits heard over the lung fields are caused by turbulent blood flow through partially occluded or recanalized thrombi. These flow murmurs are heard in 30% of patients with CTEPH and are not found in idiopathic PH.[36]

Late in the disease process patients experience exertion-related syncope and resting dyspnea. The physical signs are far from uniform, and the physical examination may be surprisingly unrewarding if right ventricular (RV) failure is not yet present, even in patients with severe dyspnea. Physical findings of RV failure such as jugular venous distention, RV lift, fixed splitting of the second heart sound, murmur of tricuspid regurgitation (TR), RV gallop, hepatomegaly, ascites, and edema may appear in later stages of the disease. Most patients are hypoxic, with room-air arterial oxygen tension in the range of 65 mm Hg.[37] This hypoxia is a result of ventilation/perfusion ($\dot{V}/\dot{Q}$) mismatch and low mixed venous oxygen saturation.[38,39] Marked hypoxemia at rest implies severe RV dysfunction or the presence of a considerable right-to-left shunt, typically through a patent foramen ovale (PFO). Carbon dioxide tension is slightly reduced with metabolic compensation (reduced bicarbonate). Dead-space ventilation is increased, along with $\dot{V}/\dot{Q}$ mismatch, although these features correlate poorly with the degree of pulmonary vascular obstruction.[40]

Diagnostic Evaluation

Pulmonary Function Studies

Basic pulmonary function studies do not provide specific clues to the diagnosis of CTEPH, and these tests are most useful in evaluating patients for coexisting parenchymal lung disease or airflow obstruction. Twenty percent of patients with CTEPH exhibit a mild-to-moderate restrictive defect, often a result of parenchymal scarring from previous lung infarction.[41] Similarly, a modest reduction in single-breath diffusing capacity of the lung for carbon monoxide (DLCO) may be present in some patients with CTEPH. A normal value does not exclude the diagnosis,[38] and severe reduction in DLCO indicates that the distal pulmonary vascular bed is significantly compromised, thus making an alternative diagnosis likely.

Chest Radiography

The chest radiograph may be unremarkable in the early stages of CTEPH. However, as the disease progresses with the development of PH, the proximal pulmonary vascular bed enlarges. In some patients with chronic thromboembolic disease of the main or lobar PAs, this central PA enlargement can be asymmetric (Fig. 26.2). This is not a radiographic finding in those patients with PH resulting from small-vessel disease.[42] As the right ventricle adapts to the rise in PVR, radiographic signs of chamber enlargement such as obliteration of the retrosternal space and prominence of the right heart border can be observed.[43,44] Relatively avascular lung regions can be appreciated if an organized thrombus has compromised blood flow to that area. In these poorly perfused lung regions, peripheral alveolar opacities, linear scarlike lesions, and pleural thickening may be found as a result of parenchymal injury and infarction.

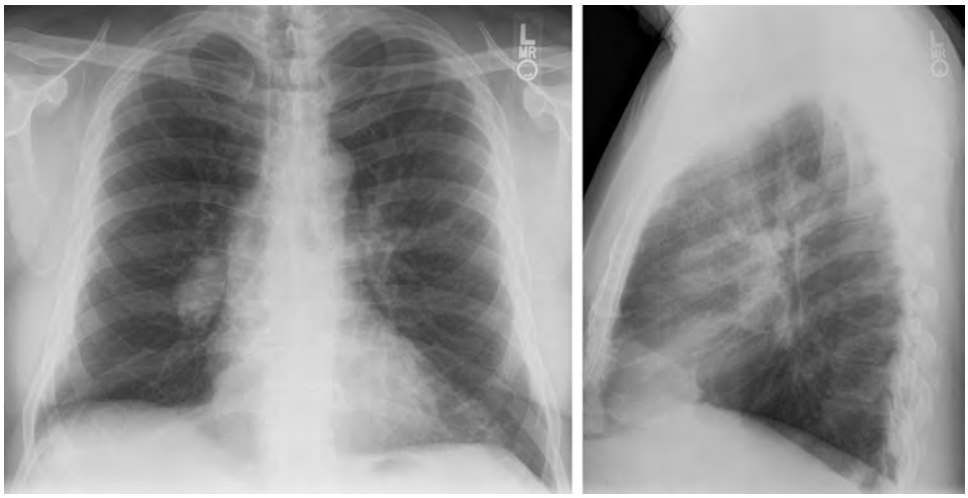

Fig. 26.2 Chest radiographs of a patient with chronic thromboembolic pulmonary hypertension showing asymmetric pulmonary artery enlargement, with a "knobby" appearance of the right pulmonary artery. No cardiomegaly is seen on the posteroanterior view, although the retrosternal space is obliterated on the lateral view.

Transthoracic Echocardiography

Transthoracic echocardiography (TTE) is a frequently used screening modality in patients with suspected PH. It often provides the first objective indication of the presence of elevated PAPs or RV compromise. Current technology allows for estimates of systolic PAP (using Doppler analysis of the velocity of TR), along with CO and RV performance.[45,46] Enlargement of the right heart chambers and the resultant TR, flattening or paradoxical motion of the interventricular septum, and encroachment of an enlarged right ventricle on the LV cavity resulting in impaired LV filling are findings in patients with significant PH.[47] Contrast echocardiography using intravenous agitated saline may show the presence of an intracardiac shunt, as a result of a PFO or another previously undetected septal defect. The echocardiogram is also useful in excluding LV dysfunction, valvular disease, or congenital heart disease, which may cause PH. In some patients with suspected CTEPH, TTE showing normal or minimally elevated PAPs at rest can sometimes demonstrate a substantial rise in PAP or dilatation of the right ventricle with exertion.

Ventilation/Perfusion Scintigraphy

The next step in the evaluation of patients for CTEPH is the acquisition of a $\dot{V}/\dot{Q}$ scan. For those patients with diagnosed PH, and for patients with dyspnea of unclear origin and suspected pulmonary vascular disease, the $\dot{V}/\dot{Q}$ scan is the recommended screening test for CTEPH.[10] In a retrospective survey comparing $\dot{V}/\dot{Q}$ scanning with computed tomography (CT) pulmonary angiography (CTPA) in 227 patients with PH, the sensitivity was 97.4% for $\dot{V}/\dot{Q}$ scanning compared with 51% for CT angiography (CTA) in the detection of CTEPH.[48] In a small study of 12 patients with CTEPH, Soler and associates[49] demonstrated that single-photon emission CT (SPECT) perfusion scintigraphy was more sensitive in detecting obstructed vascular segments when compared with CTPA, with a sensitivity of 62 ± 4.1% versus 47.8 ± 2.9%, respectively. However, a more recent study by He and colleagues[50] comparing the two modalities demonstrated $\dot{V}/\dot{Q}$ sensitivity, specificity, and accuracy of 100%, 93.7%, and 96.5% (high and intermediate probability), respectively, as compared with CTPA sensitivity, specificity, and accuracy of 92.2%, 95.2%, and 93.9%, respectively. These findings suggest that an interpretation of CTPA by an experienced examiner provides comparable detection of chronic thromboembolic disease. In CTEPH, at least one, and more commonly several, segmental or larger mismatched perfusion defects are present (Fig. 26.3). In those patients with small-vessel pulmonary vascular disease, perfusion scan results either are normal or exhibit a "mottled" appearance characterized by nonsegmental defects.[51,52] Exceptions can be seen in pulmonary veno-occlusive disease or pulmonary capillary hemangiomatosis, in which perfusion scans can demonstrate multiple, large mismatched defects.[53,54] The greatest value of a $\dot{V}/\dot{Q}$ scan as a screening study is that a relatively normal perfusion pattern excludes the diagnosis of surgical CTEPH. Investigators have also observed that the magnitude of perfusion defects exhibited by patients with CTEPH with operable disease may understate the degree of pulmonary vascular obstruction determined by angiography.[55] Therefore CTEPH should be considered and an evaluation for operable disease is warranted even if the $\dot{V}/\dot{Q}$ scan demonstrates a limited number of mismatched perfusion defects or regions of relative hypoperfusion ("gray zones").

Although an abnormal perfusion scan finding is observed in patients with CTEPH, this finding lacks specificity. Several other disorders affecting the proximal pulmonary vessels may result in scan findings similar to those in CTEPH,[56–58] and as such, further diagnostic imaging is necessary. Depending on imaging modality availability, and interpretive expertise, conventional catheter-based angiography, CTPA, and magnetic resonance imaging (MRI) are most valuable methods for defining large-vessel, pulmonary vascular anatomy and providing the necessary diagnostic information for the confirmation of CTEPH.

Catheter-Based Pulmonary Angiography

Catheter-based pulmonary angiography has traditionally been considered the gold standard for confirming the diagnosis of CTEPH and assessing the proximal extent of chronic thromboembolic disease in evaluating patients for PTE. In most circumstances, a properly performed pulmonary angiogram, including lateral projections, provides sufficient information on which to base a decision regarding chronic thrombus location and surgical accessibility. The angiographic appearance of CTEPH is distinct from the well-defined, intraluminal filling defects of acute PE. The angiographic patterns encountered in CTEPH reflect the complex patterns of organization and recanalization that occur following an acute thromboembolic event. Several angiographic patterns have been described in CTEPH, including "pouch defects," PA webs or bands, intimal irregularities, abrupt and frequently angular narrowing of the major PAs, and complete obstruction of main, lobar, or segmental vessels at their point of origin.[22] In most patients with CTEPH, two or more of these angiographic findings are present, typically involving both lungs (Fig. 26.4).

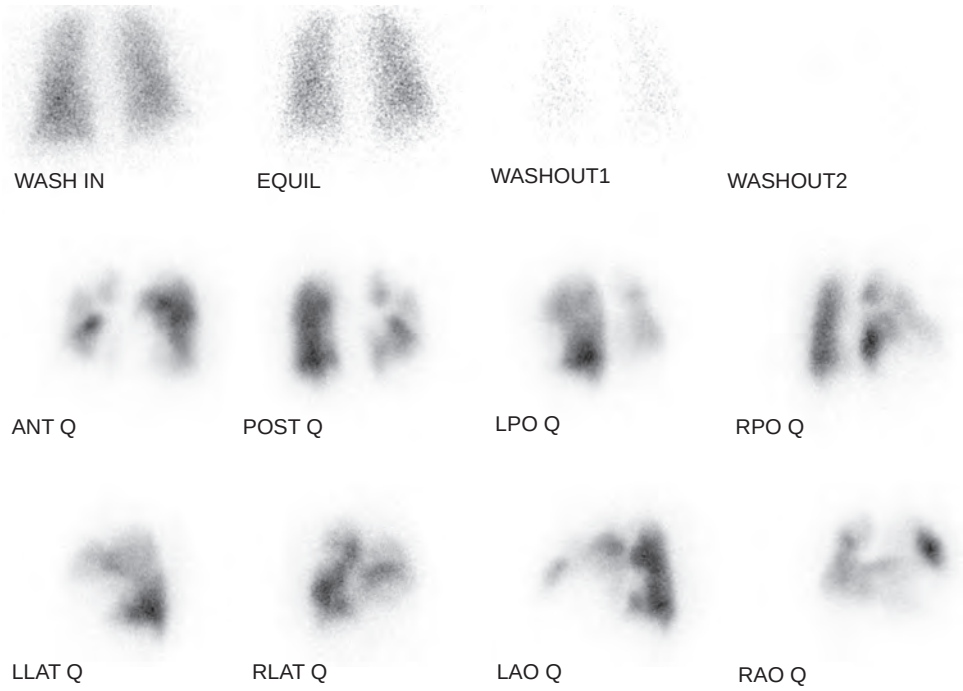

Fig. 26.3 Lung ventilation-perfusion scan of the same patient as in Fig. 26.2. Unmatched perfusion abnormalities include "hypoperfused" left upper lobe, with scattered segmental perfusion defects in the lingula and throughout the right lung. *ANT,* Anterior; *EQUIL,* equilibrium; *LAO,* left anterior oblique; *LLAT,* left lateral; *POST,* posterior; *Q,* perfusion; *RAO,* right anterior oblique; *RLAT,* right lateral.

Computed Tomography of the Chest

With advances in technology, CTPA of the chest has played an increasing role in the evaluation for CTEPH. Certain vascular and parenchymal CT findings are seen in patients with chronic thromboembolic disease. These include "mosaic perfusion" of the lung parenchyma, enlargement of the central PAs and right heart chambers, variability in the size of lobar and segmental-level vessels with a reduction in vessel caliber of those involved with chronic thrombi, and peripheral, scarlike lesions in poorly perfused lung regions.[59] With contrast enhancement of the pulmonary vasculature during CT imaging, organized thrombus can be seen to line the pulmonary vessels, often in an eccentric manner. Associated narrowing of PAs, web strictures or bands, poststenotic vessel dilatation, and other irregularities of the intima may also be

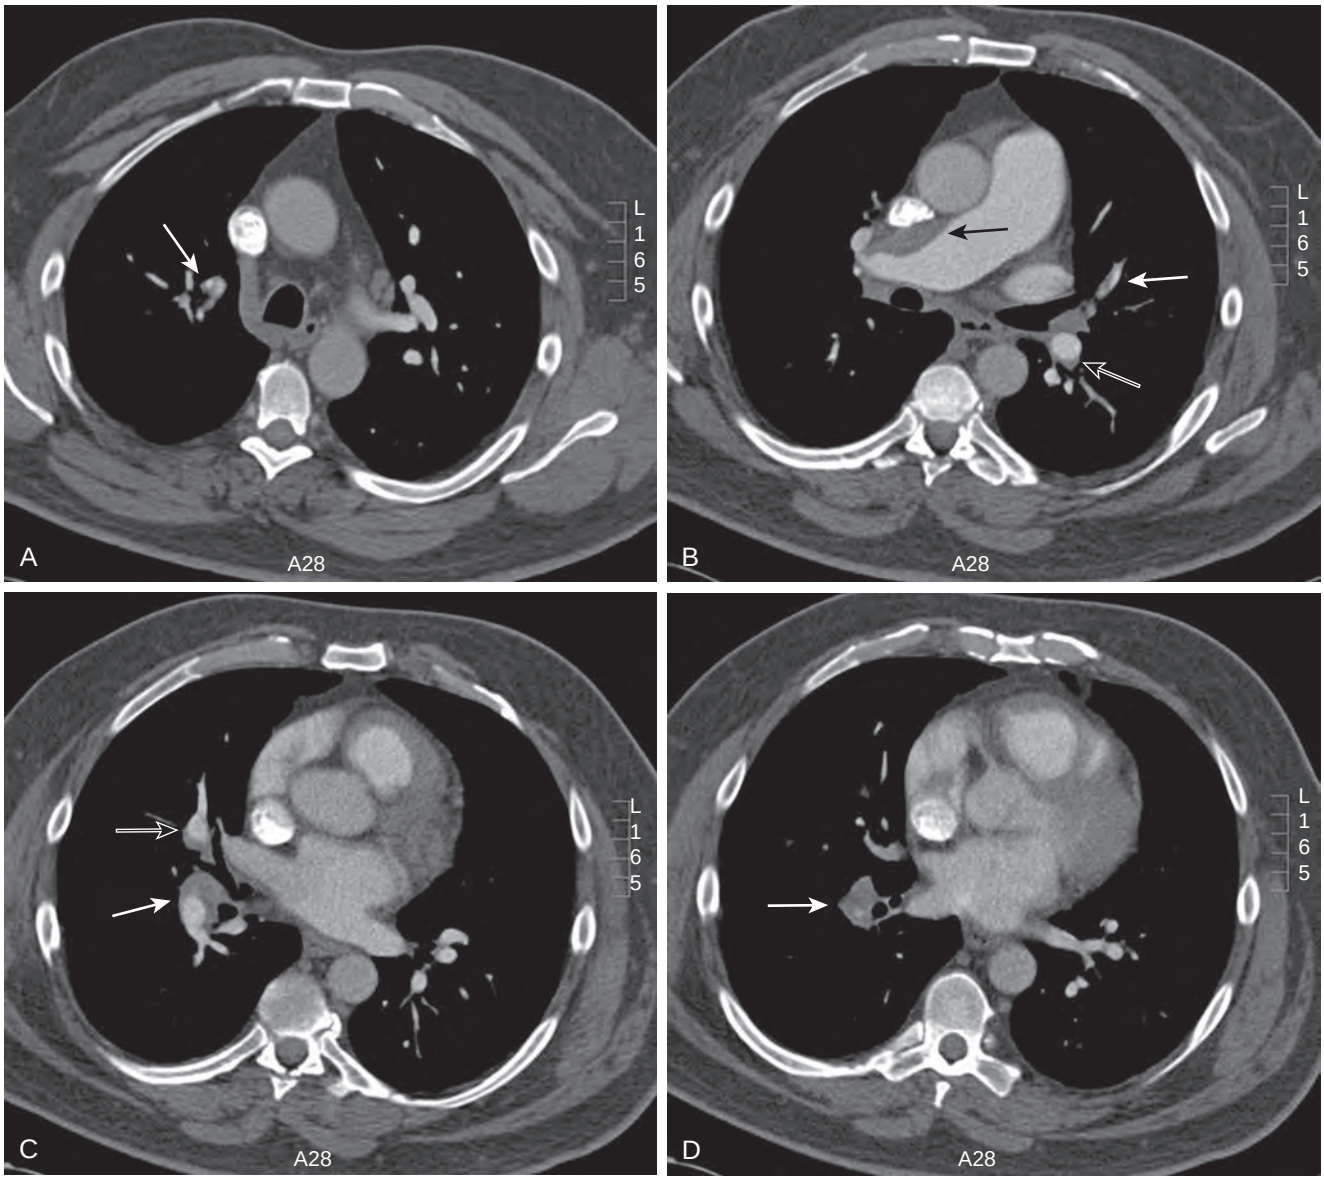

Fig. 26.5 (A–D) Cephalad to caudad presentation of the computed tomography angiogram of the patient undergoing pulmonary thromboendarterectomy who was presented in previous figures showing features of chronic thromboembolic pulmonary hypertension. (B) Intravascular "web," proximal lingula *(solid white arrow),* lining thrombus, right main pulmonary artery *(PA) (black arrow)* and intimal thickening in distal left descending PA *(open white arrow).* Main PA enlargement was consistent with significant pulmonary hypertension. (C) Eccentric lining thrombus, proximal right middle lobe *(open white arrow)* and right descending PAs *(solid white arrow),* leading to (D) complete occlusion and attenuation at the level of the right lower lobe vessels *(solid white arrow).*

appreciated (Fig. 26.5).[60,61] These radiologic signs are distinct from the isolated finding of intraluminal filling defects observed with acute thromboemboli.[59] With appropriate timing of the intravenous contrast bolus for CTPA, opacification of both the pulmonary and systemic circulation is possible. This type of imaging allows examination of both the pulmonary vascular bed and several cardiac features including cardiac chamber size, the position and shape of the interventricular septum (deviated toward the left ventricle in the setting of significant RV pressure overload), the presence of congenital cardiac abnormalities, anomalous pulmonary venous drainage, and the size and distribution of collateral vessels arising from the systemic arterial circulation, such as bronchial arteries off the aorta and collateral vessels arising from coronary vessels.[59,62,63]

What remains incompletely evaluated is the utility of CTPA in determining operability in certain subgroups of patients with CTEPH. This has become particularly relevant because operative techniques allow for resection of chronic thromboembolic material at the segmental vessel level. Clinical experience has demonstrated that the absence of lining thrombus or thickened intima of the central vessels on CTPA does not exclude the diagnosis of CTEPH or the possibility of surgical resection. Studies directly comparing CTPA with conventional pulmonary angiography are limited. In one such study, CTPA and digital angiography were nearly equivalent in terms of identifying complete vessel occlusion at the segmental level. However, for nonocclusive changes, CTPA was significantly inferior to angiography,[64] although with technologic advances in scanners, the accuracy of CTPA

has improved. A comparative study of electrocardiographically gated multidetector (40-row or 64-row) CTA (MDCTA), contrast-enhanced magnetic resonance angiography (MRA), and selective digital subtraction angiography (DSA) was conducted in 24 patients with CTEPH. The sensitivity and specificity of MDCTA for "CTEPH-related changes" at the main and lobar and segmental level were 100% and 100%, respectively, and 100% and 99%, respectively, in comparison with 65.7% and /100%, respectively, and 75.8% and 100%, respectively for DSA. The image quality of MDCTA in this study was rated as "significantly better" than that of DSA.[65] In a study of 44 patients with suspected CTEPH, Sugiura and associates[66] compared pulmonary DSA with enhanced, electrocardiographically gated 320-slice CT in the detection of thrombi within the pulmonary vascular bed. The sensitivity and specificity of CT to detect chronic thromboembolic lesions were 97.0% and 97.1%, respectively, at the main and lobar vessel level; at the segmental level, the corresponding values for DSA were 85.8% and 94.6%, respectively.[66]

Supplemental information provided by CT is of considerable value, not only in detecting disorders of the pulmonary parenchyma and mediastinum but also in differentiating CTEPH from "radiologic mimics."[59] In patients with CTEPH and coexisting interstitial lung disease or emphysema, CT can define the extent and location of the parenchymal lung process. An attempted PTE leading to diseased lung parenchyma risks an undesirable postoperative outcome; such circumstances therefore should exclude a patient from surgical consideration. When a $\dot{V}/\dot{Q}$ scan demonstrates absence or nearly complete absence of perfusion to an entire lung, CT is an essential study to rule out extrinsic pulmonary vascular compression from mediastinal adenopathy, fibrosis, or neoplasm.[44] CTEPH "mimics" such as primary sarcomas of the proximal pulmonary vessels, arteritis of medium to large pulmonary vessels (eg, Takayasu arteritis or sarcoidosis), and mediastinal fibrosis involving the proximal PAs or pulmonary veins are often revealed with CT.[59]

Magnetic Resonance Imaging

At some CTEPH specialty centers, MRI and MRA to visualize the pulmonary vascular bed have been shown to be reliable methods for diagnosing CTEPH and for determining surgical candidacy.[67] Kreitner and colleagues[68] showed that contrast-enhanced MRA can demonstrate the vascular changes typical of CTEPH. In a study of 34 patients with CTEPH, wall-adherent thromboembolic material involving the central PAs down to the segmental level could be seen. Intraluminal webs and bands, as well as abnormal vessel tapering and cutoffs, were also detected. Additionally, these investigators showed that MRA was superior to DSA in determining the proximal location of resectable chronic thromboembolic material.[68] An additional study comparing MRI techniques with conventional contrast angiography included 29 patients with either CTEPH or idiopathic PAH. The combined interpretation of MRI perfusion imaging and MRA led to a correct diagnosis of idiopathic PAH or CTEPH in 26 (90%) of the 29 patients when compared with the reference diagnosis based on $\dot{V}/\dot{Q}$ scintigraphy, DSA, or CTPA. The interpretation of MRA alone had a sensitivity of 71% for wall-adherent thrombi, 50% for webs and bands, and between 83% and 86% for detection of complete vessel obstruction and free-floating thrombi when compared with DSA or CTA.[69]

More recently, Rajaram and associates[70] retrospectively evaluated the accuracy of contrast-enhanced MRA compared with CTPA in a group of 53 patients with CTEPH. The sensitivity and specificity of MRA in detecting proximal and distal vessel chronic thromboembolic disease were 98% and 94%, respectively, and the sensitivity of MRA diagnosis of central vessel disease considerably improved when images were analyzed with unenhanced proton MRA (50–88%). Overall, MRA identified more stenosis, poststenotic dilatation, and occlusive lesions when compared with CTPA.[70] However, as referenced earlier, in a small study of 24 patients with CTEPH in whom all 3 diagnostic modalities were performed within a 3-day period, Ley and colleagues[65] compared DSA, electrocardiographically gated MDCTA, and contrast-enhanced MRA in the detection of vascular changes associated with chronic thromboembolic disease. Based on comparison with reference standards, the investigators concluded that MDCTA provided the best image quality and highest level of sensitivity and specificity for detection of vascular abnormalities at the main, lobar, and segmental levels.[65]

Additional features of MRI that can be useful in the evaluation of patients with CTEPH include cine imaging, which allows an assessment of RV and LV function and provides data on end-systolic and end-diastolic volumes, ejection fraction, and muscle mass.[71,72] Furthermore, phase-contrast imaging may be used to measure CO, along with pulmonary and systemic arterial flow.[68]

Evaluation of the Patient With Chronic Thromboembolic Pulmonary Hypertension for Pulmonary Thromboendarterectomy

The evaluation of a patient with suspected CTEPH has the objectives of establishing the diagnosis, determining whether PTE is feasible, and, after careful assessment of comorbidities, risks, and anticipated benefits, whether surgical treatment should be pursued. Once the diagnosis of CTEPH has been confirmed, the next consideration in establishing the surgical candidacy of any patient is the determination of surgical accessibility of the chronic thrombotic lesions and, as such, "operability" (Box 26.2). Despite advances in diagnostics and an expanding surgical experience, this assessment remains subjective. Experience with interpretation of the diagnostic studies outlined in the previous sections and knowledge of the capabilities of the surgical team at a specialized center for PTE dictate which chronic thromboembolic lesions can be removed. As surgical experience is gained, it becomes possible to resect not only main PA and lobar level disease, but also more distal, segmental chronic thromboembolic lesions (Fig. 26.6).[73,74] Although early experience with PTE procedures focused on the treatment of patients with PH and RV failure, the indications for surgical intervention have expanded to include those patients with symptomatic chronic thromboembolic disease without PH at rest. A report of 42 patients with symptomatic chronic thromboembolic disease and a baseline mPAP lower than 25 mm Hg concluded that PTE resulted in a significant improvement in functional status and quality of life.[75] Thromboendarterectomy and reperfusion of lung regions before the development of significant PH may prevent the development of the small-vessel arteriopathy in this patient group.

Equally essential in defining surgical candidacy is the assessment of perioperative risks. Properly performed right-sided heart catheterization enables a clinician accurately to determine the severity of PH and the degree of RV dysfunction in patients with CTEPH undergoing surgical evaluation. Early observations indicated that patients with severe PH, as defined by a PVR greater than 1000 dynes·s·cm^{-5}, bear a greater perioperative mortality risk.[76] Hartz and associates[77] reported that a preoperative PVR greater than 1100 dynes·s·cm^{-5} was associated with 41% mortality compared with less than 6% if PVR was less

BOX 26.2 PATIENT SELECTION CRITERIA FOR PULMONARY THROMBOENDARTERECTOMY

- Presence of surgically resectable chronic thromboembolic disease
- Symptomatic chronic thromboembolic disease, with or without pulmonary hypertension and right-sided heart dysfunction at rest
- Absence of concurrent illnesses representing an immediate threat to life
- Patient's desire for surgical treatment based on dissatisfaction with poor cardiorespiratory function or prognosis
- Patient's willingness to accept the mortality risk of the pulmonary thromboendarterectomy surgical procedure

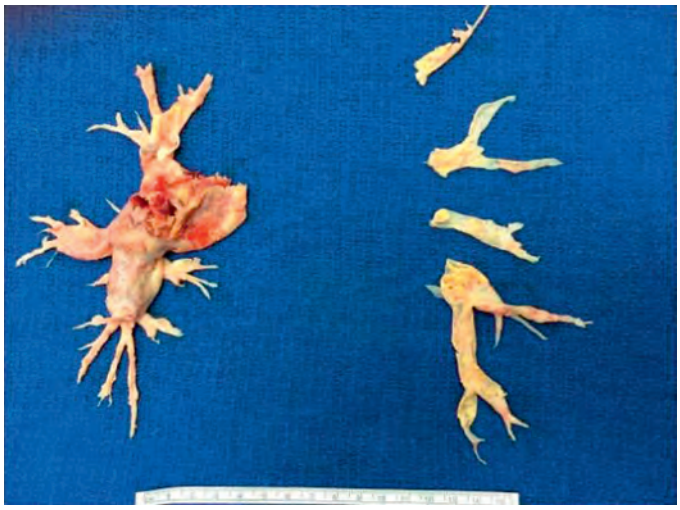

Fig. 26.6 Material removed at the time of pulmonary thromboendarterectomy that shows organized thrombus accompanied by semiorganized clot beginning in the right main pulmonary artery, whereas on the left, segmental level thrombus was endarterectomized. Preoperative pulmonary hemodynamics: mean atrial right pressure, 10; pulmonary artery pressure, 88/33 (55 mean); cardiac index, 2.09 L/min/m^2. Postoperative hemodynamics: central venous pressure, 9; pulmonary artery pressure, 43/15 (24 mean); cardiac index, 4.8 L/min/m^2 per minute.

than 1100 dynes·s·cm^{-5}. Another group later reported an increased postoperative mortality of 20% for patients with preoperative PVR greater than 1,200 dynes·s·cm^{-5} compared with 4% mortality if the preoperative PVR was less than 900 dynes·s·cm^{-5}.[78] Although worldwide perioperative mortality rates have declined, patients with more severe PH and those with decompensated RV failure from CTEPH remain at greater risk.[79] Madani and colleagues[74] reported a declining overall operative mortality risk of 2.2% following PTE in 500 patients operated on between 2006 and 2010; in this same group, those patients with a preoperative PVR greater than 1000 dynes·s·cm^{-5} had a mortality rate of 4.1% compared with 1.6% in those patients with a PVR lower than 1000 dynes·s·cm^{-5}. A subsequent report by de Perrot and colleagues[79] compared PTE outcomes in those patients with CTEPH with a preoperative PVR greater than (n = 26) or less than (n = 78) 1200 dynes·s·cm^{-5}. The overall in-hospital mortality rate after PTE was 4%; all deaths occurred in patients with PVR greater than 1200 dynes·s·cm^{-5} and decompensated RV failure on presentation.[79]

Finally, one should anticipate PTE will result in a meaningful outcome for the patient undergoing this complex and technically challenging procedure. Patients with significant comorbid conditions such as severe emphysema or those with a life-limiting malignant disease are not only at considerable perioperative risk but also are unlikely to realize the functional status benefit from PTE. Although the operation would possibly be technically feasible, such an aggressive intervention could be ill-advised. Furthermore, when the degree of PH appears out of proportion to the extent of accessible chronic thromboembolic disease apparent by angiography, and surgical resection is not expected to result in a substantive improvement in pulmonary hemodynamics, surgical treatment should not be undertaken. Unfortunately, this assessment continues to be subjective. In previous attempts to establish objective criteria whereby small-vessel disease could be contributing to the PVR in patients with CTEPH, PA occlusion waveform analysis was used to "partition" the proximal versus distal components of vascular resistance. Although specialized equipment is required and obtaining adequate occlusion waveforms may be difficult in this patient population, the available data from this technique underscore the heterogeneity of pulmonary vascular lesions present in CTEPH; those patients with operable disease had a greater degree of upstream resistance.[80] In a small series of 26 patients with CTEPH, Kim and associates,[81] using this waveform analysis, demonstrated an inverse correlation between upstream resistance and postoperative mPAP and PVR. In addition, all four deaths in this series occurred in patients with upstream resistance of less than 60%.[81] However, such a discriminatory demarcation was not observed by Toshner and colleagues[80]; both of their patients with CTEPH who died following PTE had an upstream resistance of 68% and 73%. Consequently, available information fails to provide enough "objective data" to exclude patients from surgical consideration on the basis of hemodynamic measures alone.

Operation

Historical Background

Chronic thromboembolic disease was not recognized as a distinct diagnostic entity until the late 1920s. The first surgical attempt to remove the adherent thrombus from the PA wall was reported by Hurwitt and associates in 1958.[82] This landmark operation distinguished endarterectomy, rather than embolectomy, as the surgical procedure of choice for chronic thromboembolic disease. In 1961 and 1962, systemic hypothermia with cardiopulmonary bypass (CPB) standby was used to perform two successful endarterectomies. A historical review of the world's experience with PTE up to 1985, published by Chitwood and colleagues,[83] revealed an overall perioperative mortality rate of 22% in 85 patients who underwent surgical endarterectomy. Moser and associates[37] published their experience of 42 patients with CTEPH who underwent PTE, with an in-hospital mortality rate of 16.6%. Of the 35 survivors (mean follow-up, 28 months), 16 had New York Heart Association (NYHA) functional class I disease, 18 had class II, and 1 had class III. PVR declined significantly after the surgical procedure from 897 ± 352 to 278 ± 135 dynes·s·cm^{-5}. This study confirmed the substantial improvements in functional ability experienced by these patients 1 year postoperatively.[37]

Seven surgeons have been involved with the UCSD program and have performed more than 3300 PTE procedures since 1970. Drs. Braunwald, Utley, Daily, and Dembitsky, who together performed 188 procedures between 1970 and 1989, made progressive modifications to the surgical technique, including the use of median sternotomy and hypothermic circulatory arrest. Drs. Jamieson and Kapelanski performed more than 1400 operations from 1989 to early 2000. Since 2000, Drs. Jamieson and Madani have extended the total number of cases to more than 3000, and Drs. Madani and Pretorius currently perform approximately 180 such procedures annually, with mortality rates of approximately 1% to 2%. UCSD is the world's pioneer in PTE surgery, and most of the surgical experience with PTE to date has been reported from that institution; hence this chapter is based on that extensive experience (Fig. 26.7).

Pulmonary Thromboendarterectomy Procedure

PTE is the only curative treatment for CTEPH, with periprocedural mortality rates lower than 2% to 5% in experienced centers,[74] nearly normalized hemodynamics, and substantial improvement in clinical symptoms in the majority of patients. Treatment decisions in CTEPH should be made by a CTEPH team and based on interdisciplinary discussions among internists, radiologists, and expert surgeons. A patient's condition should not be considered inoperable unless at least two independent experienced PTE surgeons have evaluated the patient. Detailed preoperative patient evaluation and selection, surgical and anesthetic technique, and meticulous postoperative management are essential for surgical success. Following complete endarterectomy, a significant decrease in PVR can be expected with near normalization of pulmonary hemodynamics. A center can be considered to have adequate expertise if it performs at least 20 to 30 operations per year with a mortality rate lower than 10%,[14] although an expert center typically performs more than 50 such operations annually and has a mortality rate of less than 4% to 5% while achieving excellent outcomes even in patients with distal disease. The techniques of this procedure have

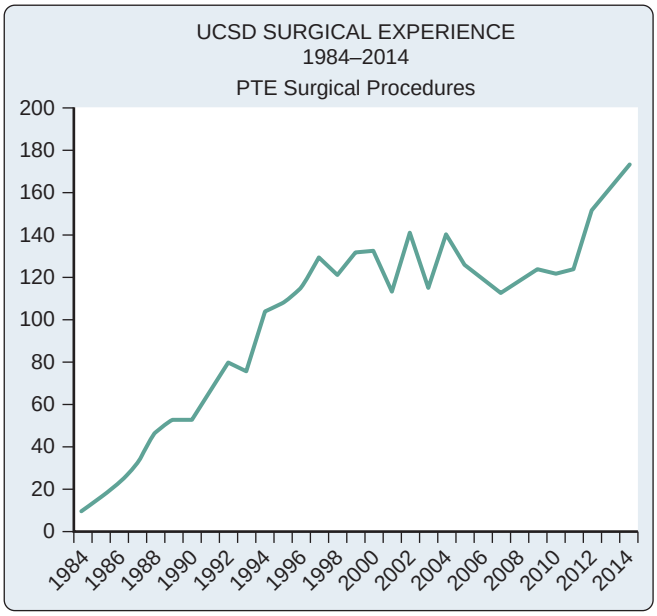

Fig. 26.7 University of California San Diego surgical experience from 1984 to 2014. *PTE,* Pulmonary thromboendarterectomy.

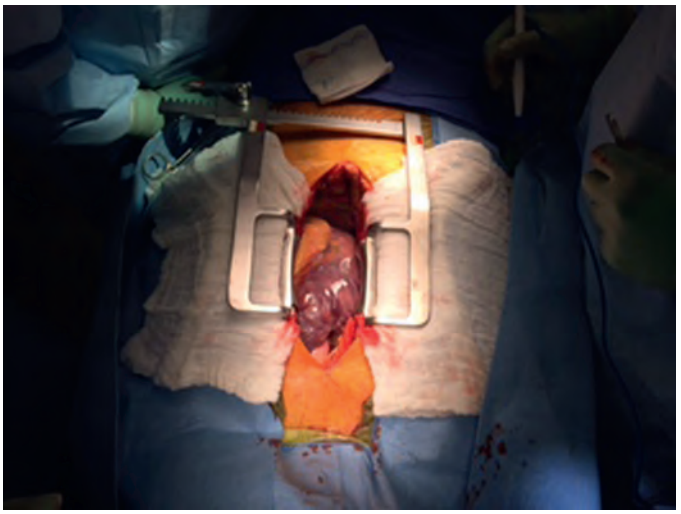

Fig. 26.8 A median sternotomy demonstrating an enlarged, tense right atrium.

been described elsewhere.[84,85] The procedure follows four basic but important principles:

1. The endarterectomy must be bilateral; therefore the approach is through a median sternotomy.
2. Identification of the correct dissection plane is crucial, and the plane must be identified in each of the segmental and subsegmental branches.
3. Perfect visualization is essential, and thorough distal endarterectomy cannot be performed without the use of circulatory arrest. Circulatory arrest is usually limited to 20 minutes at a time and is supported by cooling to 18°C.
4. Complete endarterectomy all the way to the distal ends of the smallest vessels is essential.

The endarterectomy must be bilateral because bilateral thromboembolic disease is present in almost all patients with CTEPH, and PH is a bilateral phenomenon. Historically, many reports described unilateral operations, and, occasionally these are still performed by lateral thoracotomy in inexperienced centers. However, the unilateral approach ignores the disease on the contralateral side, subjects the patient to hemodynamic jeopardy during clamping of the PA, does not allow adequate visibility because of the continued presence of bronchial blood flow, and exposes the patient to a repeat operation on the contralateral side. In addition, collateral channels develop in CTEPH not only through the bronchial arteries, but also from diaphragmatic, intercostal, and pleural vessels. Dissection of the lung in the pleural space through a thoracotomy incision can therefore be extremely bloody. The median sternotomy, apart from providing bilateral access, avoids entry into the pleural cavities and allows the ready institution of CPB.

CPB is essential to ensure cardiovascular stability when the operation is performed and to cool the patient to allow circulatory arrest. Excellent visibility is required, in a bloodless field, to define an adequate endarterectomy plane and to then follow the PTE specimen deep into the subsegmental vessels. Because of the copious bronchial blood flow usually present in these cases, periods of circulatory arrest are necessary to ensure perfect visibility. Although sporadic reports have described the performance of this operation without circulatory arrest, we emphasize that although endarterectomy is possible without circulatory arrest, *complete* endarterectomy is not. We always initiate the procedure without circulatory arrest; a variable amount of dissection is possible before the circulation is stopped, but never complete dissection. The circulatory arrest periods are limited to 20 minutes, with restoration of blood flow between each arrest. With experience, the endarterectomy usually can be performed with a single period of circulatory arrest on each side. A true endarterectomy in the plane of the media must be accomplished. It is essential to appreciate that the removal of visible thrombus is largely incidental to this operation. Indeed, in most patients, no free thrombus is present, and on initial direct examination, the pulmonary vascular bed may appear normal. The early literature on this procedure indicates that thrombectomy was often performed without endarterectomy; in these cases, the PVR did not improve, often with the resultant death of the patient. After median sternotomy the pericardium is incised longitudinally and is attached to the wound edges. Typically, the right side of the heart is enlarged, with a tense right atrium and a variable degree of TR (Fig. 26.8). Severe RV hypertrophy is usually present, and with critical degrees of obstruction, the patient's condition may become unstable with manipulation of the heart.

Anticoagulation is achieved with the use of heparin sodium (400 U/kg, intravenously) administered to prolong the activated coagulation time beyond 400 seconds. Full CPB is instituted with high ascending aortic cannulation and two caval cannulas. The heart is emptied on CPB, and a temporary PA vent is placed in the midline of the main PA 1 cm distal to the pulmonary valve. This location marks the beginning of the left pulmonary arteriotomy.

When CPB is initiated, surface cooling with both a head-wrap jacket and a body cooling blanket is begun, and the blood is cooled with the pump oxygenator. During cooling, no more than a 10°C gradient between arterial blood and bladder or rectal temperature is maintained.[86] Cooling generally takes 45 to 60 minutes. When ventricular fibrillation occurs, an additional vent is placed in the left atrium through the right superior pulmonary vein. This vent prevents left atrial (LA) and LV distention from the large amount of bronchial blood flow.

During the cooling period, some preliminary dissection can be performed, with full mobilization of the right PA from the ascending aorta. The superior vena cava (SVC) also is fully mobilized. The approach to the right PA is made medial, not lateral, to the SVC. All dissection of the PAs takes place intrapericardially, and neither pleural cavity should be entered. An incision then is made in the right PA from beneath the ascending aorta out under the SVC and entering the lower lobe branch of the PA just after the take-off of the middle lobe artery. It is important that the incision stays in the center of the vessel and continues into the lower rather than the middle lobe artery.

Any loose thrombus, if present, is removed. Embolectomy without subsequent endarterectomy is ineffective, and in most patients with

BOX 26.3 UNIVERSITY OF CALIFORNIA SAN DIEGO CHRONIC THROMBOEMBOLI CLASSIFICATION

Level I: Chronic thromboembolic disease in the main pulmonary arteries
Level IC: Complete occlusion of one main pulmonary artery with chronic thromboembolic disease
Level II: Chronic thromboembolic disease starting at the level of the lobar arteries or in the main descending pulmonary arteries
Level III: Chronic thromboembolic disease starting at the level of the segmental arteries
Level IV: Chronic thromboembolic disease starting at the level of the subsegmental arteries
Level 0: No evidence of chronic thromboembolic disease in either lung

From Madani MM, Jamieson SW, Pretorius V, et al. Subsegmental pulmonary endarterectomy: time for new surgical classification. Abstract presented at the International CTEPH Conference, Paris, 2014.

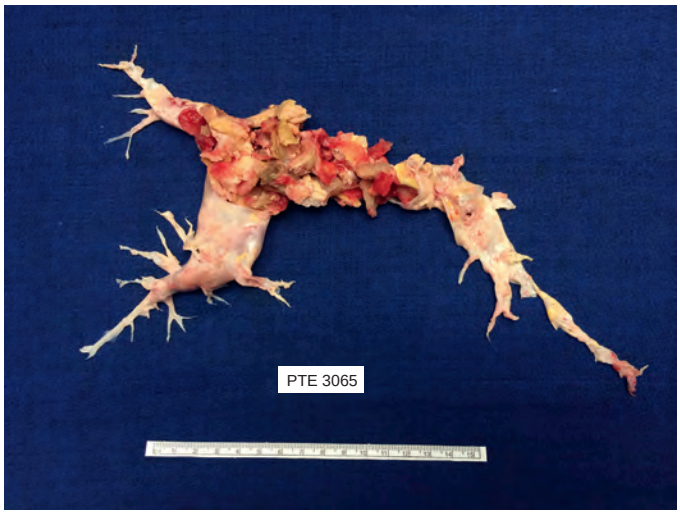

Fig. 26.9 University of California San Diego chronic thromboemboli classification level I, right and left sides. *PTE,* Pulmonary thromboendarterectomy.

CTEPH, direct examination of the pulmonary vascular bed at operation generally shows no obvious embolic material. Therefore, to the inexperienced surgeon or at cursory glance, the pulmonary vascular bed may well appear normal even in patients with severe CTEPH.

If the bronchial circulation is not excessive, the endarterectomy plane can be found during this early dissection. However, although a small amount of dissection can be performed before the initiation of circulatory arrest, it is unwise to proceed unless perfect visibility is obtained because the development of a correct plane is essential.

Five categories of pulmonary occlusive disease related to thrombus can be appreciated. The UCSD classification system describes the different levels of the thromboembolic specimen and corresponds to the degree of difficulty of the endarterectomy (Box 26.3).[87] Level 0 is no evidence of chronic thromboembolic disease present. In other words, a misdiagnosis has occurred, or perhaps one lung is completely unaffected by thromboembolic disease; both situations are rare. This entity is characterized by intrinsic small-vessel disease, although secondary thrombus may occur as a result of stasis. Small-vessel disease may be unrelated to thromboembolic events ("primary" PH) or may occur in relation to thromboembolic hypertension as a result of a high-flow or high-pressure state in previously unaffected vessels similar to the generation of Eisenmenger syndrome. Investigators believe that sympathetic "cross-talk" from the affected contralateral side or stenotic areas in the same lung may also be present.

Level I disease (Fig. 26.9) refers to the condition in which thromboembolic material is present and readily visible on the opening of the main left and right PAs. A subset of level I disease, level Ic, is complete occlusion of either the left or right PA and nonperfusion of that lung. Complete occlusion may represent an entirely different disease, especially when it is unilateral and on the left side (Fig. 26.10). This group of patients, typically young women with complete occlusion of the left PA, may not have reperfusion of their affected lung despite a complete endarterectomy, thus indicating a different intrinsic pulmonary vascular disease unrelated to thromboembolic disease.

In level II (Fig. 26.11), the disease starts at the lobar or intermediate-level arteries, and the main PA is unaffected. Level III disease is limited to thromboembolic disease originating in the segmental vessels only (Fig. 26.12). Level IV is disease of the subsegmental vessels (Fig. 26.13), with no other disease appreciated at more proximal levels. Level III disease and level IV disease present the most challenging surgical situations. The disease is very distal and is confined to the segmental and subsegmental branches. These levels are most often associated with presumed repetitive thrombi from upper extremity sources, long-term indwelling catheters, pacemaker leads, or ventriculoatrial shunts.

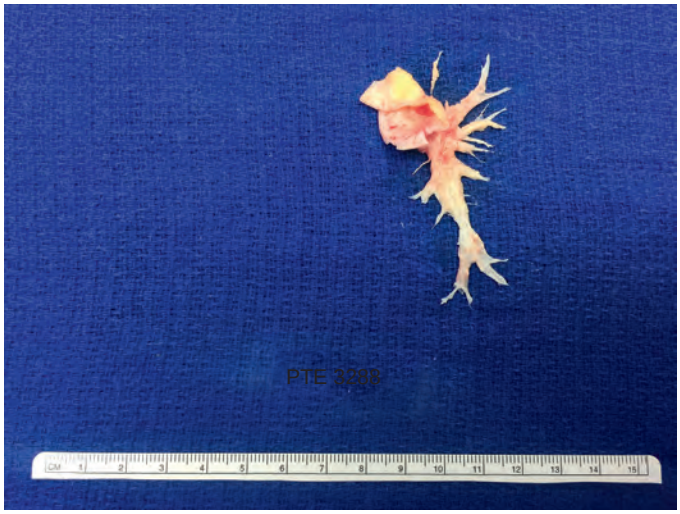

Fig. 26.10 Example where no disease is present on the right side (level 0) and complete occlusion is present on the left side (level 1C). *PTE,* Pulmonary thromboendarterectomy.

When the patient's temperature reaches 18°C, the aorta is cross-clamped, and a single dose of cold cardioplegic solution (1 L) is administered. Additional myocardial protection is obtained by the use of a cooling jacket. The entire procedure is performed with a single aortic cross-clamp period with no further administration of cardioplegia.

When blood obscures direct vision of the pulmonary vascular bed, circulatory arrest is initiated, and the patient undergoes exsanguination. All monitoring catheters to the patient are turned off to prevent aspiration of air. Snares are tightened around the cannulas in the SVC and inferior vena cava (IVC). Although antegrade cerebral perfusion or retrograde cerebral perfusion has been advocated for circulatory arrest in other procedures, these methods are not helpful in this operation because they do not allow a completely bloodless field, and, with the short arrest times that can be achieved with experience, they are not necessary. Any residual loose, thrombotic debris encountered is removed. Then a microtome knife is used to develop the endarterectomy plane posteriorly. Dissection in the correct plane is critical because if the plane is too deep, the PA may perforate, with fatal results; and if the dissection plane is not deep enough, inadequate amounts of the thromboembolic material will be removed. When the proper plane

Fig. 26.11 University of California San Diego chronic thromboemboli classification level II, right and left sides. *PTE,* Pulmonary thromboendarterectomy.

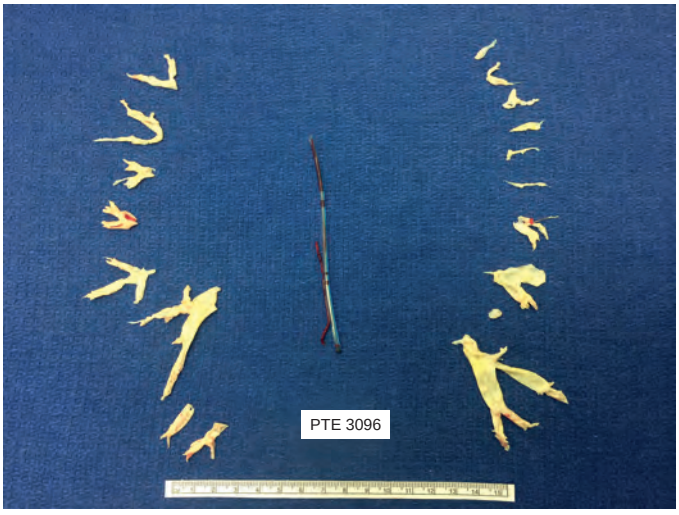

Fig. 26.12 University of California San Diego chronic thromboemboli classification level III, right and left sides. *PTE,* Pulmonary thromboendarterectomy.

is entered, the layer strips easily, and the material left with the outer layers of the PA appears somewhat yellow. The ideal layer is marked with a pearly white plane, which strips easily. No residual yellow plaque should remain. If the dissection is too deep, a reddish or pinkish color indicates that the adventitia has been reached. A more superficial plane should be sought immediately.

Once the plane is correctly developed, a full-thickness layer is left in the region of the incision to ease subsequent repair. The endarterectomy then is performed with an eversion technique, using a specially developed dissection instrument (Jamieson aspirator, Fehling Corporation, Acworth, Ga) and specially designed double-action forceps (Madani PTE Forceps, Wexler Surgical, Houston, Tex). Because the vessel is partly everted and subsegmental branches are being worked on, a perforation here becomes completely inaccessible and invisible later. This is why perfect visualization in a completely bloodless field provided by circulatory arrest is essential. It is important that each subsegmental branch is followed and freed individually until it ends in a "tail," beyond which no further obstruction is encountered. Residual material should never be cut free; the entire specimen should "tail off" and come free spontaneously. Once the right-sided endarterectomy is completed, circulation is restarted, and the arteriotomy is repaired with a continuous 6-0 polypropylene suture. The hemostatic nature of this closure is aided by the nature of the initial dissection, with the full thickness of the PA preserved immediately adjacent to the incision.

After completion of the repair of the right arteriotomy, the surgeon moves to the patient's right side. The pulmonary vent catheter is withdrawn, and an arteriotomy is made laterally beneath the pericardial reflection, and again into the lower lobe, but avoiding entry into the left pleural space. Additional lateral dissection does not enhance intraluminal visibility, may endanger the left phrenic nerve, and makes subsequent repair of the left PA more difficult. A lymphatic vessel is often encountered on the left PA at the level of the pericardial reflection, and it is wise to clip this vessel before it is divided with the PA incision.

The left-sided dissection is virtually analogous in all respects to that accomplished on the right. By the time the circulation is arrested once more, it will have been reinitiated for at least 10 to 15 minutes, by which time the venous oxygen saturations are in excess of 90%. The duration of circulatory arrest intervals during performance of the left-sided dissection is subject to the same restriction (≈20 minutes) as the right.

After completion of the endarterectomies, CPB is reinstituted and warming is commenced. Methylprednisolone (500 mg, intravenously) and mannitol (12.5 g, intravenously) are administered, and during warming no more than a 10°C temperature gradient is maintained between the perfusate and body temperature, with a maximum perfusate temperature of 37°C. If the systemic vascular resistance (SVR) is high, nitroprusside is administered to promote vasodilatation and warming.

When the left pulmonary arteriotomy has been repaired, the PA vent is replaced into the left PA. Once the arteriotomy is closed, the heart is returned to its natural anatomic position. If the intraoperative transesophageal echocardiogram (TEE) showed evidence of a septal defect, the right atrium is opened and examined. Any intraatrial communication is closed. Although TR is invariable in these patients and is often severe, tricuspid valve repair is not performed unless an independent structural abnormality of the tricuspid valve is present. If the tricuspid valve morphology is normal, tricuspid valve competence returns with RV remodeling over the course of a few days postoperatively. If other cardiac procedures are required, such as coronary artery or mitral or aortic valve operations, these are performed during the systemic rewarming period. Myocardial cooling is discontinued once all cardiac procedures have been concluded. The LA vent is removed, and the vent site is repaired. All air is removed from the heart, and the aortic cross-clamp is removed. When the patient has rewarmed, CPB is discontinued. Temporary atrial and ventricular epicardial pacing wires are placed. Despite the duration of CPB, hemostasis is readily achieved, and blood products are generally unnecessary. Wound closure is routine. Vigorous diuresis is usual for the first few hours after CPB.

Anesthetic Management of Patients Undergoing Pulmonary Thromboendarterectomy

Preoperative Assessment

Patients are admitted preoperatively for a full workup. Right-sided heart catheterization is the gold standard for diagnosing PH and the only way of accurately measuring right atrial (RA) pressures and PAP and assessing the severity of PAH. Jamieson and colleagues,[84] in their experience with 1500 cases, found that a postoperative mortality rate of 10% was associated with a preoperative PVR greater than 1000 dynes·s·cm^{-5}, compared with 1.3% in patients with a preoperative PVR lower than 1000 dynes·s·cm^{-5}. PH is defined by mPAP greater than 25 mm Hg and a PVR greater than 300 dynes·s·cm^{-5}. RV diastolic pressures greater than 14 mm Hg together with elevated RA pressures suggest RV failure. An mPAP value greater than 50 mm Hg and PVR greater than 600 dynes·s·cm^{-5} signify severe PH. CO and cardiac index (CI) also provide an insight into RV dysfunction. Preoperatively, all patients who will undergo PTE have IVC filter placement to prevent future PE after the endarterectomy.

Hemodynamic Considerations and Anesthetic Induction

On the day of the operation, a large-bore peripheral intravenous catheter and a radial arterial catheter are placed in the preoperative area. Benzodiazepines occasionally are administered for sedation but with extreme caution, with full monitoring, and preferably in the operating room. Sedation should be individualized on a case-by-case basis, noting that anxiety and pain can increase PVR, whereas excessive sedation can cause hypercarbia and hypoxia, leading to acidosis that exacerbates high PVR. A PA catheter (PAC) may be placed preoperatively but usually is placed after anesthetic induction.

CTEPH, according to its classification as precapillary PH, is characterized by normal LV systolic function and abnormal right-sided hemodynamics. Thus induction and decision making are centered on RV function. The right ventricle typically is hypertrophied and dilated and is associated with a dilated right atrium. Patients undergoing PTE have a fixed PVR and concomitant RV dysfunction; therefore any significant decrease in mean arterial pressure during induction may compromise RV perfusion and cause cardiovascular collapse and death. Maintenance of adequate SVR, an adequate inotropic state, and a normal sinus rhythm serves to preserve systemic hemodynamics, as well as RV coronary perfusion. Attempts to reduce PVR pharmacologically by using nitroglycerin or nitroprusside should be avoided because these agents have minimal efficacy in treating the relatively fixed PVR, and they result in SVR reduction that compromises RV coronary perfusion and RV function, thus rapidly leading to hypotension and cardiovascular collapse. Inhaled nitric oxide (NO) is safe to use, but some patients are not responsive to NO, and it is rarely required on induction. Administration of vasopressors, such as phenylephrine or vasopressin, is vital in treating hypotension and promoting adequate RV perfusion. Despite a relatively fixed PVR, attempts should be made to minimize conditions that increase PVR further such as episodes of hypoxia and hypercarbia.

The choice of anesthetic induction drugs depends on the degree of hemodynamic instability. Etomidate frequently is used because it maintains sympathetic tone and does not have a significant direct myocardial depressant effect. Succinylcholine or rocuronium can be used to achieve a rapid intubation environment and control of the airway. It is recommended that titration of narcotics to blunt the response to intubation takes place after control of ventilation to avoid rigidity and hypoventilation. Inotropic support with an infusion of a catecholamine is used in patients who are at high risk for cardiovascular collapse (Box 26.4).

A PAC is routinely placed after induction rather than before because the right-sided heart catheterization data are usually available for review preoperatively. The TEE can be very useful to guide PAC placement and confirm the position of the PAC in the PA. Patients undergoing PTE tend to have a dilated right atrium and right ventricle, thereby potentially making placement of the PAC difficult. A PAC is vital to assess the impact of surgical intervention on pulmonary vascular reactivity. Patients with advanced disease may be unable to lie supine or in the Trendelenburg position, which sometimes can lead to cardiorespiratory collapse. If the preoperative TTE reveals evidence of RA, RV, or main PA thrombi, TEE is performed immediately after induction and before placement of the PAC. In this instance, PAC placement is guided with TEE, and the PAC is left in the SVC (at 20 cm) until completion of the surgical procedure. Because all patients undergoing PTE also undergo prolonged CPB and circulatory arrest, a femoral arterial catheter is placed after induction to monitor arterial pressure after CPB because a radial artery catheter significantly underestimates systemic arterial pressure with a gradient of as much as 20 mm Hg. This phenomenon has been observed by Mohr and associates[88] and Baba and colleagues,[89] who proposed redistribution of blood flow away from the extremity as the cause. A screen shot displaying all the various hemodynamics used to monitor the patient during PTE is shown in Fig. 26.14.

SEDLine brain-function monitoring (Hospira, Lake Forest, Ill) is used to monitor the electroencephalogram. This four-channel processed electroencephalograph provides confirmation of cerebral isoelectricity and thus minimal use of oxygen by the brain before circulatory arrest. It also serves as a monitor for the level of consciousness during the procedure. Cerebral near-infrared spectroscopy, such as with the FORE-SIGHT (CAS Medical Systems, Branford, Conn) is used to monitor the patient's cerebral oxygen saturation status within tissues of the frontal lobe during the procedure and circulatory arrest. The device is a noninvasive method of estimating jugular bulb venous oxygen saturation ($SjvO_2$) and therefore global cerebral oxygen balance in the clinical setting, as demonstrated by Ikeda and associates.[90] In a retrospective study of more than 2000 patients, Goldman and colleagues[91] confirmed that the institution of cerebral oximetry in their practice decreased the stroke rate in cardiac surgical patients. Yao and associates[92] observed an association between cerebral desaturation and neurocognitive dysfunction in 101 patients undergoing cardiac surgical

procedures. These investigators found that patients with a cerebral oxygen saturation of less than 40% for longer than 10 minutes had an increased incidence of neurocognitive dysfunction (see Chapter 18).

Temperature monitoring is achieved in several ways during all PTE procedures to allow accurate quantification of thermal gradients and to ensure even cooling and rewarming. Bladder temperature and rectal probes are used for core temperature estimation. A tympanic membrane probe is used for brain temperature estimation, and the PAC measures blood temperature.[93]

Acute normovolemic hemodilution often is used in the setting of an increased starting hematocrit without the presence of any concomitant cardiac disease. Typically, 1 to 2 units of whole blood is harvested after anesthetic induction, depending on the starting hematocrit, and it is replaced with colloid if needed to maintain hemodynamic stability. Acute normovolemic hemodilution has added benefits for deep hypothermic circulatory arrest because it will help decrease blood viscosity, optimize capillary blood flow, and promote uniform cooling.[94] This autologous harvested whole blood is reinfused after protamine administration, thus providing platelets and factors and replacing the diluted clotting factors resulting from the pump prime. Antifibrinolytic agents are not used routinely with PTE because patients are often inherently hypercoagulable.

TEE is used routinely in patients undergoing PTE to monitor hemodynamics, evaluate RV and LV function, identify intracardiac thrombus or valvular disease, and evaluate RV function and de-airing after bypass. A thorough intraatrial septal evaluation is performed to rule out a PFO, which has an incidence of 35% in the PTE population.[95] All patients are evaluated with two methods: color-flow Doppler and agitated echocardiographic contrast. Agitated echocardiographic contrast imaging is particularly useful if results of color-flow Doppler imaging are inconclusive. Positive pressure at 30 cm H_2O is applied for 10 seconds, and with release of the Valsalva maneuver, the agitated echocardiographic contrast (agitated blood or 5% albumin without adding any air) is injected. The echocardiographic contrast study is preferably performed after the patient is prepared and draped because instances of hemodynamic collapse have occurred following contrast injection. Most PFOs are repaired intraoperatively. An algorithm for PFO study assessment is shown in Fig. 26.15. In rare instances when results of the operation are not favorable, and high right-sided pressures are expected, the PFO is left open as a "pop-off" to improve RV function and increase CO at the expense of some hypoxemia. In this instance, closure of a PFO can be detrimental to clinical status by reducing LV filling and increasing filling of the noncompliant right ventricle.[84,96]

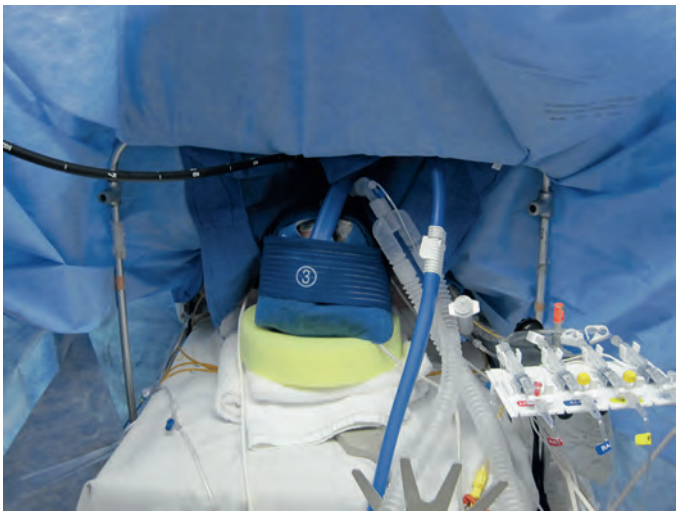

Fig. 26.16 Polar Care 500 cooling blanket used during circulatory arrest during pulmonary thromboendarterectomy procedures. *(Courtesy Breg, Vista, Calif.)*

The patient's head is wrapped in a cooling blanket because all PTE-treated patients undergo circulatory arrest. The head-wrap system (Polar Care, Breg, Vista, Calif) is composed of two items: the Polar Care 500 cooling device (cooling bucket, pump, pump bracket, and AC power transformer), which is reusable, and the actual wrap, which is a single-use item (Fig. 26.16). In a series of 55 patients who used this device during circulatory arrest, the mean tympanic membrane temperature was 15.1°C. The head wrap provides sufficient cooling to the brain, wraps the whole head, and is much easier to use than ice bags. It has been used in more than 3000 cases without any complications.

Cardiopulmonary Bypass Prime, Cooling and Hypothermic Circulatory Arrest

The prebypass time is typically short unless concomitant coronary artery bypass grafting is planned. The bypass system is primed with 1000 mL of Plasma-Lyte A (Baxter, Deerfield, Ill), 100 mL of 25% albumin, 5 to 12 mL (100 units/kg) of heparin, 12.5 g mannitol, and 8.4% 50 mL sodium bicarbonate. For circulatory arrest, 30 mg/kg of

methylprednisolone to a maximum dose of 3 g is added to the prime, and an additional 500 mg is added at rewarming. The steroid theoretically functions as a cell membrane stabilizer and antiinflammatory agent.[97] Phenytoin (15 mg/kg) is administered by the perfusionist for postoperative seizure prophylaxis, after initiation of bypass.

Cooling begins immediately after initiation of bypass, by using CPB temperature adjustment and the cooling blankets present under the patient, together with the head wrap. Allowing appropriate time to cool and warm the patient in each direction using rectal, bladder, tympanic, PA, and perfusate temperatures with appropriate thermal gradients ensures even and thorough cooling and warming, respectively. Propofol, 2.5 mg/kg, is administered immediately before initiation of deep hypothermic circulatory arrest to ensure complete isoelectricity. SEDLine brain-function monitoring is used for this purpose because brain cooling may be uneven or incomplete, and cerebral emboli may occur, given that PTE is an open procedure; in case of sparse electroencephalographic activity, it will monitor for any residual activity (Fig. 26.17).[98]

The following must be confirmed before circulatory arrest: the electroencephalogram is isoelectric, the tympanic membrane temperature is lower than 18°C, bladder and rectal temperatures are lower than 20°C, and all monitoring catheters to the patient are turned off, to decrease the risk for entraining air into the vasculature during exsanguination.

Fig. 26.17 Burst suppression, flat electroencephalogram monitored by SEDLine brain-function monitoring. *(Courtesy Hospira, Lake Forest, Ill.)*

Rewarming Phase and Separation From Bypass

The rewarming perfusate should not exceed 37°C, and the gradient between blood and bladder or rectal temperatures should not be more than 10°C. Warming too quickly promotes systemic gas bubble formation, cerebral oxygen desaturation, and uneven warming, which can aggravate cerebral ischemia and increase the chance of hypothermia in the postoperative period (after-drop). The rewarming period can take up to 120 minutes to achieve a core temperature of 36.5°C, depending on the patient's body mass and systemic perfusion.

Separation from CPB follows the same process as in most other cardiac operations, with a few minor exceptions. Communication with the surgeon is of paramount importance because surgical classification of the thromboembolic disease and the amount of organized clot that was successfully removed will dictate how much inotropic and vasopressor support (if any) is needed to separate from bypass. With successful endarterectomy, substantial reduction in PVR and improved RV function occur, as revealed immediately after bypass with TEE[99] (Fig. 26.18).

If residual PH is observed, the patient may need aggressive inotropic support (eg, dopamine, 3–7 µg/kg per minute; or epinephrine, 0.03–0.15 µg/kg per minute), together with pulmonary vasodilators, such as milrinone, and inhaled prostacyclin or NO. Inhaled NO is preferred because it acts on the pulmonary vasculature with minimal systemic effects. The right atrium is routinely paced at a rate of 90 to 100 beats/min with temporary epicardial pacing electrodes to ensure incomplete RV filling reducing wall tension. Ventricular epicardial electrodes are placed as well, but they are used only if atrioventricular conduction is impaired. End-tidal carbon dioxide is a poor measure of ventilation adequacy and does not represent the true arterial carbon dioxide in these patients both before and after CPB because dead-space ventilation is an integral part of the disease process. The arterial end-tidal carbon dioxide gradient usually improves after successful surgical treatment, but the response and time course vary. Higher minute ventilation is often required to compensate for metabolic acidosis that develops from CPB, circulatory arrest, and hypothermia. Before separation from CPB, intracardiac air and RV and LV function are assessed with TEE and PAC. With successful operative results, immediate improvements of RV function and resolution of the interventricular septal distortion and flattening are seen on intraoperative

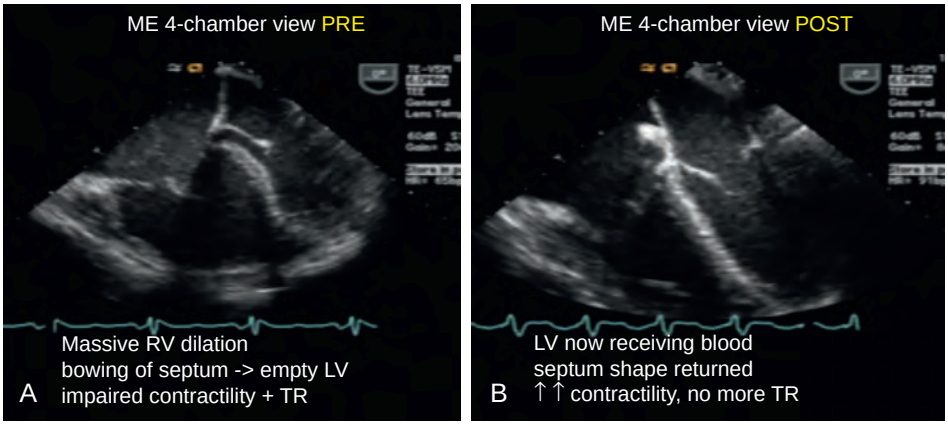

Fig. 26.18 (A) Midesophageal *(ME)* four-chamber view in a patient with chronic thromboembolic pulmonary hypertension before pulmonary thromboendarterectomy (PTE). Note the severely dilated right atrium, right ventricle, and the interatrial and intraventricular septum bulging toward the left atrium and left ventricle *(LV)*. (B) After successful PTE, note the improvement in the right atrial and right ventricular *(RV)* size. *TR,* Tricuspid regurgitation.

TEE. With the dramatic resolution of PH following PTE, transmitral diastolic flow improves in a predictable manner. Not surprisingly, this change correlates with improvements in the CO and CI.[100]

To standardize ventilation and maintain hyperventilation postoperatively, a portable transport ventilator is used to transport patients to the intensive care unit after PTE. If postoperative care is uneventful, most patients are discharged from the unit on the second or third postoperative day, with subsequent hospital discharge approximately 1 to 2 weeks after the operation.

Management of Airway Bleeding

Reperfusion pulmonary edema and airway bleeding are two of the most dreaded complications of PTE. Anesthesiologists must therefore be prepared to provide diagnostic and therapeutic maneuvers for these rare complications and routinely check the endotracheal tube during the rewarming phase before separation from CPB to inspect for bleeding or frothy fluid in the endotracheal tube.[101]

Most cases of bleeding are spontaneous and are discovered only after resuming cardiac ejection. However, the surgeon may anticipate bleeding if an adventitial injury is suspected during PTE and will help in promptly identifying the bronchial side that needs to be isolated. If dark frank blood is seen in the endotracheal tube after separation from CPB, it usually indicates a surgical violation of the blood-airway barrier in one of the PA branches. In contrast, pink frothy blood usually indicates early and severe reperfusion injury and is suspected when the PTE increased blood flow to a previously occluded vessel. Management of airway bleeding centers on prevention of exsanguination and maintenance of adequate gas exchange. Conservative management consists of positive end-expiratory pressure, lung isolation of the segment bleeding with a bronchial blocker, reversal of heparin, and correction of coagulopathies. These maneuvers often reduce minor bleeding and reperfusion injury.[102,103] If bleeding is recognized before separation from CPB, to the surgeon should allow the heart to eject briefly with the bleeding area under direct visualization with fiberoptic bronchoscopy to establish the location of bleeding. An attempt is made to isolate the affected segment by using bronchial blockade to prevent spilling blood into other segments and causing further impaired air flow and gas exchange. Therefore, immediately before separation from CPB, special attention should be paid to optimizing oxygenation and ventilation. In addition, while the patient is undergoing CPB and with the PA vent on suction, an attempt may be made to exchange the endotracheal tube with a larger (9–10 mm) endotracheal tube. This allows the use of a large bronchoscope together with a 9-Fr Uniblocker (LMA North America, San Diego, Calif). We recommend the use of an airway exchange catheter because of the high incidence of poor direct visualization resulting from bleeding, edema, and suboptimal conditions. Use of the Uniblocker is good for isolation of a lung or lobe, and the Arndt blocker (Cook Medical, Bloomington, Ind) is more appropriate for isolation of a specific segment. The use of a double-lumen tube is not recommended because it presents a challenge when using a large bronchoscope that has superior suction and diagnostic capabilities. In cases of minor adventitial injuries, the blocker balloon can be deflated under direct visualization, and normal ventilation can be resumed; however, if persistent hemorrhage is noted, continued lung isolation is needed.

In severe circumstances in which inadequate oxygenation, ventilation, and hemodynamics persist, various forms of extracorporeal life support should be considered. Three options exist:

1. With biventricular dysfunction, venoarterial extracorporeal membrane oxygenation (ECMO) can be used with anticoagulation.
2. With RV dysfunction and persevered LV function, ECMO with RA inflow and PA outflow cannula bypassing and unloading the right ventricle aids in gas exchange and supports RV function.
3. With preserved RV and LV function, venovenous ECMO using a heparin-bonded circuit, without systemic anticoagulation, improves oxygenation but does not provide ventricular support (see Chapters 28 and 33).

An algorithm for management of post-CPB hemorrhage is presented in Fig. 26.19. The Avalon Elite Bicaval Dual-Lumen Catheter (Maquet, Rastatt, Germany) typically is inserted via the Seldinger technique into the right internal jugular vein with ultrasound and TEE guidance. A bicaval view using color-flow Doppler is used to ensure that the outflow jet is toward the tricuspid valve.[102,104,105] This technique is efficient, requires no anticoagulants, and maintains appropriate gas exchange with preservation of pulsatile pulmonary and systemic flow while allowing natural hemostatic processes to repair the affected PA or capillary bed. The natural repair is usually complete after 24 to 48 hours, thus allowing weaning from ECMO. The third most common cause of perioperative death in patients undergoing PTE is massive pulmonary hemorrhage after PTE, with residual PH and reperfusion pulmonary edema as the leading two causes.

Management of the Postoperative Patient

In many respects the principles of postoperative management of patients undergoing PTE are similar to those following other procedures requiring sternotomy and CPB. The desire to minimize the time of mechanical ventilation, the use of vasoactive medications for inotropic and hemodynamic support, wound care, mediastinal chest tube management, the use of "prophylactic" antibiotics, pain management, and treatment of postoperative arrhythmias and coagulopathies are common issues faced by the physicians, nurses, pharmacists, and respiratory therapists caring for patients after PTE.

However, several aspects of this operation frequently present unique postoperative challenges. For example, the median duration of CPB of approximately 4 hours is a risk factor for coagulopathy and a reduction in platelet count that may result in transient, albeit significant, mediastinal blood loss. A modest rise in creatinine level postoperatively is also frequently observed, although the need for dialysis is rare. A transient increase in serum transaminase levels, presumptively from prolonged hypoperfusion, is also observed. Deep hypothermia frequently results in postoperative metabolic acidosis during the rewarming phase, and prolonged circulatory arrest has been associated with postoperative mental status changes and delirium.[106] The endarterectomy procedure itself dramatically alters cardiopulmonary physiology in the immediate postoperative period. After successful PTE, a significant reduction in RV afterload occurs, and lung regions supplied by vessels previously occluded by organized thrombus receive dramatically increased pulmonary blood flow. Understanding of these immediate physiologic changes provides a rationale for the unique management of the post-PTE patient.[107]

Post–Pulmonary Thromboendarterectomy Hemodynamic Management and Persistent Pulmonary Hypertension

The immediate hemodynamic results following effective PTE include reductions in PAP and PVR (RV afterload) and improvements in RV function and CO.[73,78,108–111] However, transient sinus node dysfunction often requiring atrial pacing frequently occurs during the first few postoperative days. This dysfunction likely results from the residual effects of intraoperative hypothermia and cardioplegia. In addition, despite a reduction in RV afterload, some persistent RV dysfunction can be observed. As seen on echocardiography, a degree of RV strain can persist, although the pattern is different from what is noted preoperatively.[9] We believe that this RV strain may result from the residual effects of hypothermia (including the use of a cardiac cooling jacket) and cardioplegia, as a response to poor pulmonary vascular compliance, or from pericardiotomy during PTE. Modest inotropic support is usually effective in maintaining adequate CO during this brief period. Sometimes a persistently low SVR follows PTE in the absence of evidence of infection or medication effect. As in the earlier case, the profound hypothermia may be responsible for this phenomenon, and

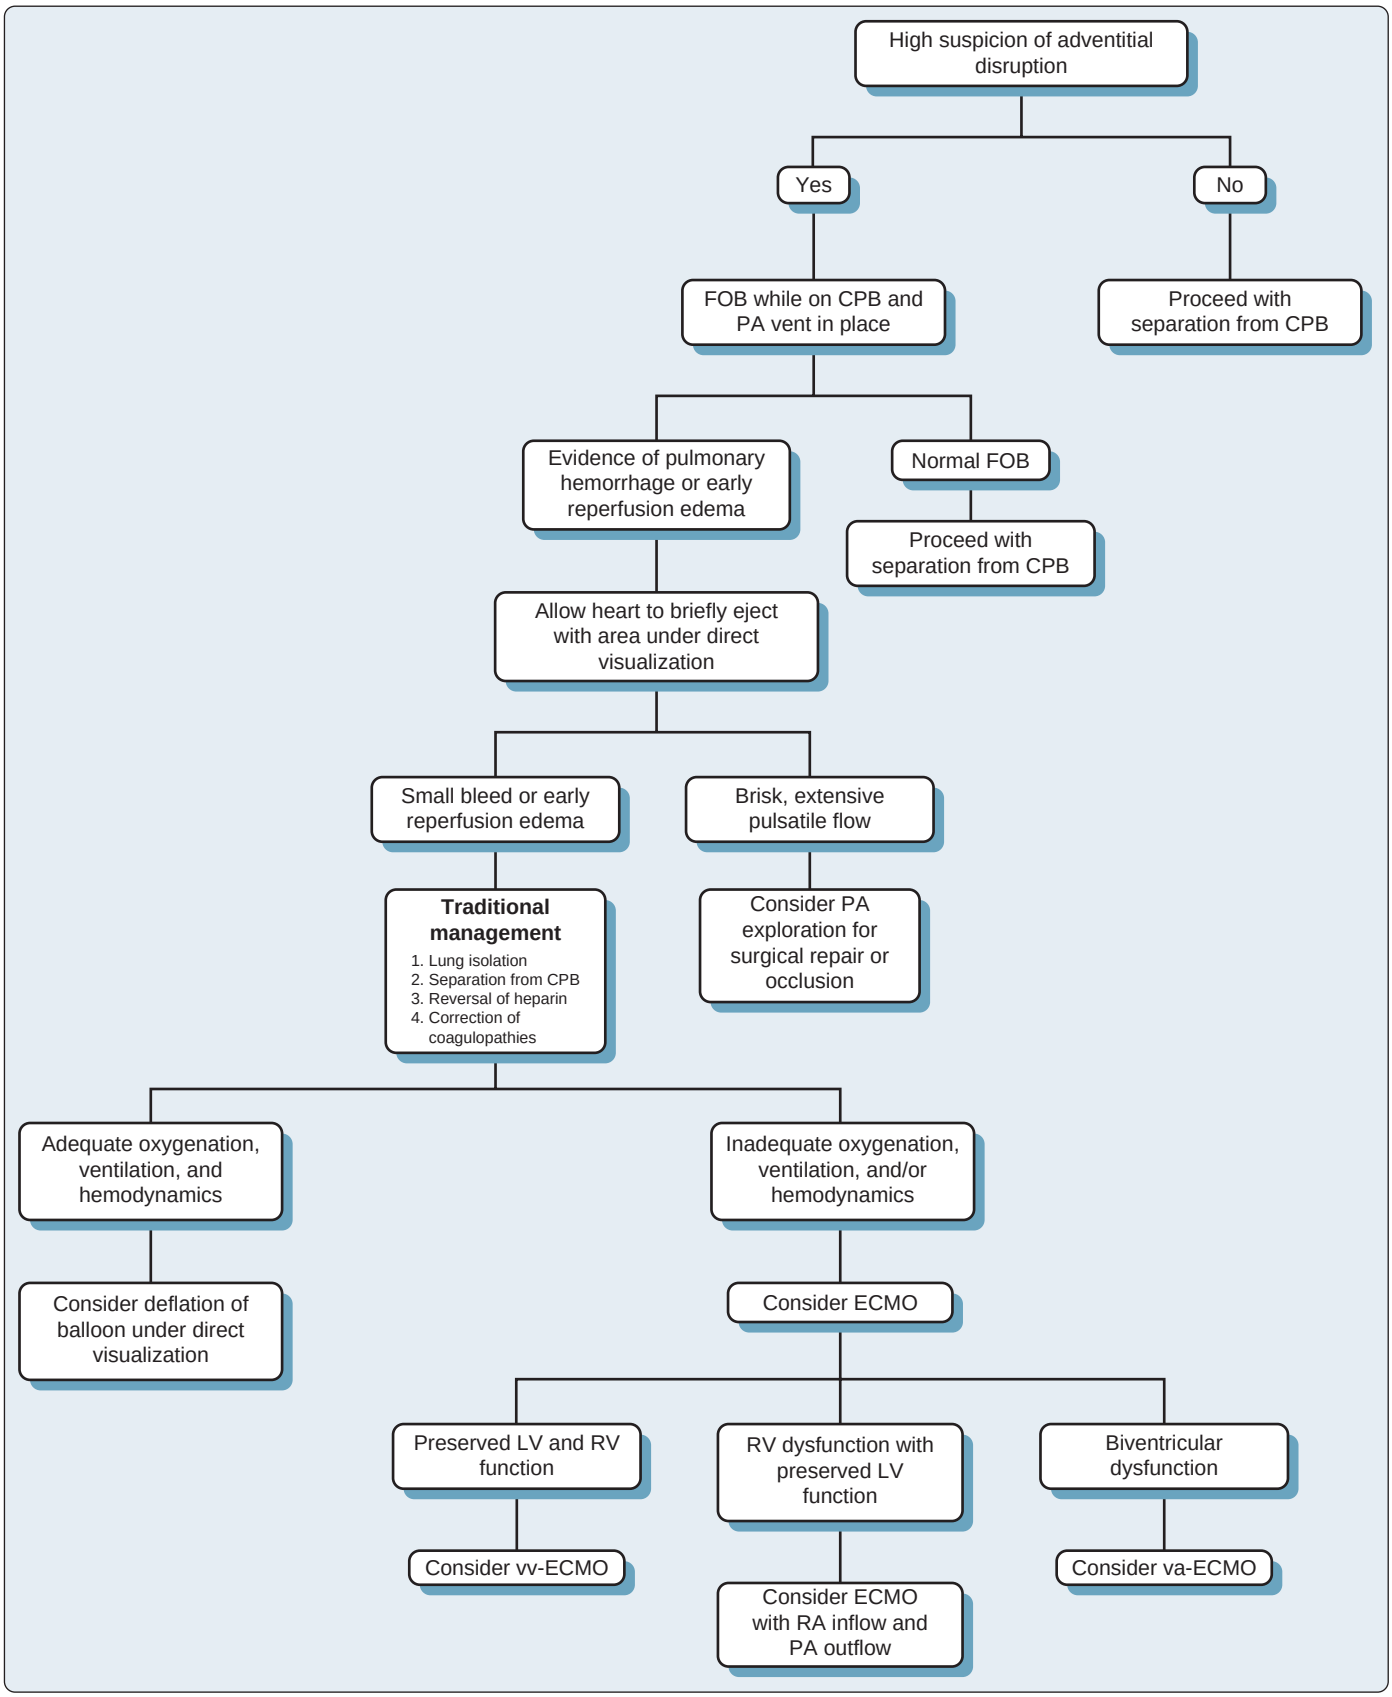

Fig. 26.19 Algorithm for management of post–cardiopulmonary bypass pulmonary hemorrhage for the pulmonary thromboendarterectomy procedure. *CPB,* Cardiopulmonary bypass; *FOB,* fiberoptic bronchoscopy; *ECMO,* extracorporeal membrane oxygenation; *LV,* left ventricular; *PA,* pulmonary artery; *RA,* right atrial; *RV,* right ventricular; *va,* venoarterial; *vv,* venovenous. *(Reprinted with permission from Cronin B, Maus T, Pretorius V, et al. Case 13—2014: management of pulmonary hemorrhage after pulmonary endarterectomy with venovenous extracorporeal membrane oxygenation without systemic anticoagulation.* J Cardiothorac Vasc Anesth. *2014;28(6):1667–1676.)*

an α-adrenergic agonist is generally effective in supporting blood pressure. On rare occasions, adrenal insufficiency may be the basis for this hypotension, and cortisol levels (after administration of adrenocorticotropic hormone) should be assessed to verify this diagnosis. Some patients do not achieve normal PAPs and RV function following PTE; the incidence is between 5% and 35% of operated patients. Plausible explanations include residual chronic thromboembolic disease that could not be surgically resected or a significant amount of coexisting small-vessel arteriopathy.

Long-term information on the level of residual PH that negatively affects functional status and survivorship is lacking.[112–116] In the immediate postoperative period, significant RV dysfunction greatly complicates the clinical course. Attention to oxygenation status and careful volume management, correction of acid-base imbalance, inotropic support, and at times the use of PH-targeted medical therapy with parenteral prostanoid administration may be necessary to support patients through this tenuous postoperative period. In extreme circumstances, ECMO support has been used when other measures fail, particularly when concurrent hypoxic respiratory failure is present.[117] Success with this approach presupposes a reversal component to the cardiopulmonary instability, and sometimes this aggressive management can be viewed as a bridge to organ transplantation in the acute setting.[118]

Other Pulmonary Considerations and Management of Hypoxemia

After successful PTE, lung perfusion shifts, with blood flow preferentially going to regions supplied by PAs that have been opened. This shift is accompanied by a reduction in perfusion in lung regions uninvolved with chronic thrombotic material, a phenomenon termed *perfusion steal*[119] (Fig. 26.20). Although this reperfusion of previously nonperfused lung parenchyma is the basis for the reduction in RV afterload, the postoperative perfusion shifts are responsible for $\dot{V}/\dot{Q}$ mismatch, an important contributor to the development of acute reperfusion lung injury.[120] This form of acute lung injury occurs in the endarterectomized lung region, is associated with varying degrees of hypoxemia (ratio of arterial oxygen partial pressure to fractional inspired oxygen [P/F ratio] <300), begins within 72 hours of operation, and occurs in the absence of an alternative clinical explanation for the pulmonary infiltrates on chest radiograph (Fig. 26.21). The pathophysiologic basis is incompletely understood, although initial observations suggested a high-permeability, inflammatory-mediated mechanism. Such observations were supported by anecdotal experience with high-dose corticosteroids resulting in reductions in both the incidence and the severity of the reperfusion response.[107] Furthermore, a randomized, placebo-controlled clinical trial examining the use of a selectin analogue to block neutrophil adhesion and migration was shown to reduce the relative risk of lung injury by 50% in patients undergoing PTE.[121] However, well-designed follow-up studies investigating the perioperative use of high-dose corticosteroids failed to show effectiveness,[122] and the declining incidence over the years of this postoperative complication without evident cause, or change in surgical or anesthetic management, brings the "inflammatory" response as the sole physiologic basis for this lung injury into question. Furthermore, reports that a higher preoperative PVR is associated with a higher incidence of lung injury after PTE,[123] and more observations that postcapillary microvascular disease can be observed in patients with CTEPH,[124] suggest that a hemodynamic component contributes to reperfusion lung injury after PTE.

The approach to patients with reperfusion lung injury is primarily supportive, and the intensity of intervention depends on the degree of hypoxemia. The difficulties in management of this patient population are augmented by the shift in pulmonary blood flow that occurs as noted previously: the normal compensatory mechanism of hypoxic pulmonary vasoconstriction is blunted in injured lung regions receiving a large percentage of blood flow, thus resulting in regions that are edematous, poorly ventilated, and noncompliant. In the mildest forms, diuresis to decrease lung edema and supplemental oxygen may be the only treatment required. For more severe lung injury, aggressive diuresis, lung-protective ventilator strategies, and prompt treatment of concurrent lung infection (if present) are mainstays of therapy. For severe lung injury, when other measures have failed, ECMO support has been used with success.[117,125] The use of inhaled NO to correct $\dot{V}/\dot{Q}$ mismatch can be associated with an improvement in oxygenation in some patients, at least initially. However, this approach was

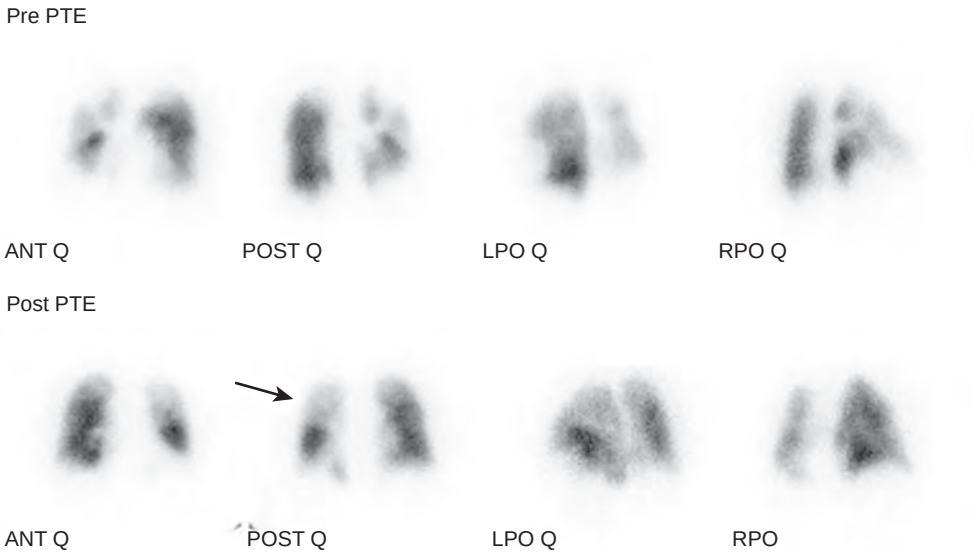

Fig. 26.20 Postoperative shifting of lung perfusion following removal of organized thrombus pictured in Fig. 26.6. The relative increase in perfusion to the right lung where an extensive amount of chronic thromboembolic material was endarterectomized resulted in hypoperfusion of the left upper lobe *(arrow)* after pulmonary thromboendarterectomy *(PTE)* (where minimal amounts of chronic thromboembolic material was endarterectomized), referred to as "perfusion steal." The postoperative scan was obtained 6 days postoperatively. *ANT,* Anterior; *LAO,* left anterior oblique; *POST,* posterior; *Q,* perfusion; *RAO,* right anterior oblique.

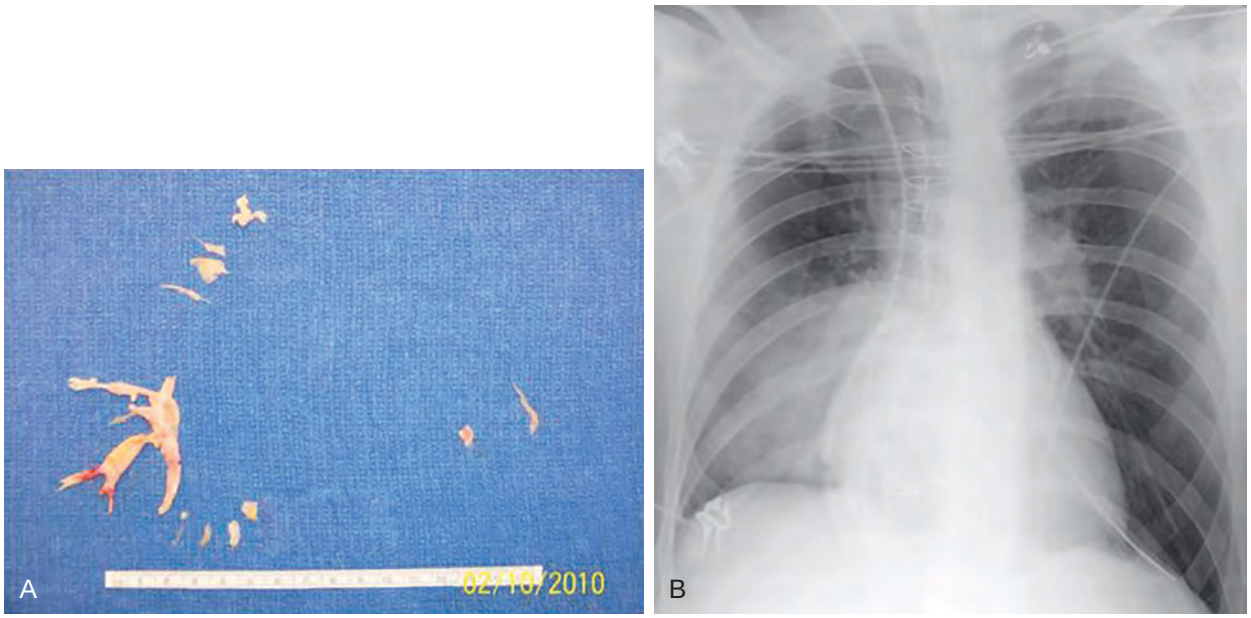

Fig. 26.21 (A) Pulmonary thromboendarterectomy (PTE) specimen from the right lower lobe (RLL). (B) Chest radiograph demonstrating pulmonary infiltrates consistent with reperfusion lung injury in the RLL within 24 hours of PTE. This finding correlates with removal of chronic thromboembolic material from vessels leading to the RLL, as pictured.

not consistently effective in a small trial of patients with other forms of lung injury.[126] Similarly, the use of a low-lung-volume ventilation strategy during the immediate post-PTE period, as an independent factor, is unlikely to prevent reperfusion lung injury.[127]

Hypoxemia during the immediate postoperative period may also simply be secondary to atelectasis in a region of newly reperfused lung. Ventilator adjustments using slightly higher tidal volumes, positive end-expiratory pressure, and lung recruitment maneuvers can be effective in improving $\dot{V}/\dot{Q}$ matching in this setting. For extubated patients, mobilization and aggressive lung recruitment maneuvers to diminish atelectasis usually improve oxygenation.

Low $\dot{V}/\dot{Q}$ and resultant hypoxemia can be observed following PTE operations in the absence of evident lung injury.[128] These findings may be the result of a high perfusion state in relatively small lung regions after endarterectomy of segmental and subsegmental vessels. Other than supportive measures and oxygen supplementation, no specific treatment exists for this condition. This perfusion shift improves over time.

Postoperative Thrombosis Prophylaxis and Anticoagulation

Once hemostasis has been achieved in the early hours following PTE, thrombosis prophylaxis is typically initiated with subcutaneous heparin and the use of pneumatic compression devices. Experience has suggested that patients with a history of antiphospholipid syndrome, those patients with CTEPH who have undergone level 1C resection, and those with evidence of a recent thromboembolic event are at greater risk for postoperative thrombosis, including within the pulmonary vessels. For these patients, therapeutic-level anticoagulation is attempted early postoperatively as long as significant hemorrhage does not occur.

Lifelong anticoagulation is strongly advised in patients who have undergone PTE.[129] Once epicardial pacing wires are removed, and further invasive procedures are unlikely, warfarin is begun with a target international normalized ratio (INR) of 2.5 to 3.5. Although data are lacking on the ideal level of anticoagulation over time, thromboembolic recurrence is rare in patients who have been maintained on long-term anticoagulation. Individualization of the care plan is emphasized. For example, in patients with antiphospholipid syndrome who have considerable thrombophilia, INR targets are frequently higher. For older patients and for those patients concurrently taking antiplatelet agents, targeting an INR between 2.0 and 3.0 is common practice. The use of the newer oral anticoagulants, targeting thrombin or factor Xa, has yet to be examined in this patient population.

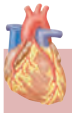
Nonsurgical Approach to Chronic Thromboembolic Disease

Pulmonary Hypertension–Targeted Medical Therapy

PTE is the preferred treatment option for patients with CTEPH. However, patient subgroups in whom PH-targeted medical therapy was examined in randomized, placebo-controlled trials include patients deemed to have inoperable CTEPH and patients with residual PH following PTE. PH-targeted medical therapy is also sometimes beneficial as a bridge to PTE in preoperative patients with severe PH and RV dysfunction (Box 26.5).

A randomized controlled trial examining the efficacy of bosentan in inoperable CTEPH was reported in 2008 by Jais and colleagues,[130] who enrolled 157 patients. Bosentan was used in 77 patients, approximately 28% of whom had previously undergone PTE procedures. Compared with baseline, 16-week treatment with bosentan resulted in an improvement in pulmonary hemodynamic parameters: a 24.1% reduction in PVR, a decline in total pulmonary resistance (treatment effect: decline of 193 dynes·s·m^{-5}), with a rise in CI (treatment effect: improvement of 0.3L/m^2 per minute). The bosentan-treated patients also had a decrease in N-terminal pro–brain natriuretic peptide (NT-proBNP) levels relative to patients receiving placebo. However, at 16 weeks, no definable improvement in exercise capacity and no statistically significant treatment effect of bosentan on WHO functional class were observed.[130]

In a double-blind, placebo-controlled, 12-week pilot study, Suntharalingham and associates[131] enrolled 19 patients with inoperable CTEPH and assessed the benefit of sildenafil with 9 patients receiving the drug. Although no significant difference was detected



BOX 26.5 PATIENT GROUPS WITH CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION TO CONSIDER FOR TARGETED MEDICAL THERAPY FOR PULMONARY HYPERTENSION

- Patients with inoperable chronic thromboembolic pulmonary hypertension
- Patients with residual pulmonary hypertension after a pulmonary thromboendarterectomy surgical procedure
- Patients with chronic thromboembolic pulmonary hypertension in whom comorbidities are so significant that surgical treatment is contraindicated.
- Patients who have severe pulmonary hypertension and right-sided heart failure, in whom targeted medical therapy for pulmonary hypertension may be a "clinically stabilizing bridge" to surgical treatment

in exercise capacity (the primary end point), improvements in WHO functional class and PVR were noted. Control subjects were then transitioned to open-label sildenafil use and were reassessed at 12 months. Significant improvements in 6-minute walk distance (6MWD), activity and symptom scores (Cambridge Pulmonary Hypertension Outcome Review [CAMPHOR]), CI, PVR, and NT-proBNP values (1000–811 pg/mL) were noted.[131]

In an open-label study, Reichenberger and colleagues[132] examined the effectiveness of sildenafil (50 mg three times a day) in 104 patients with inoperable CTEPH. After 3 months of therapy, a modest decrease occurred in PVR (863 ± 38 to 759 ± 62 dynes·s·cm^{-5}), with an increase in 6MWD from 310 ± 11 to 361 ± 15 m; this distance further improved to 366 ± 18 m after 12 months of sildenafil.[132]

The use of intravenous epoprostenol in patients with inoperable CTEPH has been examined. Cabrol and associates[133] retrospectively analyzed 27 patients with inoperable CTEPH who were treated with epoprostenol. After 3 months of therapy, decreases in mPAP (56 ± 9 to 51 ± 8 mm Hg) and total pulmonary resistance (29.3 ± 7.0 to 23.0 ± 5.0 U/m^2) and an increase in 6MWD of 66 m occurred. NYHA functional status was improved by at least one class in 11 of 23 patients.[133]

In a single-center uncontrolled observational study,[134] 28 patients with severe, inoperable CTEPH were treated with subcutaneous treprostinil, a prostacyclin analogue. Right-sided heart catheterization was repeated in 19 patients after 19 ± 6.3 months of treatment. Treprostinil therapy was associated not only with a significant reduction in PVR, but also with an improvement 6MWD, WHO functional class, BNP levels, and CO. The 5-year survival rate was 53% compared with 16% in untreated historical control subjects.[134]

Although the long-term benefit of inhaled iloprost, an aerosolized prostacyclin analogue, in patients with inoperable CTEPH has not been examined, an acute pulmonary hemodynamic benefit has been observed. With the administration of 5 μg of inhaled iloprost to 20 patients with CTEPH (12 with distal chronic thromboembolic lesions), Krug and colleagues[135] were able to show a decline in PVR from 1057 ± 404.3 to 821.3 ± 294.3 dynes·s·cm^{-5} and a reduction in mPAP from 50.55 ± 8.43 to 45.75 ± 8.09 mm Hg. This was accompanied by an increase in CO from 3.66 ± 1.05 to 4.05 ± 0.91 L/min. Of the 20 patients, 16 patients were already receiving one or more PAH-specific medical therapies at the time.[135]

Riociguat, a newer agent that stimulates soluble guanylate cyclase, either directly or by increasing the sensitivity of soluble guanylate cyclase to NO, was examined in patients with inoperable CTEPH or with residual PH after PTE (A Study to Evaluate Efficacy and Safety of Oral BAY63-2521 in Patients With CTEPH [CHEST-1] study).[136] This 16-week, randomized, placebo-controlled trial had 261 enrolled patients, 173 receiving riociguat. Those patients receiving the drug experienced an improvement in exercise capacity (6MWD increased by an average of 39 m), whereas those patients in the placebo group showed a decline in 6MWD by an average of 6 m. The treatment group also had an improvement in WHO functional status and a significant reduction in NT-proBNP levels. A decline in PVR of 226 dynes·s·cm^{-5} was measured in patients receiving riociguat (n = 151), whereas those patients in the placebo group showed an increase of 23 dynes·s·cm^{-5} (least square mean difference of −246 dynes·s·cm^{-5}). Significant improvements in CO and mPAPs were also noted in those patients receiving the drug. No significant difference was observed in the incidence of "clinical worsening events" detected between the two groups, and the occurrence of RV failure (3% in each group) and syncope (2% in the riociguat group vs 3% of placebo patients) was comparable.[136] The results of this study provided the basis for approval by the US Food and Drug Administration of riociguat for those patients with inoperable CTEPH and with residual PH following PTE. A subsequent open-label, long-term extension study (BAY63-2521: Long-term Extension Study in Patients With Chronic Thromboembolic Pulmonary Hypertension [CHEST-2]) providing riociguat to those patients previously receiving placebo confirmed the exercise and functional status benefits of this medication for up to a year, with a similar safety profile achieved in CHEST-1.[137]

PH-targeted medical therapy has also been used as bridging therapy in operable patients with CTEPH, the assumption being that if PH and RV function can be improved in high-risk patients, a reduction in postoperative mortality rates may be realized. The first attempt to prove this thesis was made by Nagaya and associates,[138] who administered intravenous prostacyclin at a mean dose of 6 ± 1 ng/kg per minute for 46 ± 12 days before PTE in 12 patients with operable CTEPH, each with a PVR greater than 1200 dynes·s·cm^{-5}. This treatment resulted in a significant preoperative reduction in PVR (1510 ± 53 to 1088 ± 58 dynes·s·cm^{-5}) and a decline in plasma BNP levels. Postoperatively, 1 patient in the treatment group died (8.3%) during the first 30 days; none died in the group of 21 patients with a preoperative PVR lower than 1200 dynes·s·cm^{-5}. Postoperative pulmonary hemodynamic results in both groups of patients were comparable.[138]

More recently, Reesink and colleagues[139] conducted a randomized, controlled, single-blind study using bosentan as a bridge to PTE. Twenty-five patients with operable CTEPH were enrolled, with 13 patients receiving bosentan for 16 weeks. Comparative differences from baseline between the groups, with therapeutic benefit achieved in those patients receiving bosentan, showed a change in PVR of 299 dynes·s·cm^{-5}, mPAP of 11 mm Hg, CI of 0.3 L/min/m^2 and 6MWD of 33 m. However, postoperative pulmonary hemodynamic outcomes were similar between groups of patients (postoperative mPAP and PVR were lower in the bosentan group; this difference did not achieve statistical significance). Similarly, the short-term postoperative clinical course (days in the intensive care unit, ventilator days, occurrence of lung injury) between groups was similar. Three patients died in the no-bosentan group postoperatively, compared with no deaths in the bosentan-treated patients.[139]

A more recent pilot study of 15 patients with operable CTEPH was conducted to assess the effect of preoperative use of bosentan on RV function.[140] Eight of these 15 patients were randomly assigned to receive bosentan in addition to "best standard of care" for 16 weeks, with pretreatment and posttreatment evaluation of RV function and "remodeling" using cardiac MRI. Discernible improvements in RV stroke volume index, RV ejection fraction, RV mass, RV isovolumic relaxation time, and LV ejection fraction were noted. These improvements were accompanied by a change in mPAP (−11 vs 5 mm Hg in the no-bosentan group), and an increase in 6MWD (20 vs −4 m in the no-bosentan group).[140]

Despite these positive trends, existing data have not justified the routine use of PH-targeted medical therapy in patients with operable CTEPH as a bridge to surgical treatment, although logic dictates that a subgroup of patients with CTEPH with severe PH and RV failure may benefit from hemodynamic stabilization before undergoing anesthetic induction and the cardiopulmonary stress of operation. Despite the uncertainties surrounding medical therapy, increasing numbers of patients with CTEPH with surgical disease are given medical treatment

preoperatively. In a retrospective analysis of patients referred for PTE between 2005 and 2007, Jensen and associates[141] reported that the use of medical therapy for PH in patients with operable CTEPH increased from 19.9% of patients in 2005, to 31.9% in 2006, and to 37.0% in 2007. These investigators additionally observed that this practice was associated with a significant delay in time to referral without having a discernible benefit on measured postoperative outcomes.[141]

Percutaneous Balloon Pulmonary Angioplasty

The use of balloon pulmonary angioplasty (BPA) in the management of selected patients with chronic thromboembolic disease has grown. Application of this technique in a patient with CTEPH was first reported in 1988.[142] In 2001, Feinstein and colleagues[143] expanded on this experience and described BPA as an alternative to PTE in patients believed to have surgically inaccessible CTEPH or in patients whose comorbidities precluded surgical consideration. BPA was performed in 18 patients, averaging 2.6 procedures and 6 balloon dilations per patient, with an overall decrease in mPAP (42 ± 12 to 33 ± 10 mm Hg). Improvements in functional status and 6MWD followed at an average of 35.9 months after the initial catheterization. Only one patient died, on postcatheterization day 7, of RV failure. However, the overall postprocedure CI was not significantly improved, the hemodynamic improvement was not comparable to that obtained in patients undergoing PTE, and the rate of reperfusion lung injury after the procedure was considerable. Those patients with a mPAP greater than 35 mm Hg were at greatest risk (incidence of 61%, 3 patients requiring mechanical ventilation).[143] Two years later, a case report described two patients with surgically inaccessible CTEPH who had hemodynamic improvement after BPA; the investigators noted that this procedure could be viewed as an alternative treatment option for patients deemed "not suited" for surgical treatment.[144]

Specialized centers in Japan have reported the greatest experience with BPA. In a prospective study of 12 patients deemed to have nonsurgical CTEPH and "stabilized" with pulmonary vasodilators (including 2 patients with residual PH after PTE), Sugimura and associates[145] performed multiple angioplasty sessions until the mPAP was less than 30 mm Hg. Not only did this approach result in an overall improvement in pulmonary hemodynamics and functional status, but also, when compared with historical controls, showed an improvement in survivorship. Mild-to-moderate hemoptysis was observed in 50% of patients following this procedure.[145] In 68 patients, Mizoguchi and colleagues[146] reported a refinement of the angioplasty procedure in which the selection of appropriate balloon size was made using intravascular ultrasound; the hypothesis was that this technique could reduce the incidence of postprocedure reperfusion lung injury. Although 60% of patients developed a degree of reperfusion injury (including the development of "hemosputum"), improvements in mPAP (45.4 ± 9.6 to 24.0 ± 6.4 mm Hg) and functional status were reported. One patient died of RV failure 28 days following the procedure. Results of right-sided heart catheterization were available in 57 patients at an average of 1.0 ± 0.9 year after the final angioplasty procedure (range, 0.3–7.0 years). The initial hemodynamic benefit was shown to be sustained, and the mPAP in this group was 24.0 ± 5.8 mm Hg.[146]

A report by Kataoka and associates[147] included 29 patients with CTEPH undergoing BPA. This group demonstrated no immediate hemodynamic improvement in 28 of 29 patients. One patient died of wire perforation 2 days after angioplasty. However, in follow-up at 6.0 ± 6.9 months, functional status, plasma BNP levels, and pulmonary hemodynamics (mPAP 45 ± 9.9 to 31.8 ± 10.0 mm Hg, CO 3.6 ± 1.2 to 4.6 ± 1.7 L/min) improved. Reperfusion lung injury complicated 27 of 51 (53%) procedures.[147]

Andreassen and colleagues[148] from Norway reported similar favorable results of performing BPA in patients with CTEPH with inoperable disease or with persistent PH after PTE. In 20 patients undergoing 18.6 ± 6.1 BPA procedures per patient (segmental and subsegmental arteries), a decrease in mPAP (45 ± 11 to 33 ± 10 mm Hg), an increase in CO (4.9 ±1.6 to 5.4 ±1.9 L/min), and a reduction in RV strain as measured by troponin and NT–proBNP levels were observed 3 months after the last BPA procedure. An overall improvement in functional status (cardiopulmonary exercise testing and NYHA functional class) was also noted. However, a 10% periprocedural mortality rate was observed, with reperfusion injury treated with supplemental oxygen and diuretics following seven procedures.[148]

The ultimate role of BPA in the treatment of patients with CTEPH requires ongoing assessment. Appropriate patient selection, the optimal procedural technique to avoid reperfusion lung injury or pulmonary vascular injury, the appropriate timing of repeated BPAs, hemodynamic benefits, and functional improvement must be determined.[149]

Intraoperative Echocardiography in Patients With Chronic Thromboembolic Pulmonary Hypertension

CTEPH results in myriad changes leading to functional and morphologic alterations of both right and left ventricles. Echocardiographic evaluation of patients with CTEPH includes a complete examination of all cardiac structures, to looking for coexisting LV or valvular disease with particular emphasis on the right side of the heart. This examination encompasses evaluation of RV anatomy and function, including dilation and hypertrophy, with attention to leftward ventricular septal motion. Patients with CTEPH may have thrombus throughout the venous circulation, hence requiring a full examination of the right side of the heart. Therefore the midesophageal (ME) four-chamber, ME ascending aortic short-axis, RV inflow-outflow, and bicaval views are essential.

This section provides a brief description of the intraoperative echocardiographic views required for evaluation of a patient with CTEPH who is undergoing a PTE procedure (see Chapters 14 to 17).

The *ME four-chamber* view is the first view used for assessment of RV dilation and hypertrophy, RA size, and tricuspid valve function. The right ventricle exhibits several changes in response to chronic pressure and volume overload to that ventricle. The response seen as a result of chronic increased afterload include volume-adapting dilatory changes, as well as pressure-related changes such as RV enlargement, hypertrophy, and paradoxical septal motion that eventually lead to RV systolic failure.

The normal right ventricle typically occupies two-thirds, in cross-sectional area, of the LV area. With RV enlargement, its size becomes greater than two-thirds, sharing the cardiac apex; whereas with severe enlargement, the right ventricle becomes larger than the left ventricle, thus forming the cardiac apex (Fig. 26.22A). An effective way to assess the right ventricle rapidly is by looking at the makeup of the cardiac apex in the ME four-chamber view.

RV hypertrophy is the compensatory mechanism for the right ventricle to maintain stroke volume in the presence of increased PVR. Normally, RV free wall thickness at end-diastole is 5 mm in diameter. With long-standing severe chronic PH, RV hypertrophy can exceed 10 mm in thickness, and a prominent moderator band may be noted (Fig. 26.22B). This measurement may be obtained in the ME four-chamber, ME RV inflow-outflow, or transgastric midpapillary views, often aided by the use of M-mode echocardiography.

The right ventricle is normally adapted to eject against a low-pressure pulmonary circuit. With acute or chronic elevation in PAP, RV systolic dysfunction ensues. The right ventricle has a characteristic "peristaltic-like" movement beginning with contraction at the inflow portion, followed by the apex, and ending with contraction of the outflow infundibulum. Several modalities have been suggested for evaluating RV systolic function.[150]

Tricuspid annular plane systolic excursion is a measure of global RV systolic function and a prognostic indicator in PH. This excursion is the amount of shortening of the base of the tricuspid valve annulus toward the apex at peak systole, thus measuring the excursion between end-diastole and end-systole. The normal value is more than 16 mm; a value of less than 15 mm is associated with mortality risk.[150,151]

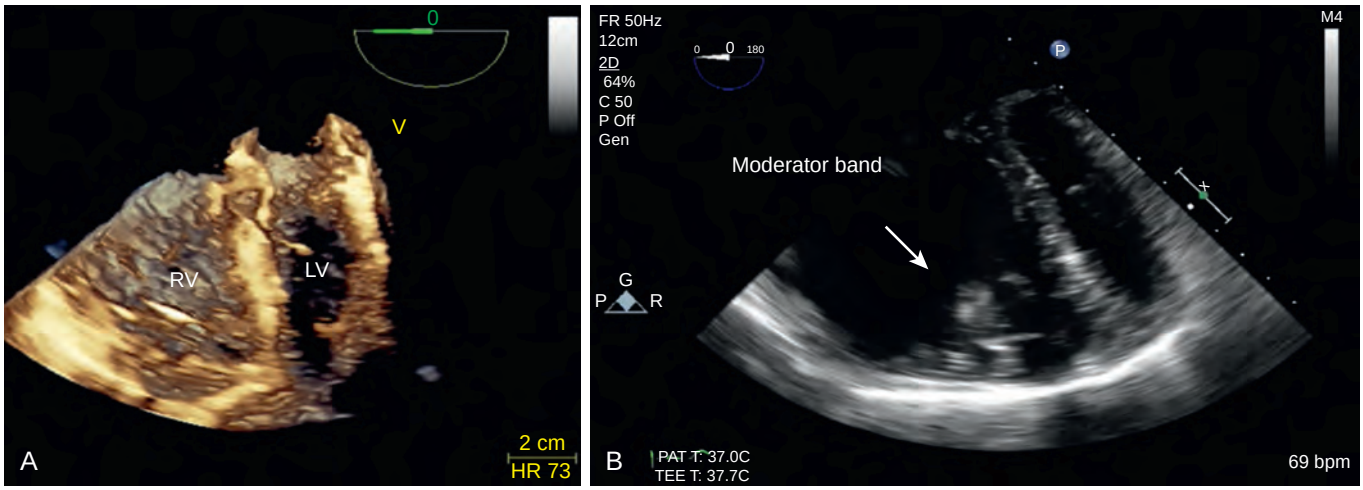


Fig. 26.22 (A) Midesophageal four-chamber view in a patient with severe chronic thromboembolic pulmonary hypertension. Note the dilated and hypertrophied right ventricle *(RV),* which is significantly larger than the left ventricle *(LV).* This is a three-dimensional picture using the General Electric Vivid E9 BT12 system. (B) Midesophageal four-chamber view in two dimensions showing a dilated and hypertrophied RV yielding a prominent moderator band *(arrow)* and an underfilled LV.

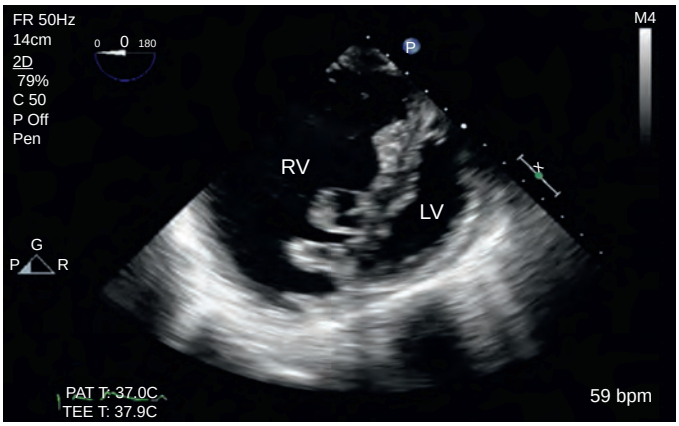

Fig. 26.23 Transgastric midpapillary short-axis view showing flattening of the interventricular septum as a result of right ventricular pressure or volume overload leading to the characteristic D-shaped sign. *LV,* Left ventricle; *RV,* right ventricle.

Interventricular septal motion is seen with RV overload, and it results in flattening of the septum and loss of the natural crescent shape of the RV, thus leading to the characteristic "D-shaped" sign most noticeable in the transgastric midpapillary short-axis view (Fig. 26.23). The right and left ventricles share the interventricular septum, which is usually concave toward the right ventricle during the entire cardiac cycle. Evaluation of the nature and timing of septal flattening relative to diastole versus systole can help differentiate between RV volume overload and RV pressure overload. In conditions characterized by RV volume overload, the septum is flattened at end-diastole, whereas in pressure overload, the septum is flattened at end-systole. With severe CTEPH and pressure overload, right-sided pressures exceed left-sided pressures in both systole and diastole, so the septum may remain deformed throughout the cardiac cycle, a condition that may eventually lead to impaired LV filling and decreased CO (Fig. 26.24). The *eccentricity index* (*EI*) is the ratio of the LV anteroposterior to septolateral diameter of the left ventricle in the transgastric mid–short-axis view.[152] In normal values, the EI has a value of 1 in both systole and diastole. In cases with pressure overload, the EI value is greater than 1 during end-systole, whereas in volume overload it is greater than 1 during end-diastole.[153]

Pulsed-wave Doppler tissue imaging allows evaluation of the peak systolic velocity (S′) of the basal RV free wall in the ME four-chamber view. A peak systolic velocity of less than 10 cm/s suggests abnormal RV function.[150] Pavlicek and associates[153] found that peak systolic velocity correlated well with RV ejection fraction using cardiac MRI.

The *RV myocardial performance index (RV MPI),* also known as the Tei index, is another global assessment of RV systolic and diastolic cardiac performance that combines both systolic and diastolic time intervals.[150] The RV MPI is easily derived using two methods:

1. Pulsed Doppler method from two separate cardiac cycles is used.
2. Tissue Doppler method from a single cardiac cycle. The RV MPI greater than 0.4 by pulsed-wave Doppler and greater than 0.55 by tissue Doppler signifies impaired RV function.[150] The Tei index is simple, noninvasive, and easy to estimate.[154]

Blanchard and colleagues[155] used the Tei index to demonstrate a correlation between improvements in RV function and decrease in the PVR after PTE. The RV Tei index is a valuable parameter for estimating PVR and following disease severity in CTEPH before and after PTE.[154] These investigators were able to demonstrate that patients with CTEPH have an abnormally increased RV Tei index that decreases after successful PTE. Their calculated MPI was 0.52 ± 0.19 in patients with CTEPH, compared with 0.27 ± 0.09 in healthy control subjects ($P > 0.0001$).[155]

Interatrial septum position and motion serve as a surrogate of RV function. In the setting of CTEPH and a failing right ventricle, high right-sided pressure is transmitted to the right atrium, thus leading to dilatation, increasing RA pressure, and shifting the interatrial septum toward the left atrium (Fig. 26.25). In the setting of long-standing PH and overt RV failure, decreased CO leads to increased right-sided volume and diastolic pressure that, when transmitted to the right atrium, causes RA dilatation. Patients with CTEPH often present with pericardial effusions correlating with increased RA pressure. Marked elevations in RV and RA pressures may lead to impaired lymphatic and venous drainage from the pericardium that results in pericardial effusions.[156] Similarly, elevated RA pressure and severe TR may impair coronary sinus drainage and lead to a dilated coronary sinus, best visualized in the deep ME four-chamber view[157] (Fig. 26.26).

Patients with CTEPH with long-standing elevated RA pressure exhibit a higher incidence of PFO than the estimated 25% seen in the adult population. The ME four-chamber, ME RV inflow-outflow, and ME bicaval views are all used to evaluate for PFO, with the aid of color-flow Doppler or agitated saline injection[158,159] (Fig. 26.27).

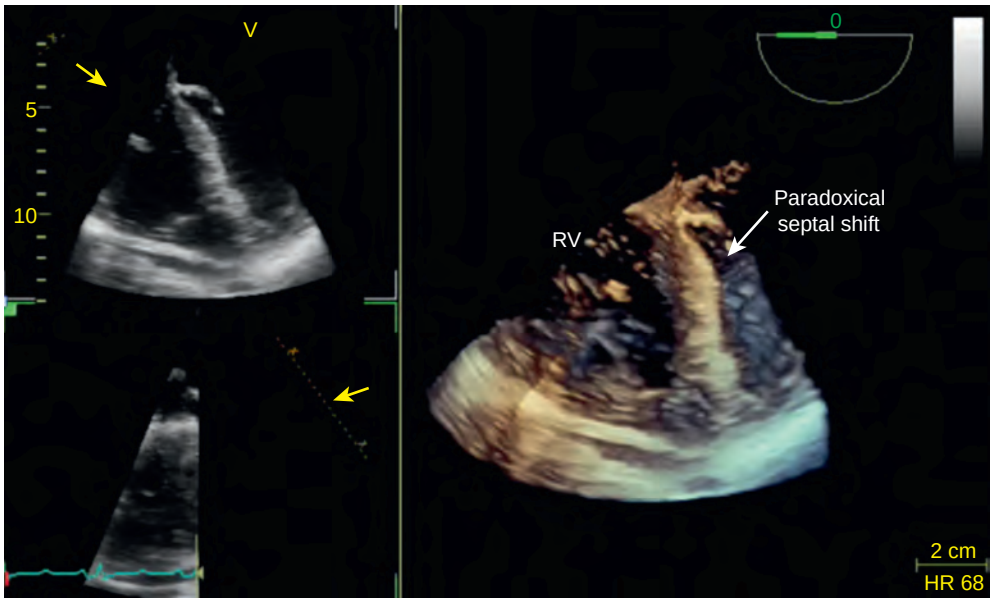

Fig. 26.24 Midesophageal four-chamber view using the General Electric Vivid E9 BT12 system, bird's-eye view showing paradoxical septal shift of the interventricular septum toward the left ventricle in three dimensions *(arrow)*. *HR,* Heart rate; *RV,* right ventricle.

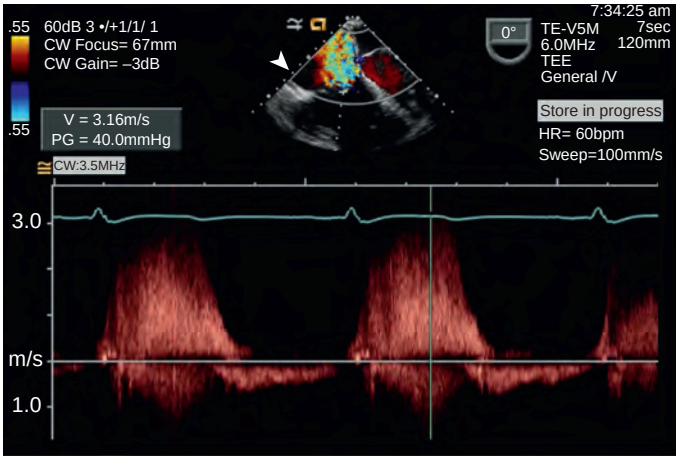

Fig. 26.28 A continuous-wave *(CW)* Doppler used to evaluate the peak regurgitation velocity yields an estimate of pulmonary artery systolic pressure. *HR,* Heart rate.

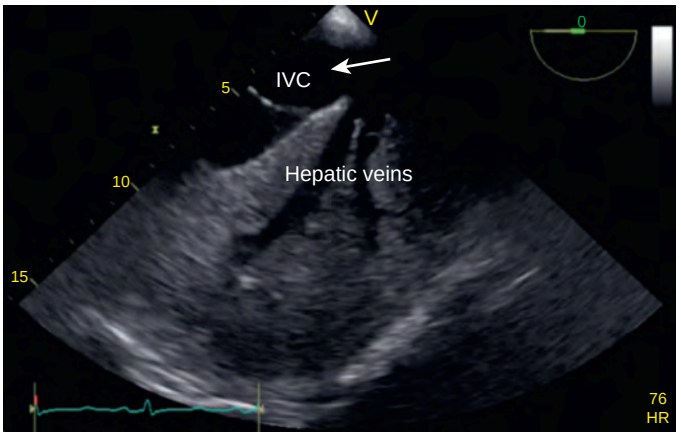

Fig. 26.29 Dilated inferior vena cava (IVC) *(arrow)* and hepatic veins.

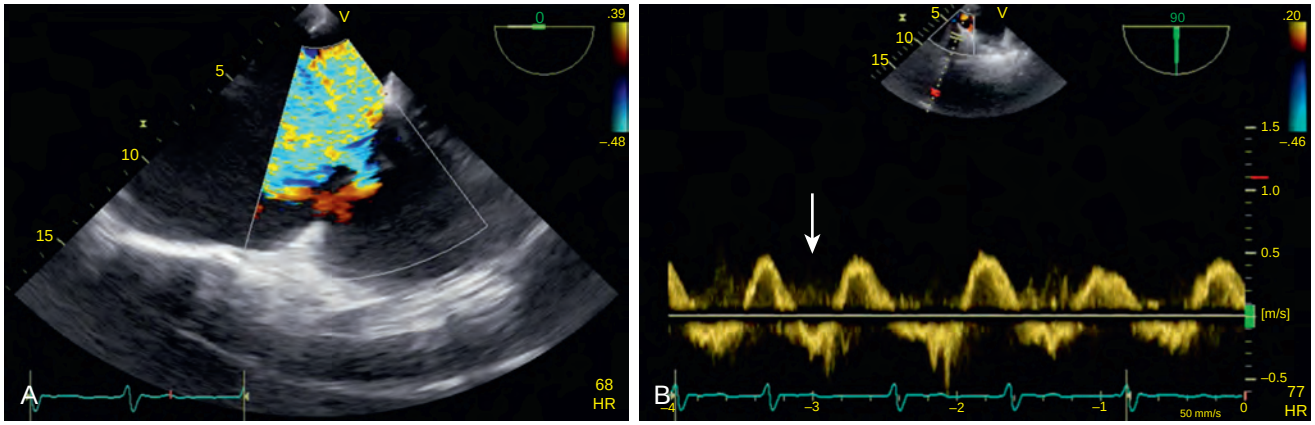

Fig. 26.30 (A) Midesophageal four-chamber view showing a dilated right ventricle with severe tricuspid regurgitation. (B) Hepatic vein reversal, with S-wave reversal *(arrow). HR,* Heart rate.

The *ME RV inflow-outflow* view is often used to assess RV free wall hypertrophy and function, as well as to evaluate peak regurgitation velocity. Systolic PAP can be easily estimated using peak TR velocity (V_{TR}) with continuous-wave Doppler and applying the modified Bernoulli equation ($\Delta P = 4v^2$) with the addition of central venous pressure[150,160] (Fig. 26.28).

It is not uncommon to encounter difficulty in floating the PAC because of severe TR, as well as a dilated right atrium and right ventricle. TEE is routinely used to float the PAC by using the bicaval and ME RV inflow-outflow views.

RA pressure can be approximated by imaging the IVC by echocardiography. The IVC diameter should not exceed 1.7 cm and should collapse by at least 50% during spontaneous inspiration in healthy persons.[161,162] The presence of a dilated IVC and the lack of more than 50% inspiratory collapse implies elevation of RA pressure in the range of 10 to 14 mm Hg. In more severe cases, in which RA pressure is greater than 20 mm Hg, the IVC diameter does not collapse at all with ventilation (Fig. 26.29).

RV failure ultimately leads to RV dilation, with a dilated tricuspid valve annulus together with chordal traction resulting in significant TR. This condition is confirmed by a *vena contracta* greater than 0.7 cm and systolic reversal of hepatic vein flow (Fig. 26.30). Notably, TR does not correlate directly with the degree of PH, but rather with the degree of RV enlargement and alterations in RV geometry. Echocardiography helps appraise the degree of TR before and after surgical treatment. Sadeghi and associates[163] looked at a series of patients with CTEPH undergoing PTE; 19 of 27 patients with baseline severe functional TR with dilated annulus had a significant decrease in TR after PTE without annuloplasty.

The *ME ascending aortic short-axis* and upper esophageal aortic arch short-axis views frequently are used to evaluate the pulmonary vasculature for the presence of clots. Therefore a thorough evaluation throughout the venous system, right side of the heart, and pulmonary vasculature is required (Fig. 26.31A and B). Indirect clues to thrombus formation include a dilated right atrium and right ventricle, intracardiac devices, or the presence of spontaneous echocardiographic contrast. Dilated main PA and RPA are common in CTEPH (Fig. 26.31C).

Mitral valve prolapse (MVP) has been described in patients with CTEPH as "pseudo-MVP." The phenomenon is thought to result from pressure deformation of the left ventricle by the right ventricle, thereby leading to distortion of the mitral valve annulus. The EI was greater for patients with MVP and deformation of the left ventricle compared with patients with no MVP without deformation.[164] Reduction of PH after PTE reversed this deformation and allowed for resolution of "pseudo-MVP."

Impaired LV relaxation seen in patients with CTEPH is largely the result of low LV volume and relative underfilling and is not solely caused by LV chamber distortion secondary to the geometric effects of RV enlargement. LV diastolic filling patterns improve with the resolution of PH after successful PTE. The transmitral E (peak early filling [E-wave]) velocity increases, and pulmonary venous S (systolic forward flow [S wave]) and D (diastolic forward flow wave [D wave])

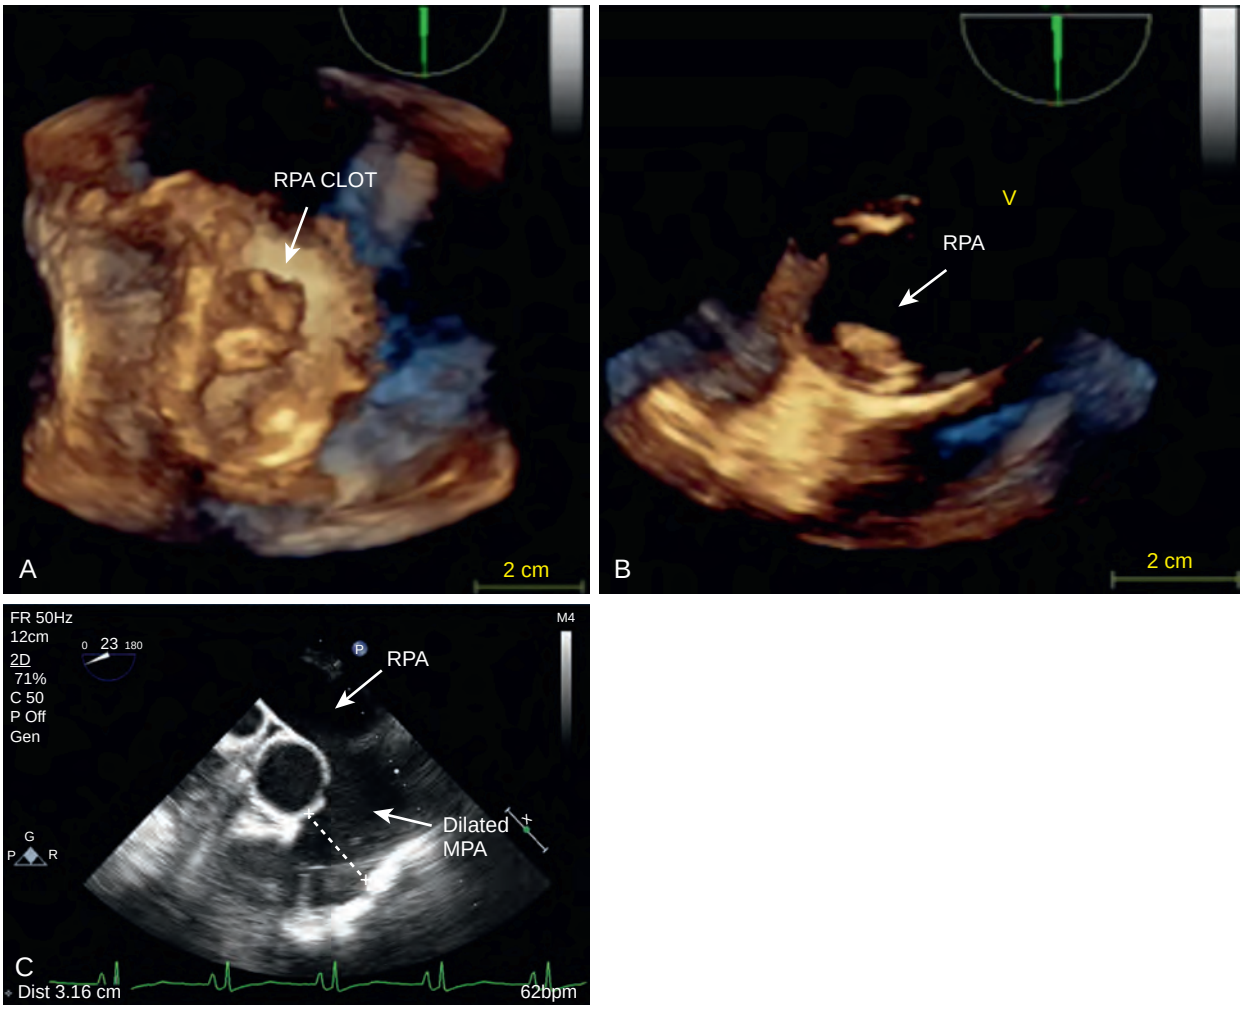

Fig. 26.31 (A) and (B) Right pulmonary artery *(RPA)* clot *(arrows)* in three dimensions using the General Electric Vivid E9 BT12 system. velocity increase significantly, suggesting higher preload with improvement in the CO.[165–167] TEE is critical in the intraoperative management of patients with CTEPH for assessment of the right ventricle, tricuspid valve, right atrium, and intracardiac thrombus or other cardiac disease. It also allows for postbypass cardiovascular evaluation and assessment of de-airing of the cardiac chambers, as well as changes affecting the right ventricle.

Pulmonary Thromboendarterectomy in Patients With Sickle Cell Disease

Management of patients with concomitant SCD and CTEPH presents unique challenges. The PTE procedure requires CPB, profound hypothermia, and periods of circulatory arrest, all of which may promote sickling. Reports noted successful completion of PTE with resolution of PH in two patients with SCD complicated with CTEPH.[168] Moser and Shea[169] and Collins and Orringer[170] confirmed the relationships among pulmonary infarction, cor pulmonale, and sickle cell states. In addition, studies by Sutton and colleagues[171] and Simmons and associates[172] reported 20% to 60% prevalence rates of PH in SCD, respectively. With innovations in the management of patients with SCD and their extended life expectancy, clinicians may expect to see more patients with SCD present with CTEPH.

Previous reports of CPB in adults with SCD involved only patients undergoing valvular or septal repair.[173,174] In contrast, patients undergoing PTE require hypothermia to 18°C to 20°C and circulatory arrest. Sickling and hemolysis during or after CPB are known risks.[175,176] Stagnation of blood, hypothermia, anemia, and acidosis resulting from circulatory arrest are expected to increase the likelihood of sickling.[177]

"Prophylactic" exchange transfusion remains controversial. A multicenter trial comparing conservative exchange transfusion with an aggressive transfusion regimen in patients with SCD found no difference, and the conservative approach resulted in dramatically decreased transfusion-associated complications.[178] In major surgical procedures, it is recommended that the level of hemoglobin S should be reduced to less than 30% and to less than 10% for patients undergoing cardiac operations.[179] Several case reports supported exchange transfusion to reduce hemoglobin S to less than10% when deep hypothermic circulatory arrest will be used,[168,180,181] Investigators have proposed that separating plasma and platelet fractions from the patient's native red cell mass in addition to hemoconcentration during CPB may reduce transfusion requirements after bypass.[180]

At our institution, the bypass system is primed with red blood cells, fresh frozen plasma, and albumin to achieve an estimated hematocrit of 25% in the prime. With initiation of CPB, all the venous blood is drained into two reservoirs. Once the desired volume is collected, the venous return is allowed to pass to the venous reservoir in the normal

fashion. In turn, the drained blood is passed through the cell salvage device, and the blood and plasma are separated with the objective of saving all the plasma components and discarding the red blood cells. The plasma products are saved in sterile fashion in a large bag and are returned to the pump circuit just before weaning from CPB. All the excess volume is hemoconcentrated. With this technique, platelet function is well preserved, and postpump hemostasis has been excellent.[180–182]

Tissue hypoxia incites sickling because of increased viscosity from a deoxygenated form of sickle hemoglobin and sickle cell adhesion to endothelial cells. Particular attention should be paid to various hypoxic complications such as atelectasis and reperfusion pulmonary edema during the postoperative period, and oxygen saturation should be maintained at or greater than 95% throughout hospitalization.

Patients with SCD who present for PTE should undergo thorough preoperative evaluation and preparation for operation, with particular attention to correction of anemia, early screening for antibodies in blood typing, preoperative and intraoperative exchange transfusion, maintenance of oxygenation and blood flow to limit end-organ ischemia, maintenance of normal acid-base status, and limitation of the duration of circulatory arrest periods.

Outcome and Future of Chronic Thromboembolic Pulmonary Hypertension

With increased awareness of CTEPH and with several major cardiovascular centers around the world performing the procedure, progress in surgical and medical management has improved outcomes.

The reported world literature on this operation (exclusive of UCSD) is more than 3000 cases. The mortality rate at UCSD has declined significantly from 16% in the 1980s to 1.3% by 2012, and despite a patient population at higher risk, the mortality rate declined to 1% to 2 % (Fig. 26.32). This change likely reflects the evolution and refinements in all aspects of patient care: Correct preoperative diagnosis, meticulous preparation for operation, advances in surgical and anesthetic technique, and improved postoperative management. The secret to the success of this procedure is the close collaboration of multiple medical teams, including pulmonary medicine, anesthesiology, perfusion, and cardiac surgery.

Efforts from the international community have put forth a prospective registry for long-term follow-up and continued awareness of CTEPH.[183] PTE has revolutionized the treatment of CTEPH, by providing significant and permanent lifestyle improvements.[184] With increased awareness of the disease, excellent surgical outcomes in specialized centers, and innovations in medical therapy, treatment of severe PH resulting from CTEPH is now within reach of many patients around the world. However, many questions remain to be answered through future studies and innovations.

Procedures in the Hybrid Operating Room

WASEEM ZAKARIA AZIZ ZAKHARY, MD | JOERG KARL ENDER, MD

KEY POINTS

1. A hybrid operating room combines advanced imaging capabilities with a fully functioning operating suite.
2. Transcatheter aortic valve replacement (TAVR) is recommended for patients with severe symptomatic aortic stenosis who are inoperable or at high risk for needing surgical aortic valve replacement and have a predicted post-TAVR survival of more than 12 months.
3. Vascular complications are the most common complications with the transfemoral approach.
4. The concept of multimodal imaging plays an important role in preprocedural assessment.
5. The presence of a heart team is a prerequisite for establishing a TAVR program.
6. Catheter-based mitral valve repair techniques are primarily guided by transesophageal echocardiography.

Hybrid operating rooms (ORs) were conceived 2 decades ago. They were first designed to combine percutaneous coronary interventions (PCIs) and stent implantations with minimally invasive coronary artery bypass grafting (CABG) procedures. However, widespread building of hybrid ORs started only after the development of transcatheter valve replacements.[1] After the first report of successful percutaneous balloon valvuloplasty in patients with severe aortic stenosis (AS) in 1983,[2] the first human transcatheter aortic valve replacement (TAVR) was performed in 2002.[3] Despite high costs and structural complexity, there has been a steady increase in new hybrid ORs as a result of the development of more and more percutaneous interventions, which require a facility that combines the capabilities of the angiographic catheterization laboratory with the cardiac surgical OR. Typical procedures performed in the hybrid ORs include TAVR, percutaneous mitral valve repair, thoracic endovascular aortic repair (TEVAR), percutaneous pulmonary valve implantation, implantable pacemaker and cardioverter-defibrillator lead explantations, and combined coronary and valve procedures.

Technical Considerations

Definition of a Hybrid Operating Room

A hybrid OR combines advanced imaging capabilities with a fully functioning operating suite. This means that angiographic, fluoroscopic, and other imaging capabilities (eg, computed tomography [CT], echocardiography) are integrated into a cardiac OR.[4]

Equipment and Layout

In addition to components of a surgical suite, the following features should be available[4–6]:

1. High-quality fluoroscopy (generally with flat-panel imaging) in a lead-lined room.
2. Integration of other modalities such as a biplane system, C-arm CT, integrated ultrasound, and electromagnetic navigation systems (optional).
3. A control area for radiologic technicians either inside or outside of the hybrid OR with a direct view to the surgical field.
4. A radiolucent, thin, nonmetallic carbon fiber operating table that can accommodate both angiography and open operations. It must also be integrated to the imaging system to avoid collisions. Because of lack of metal parts, some operating table functions are lost, such as isolated movement of upper or lower parts of the patient's body. Nevertheless, a floating tabletop with multidirectional tilt function is needed for accurate catheter maneuvering.
5. Adequate room size (800 square feet [74.3 m^2] to 1000 square feet or more) to accommodate the equipment required by cardiac or vascular surgeons and interventional cardiologists, as well as the anesthesia team, nursing team, perfusionist, and radiologic technicians. Careful equipment positioning is required to allow fast conversion to conventional surgery if needed.
6. Ceiling-mounted monitors placed in positions that allow all team members (surgeons, anesthesiologists, and interventionists) to visualize the images simultaneously. Images from angiography, echocardiography, and hemodynamic monitoring need to be displayed.
7. Circulating heating, ventilation, and laminar air flow to provide a smooth undisturbed air flow suitable for conventional surgical operations.
8. Adequate high-output lighting for surgical interventions.
9. Other inevitable requirements such as adequate number of power receptacles, gas and suction outlets for both the anesthesia machine and the cardiopulmonary bypass (CPB) system, and hot and cold water outlets for the CPB.
10. Equipment: high-definition displays and monitors, oxygen (O_2) analyzer, suction, O_2 supply, defibrillator/resuscitation cart, echocardiographic equipment, sonographers, anesthesia equipment, CPB equipment, syringe pumps, radiation protection (along with the imaging system), blood warmers and blood bank access, point-of-care laboratory monitoring for blood gases and coagulation parameters, and so on. Because of the life-threatening complications that may be encountered during the procedure, ready-made crash carts consisting of any equipment necessary in an emergency must be available.
11. A complete sterile environment.

An example of the hybrid room setup is shown in Fig. 27.1.

In 2012, the Society for Cardiovascular Angiography and Interventions (SCAI), American Association for Thoracic Surgery

Fig. 27.1 View of a hybrid cardiovascular operating room. The cardiopulmonary bypass circuit is on the far right with its own boom. The operating table is in the middle of the picture, with a floor mounted, fixed biplanar C-arm to the left. *(Courtesy of Alfred I. Dupont Hospital for Children.)*

(AATS), American College of Cardiology Foundation (ACCF), and The Society of Thoracic Surgeons (STS) together published guidelines on hybrid ORs and TAVR. These guidelines did not make the hybrid OR a prerequisite for TAVR or other procedures but allowed for the procedure to be done in a cardiac catheterization laboratory (CCL), an OR, or a hybrid OR located in either the OR suite or a CCL area.[5,7]

Whereas in the United States, 57% of TAVRs were performed in hybrid ORs,[8] in France, 72.7% were done in CCLs.[9] In the United States, hybrid ORs are located either in CCL areas or conventional OR suites, and many centers have hybrid ORs in both locations.[10]

Imaging Systems

Fluoroscopy

Fluoroscopy may be portable or fixed. In general, fixed systems enable higher imaging quality and less radiation exposure compared with portable systems. The fixed C-arm may be mounted on the ceiling or the floor. Ceiling-mounted systems do not occupy OR floor space, but they need higher ceilings, which affects lighting, monitor placement, and laminar air flow. While these disadvantages can be avoided using floor-mounted systems, this comes at the cost of the available floor space. The fluoroscopy operating system generates a considerable amount of heat and noise and it is suitable to put it outside the hybrid OR.[4]

Rotational Angiography

Many of these units have additional properties. Some can rotate fully around the patient and provide cross-sectional or three-dimensional (3D) data in a few minutes. This 3D C-arm CT (eg, Dyna-CT, Siemens, Germany)[11] (also called in-room C-arm CT with rotational angiography)[12] can assist in positioning for TAVR, especially in patients with poor calcification at the annulus, by overlaying a real-time two-dimensional (2D) image and helping to navigate the anatomy. In addition, this technique reduces the amount of contrast agent used during complex endovascular aneurysm repairs with branched grafts[4,13] or TAVR.[12] This technique was found to be comparable to multidetector CT (MDCT) with regard to final valve-visualization angle.[14,15]

Digital Subtraction Angiography

This technique is used to visualize the blood vessels and identify any abnormalities without interference from background structures. In TAVR, it is used for identification of the coronary arteries immediately before valve implantation.

Echocardiography

Transesophageal echocardiography (TEE) is used during TAVR pre-, intra-, and postprocedures for diagnosis of the disease and complications. Real-time 3D TEE can be a helpful tool that facilitates maneuvering of the delivery system and proper positioning of the aortic prosthesis.[12] Transthoracic echocardiography (TTE) may be used in interventions performed under monitored anesthetic care (MAC) in which TEE is not possible.

Systems that allow image fusion of different imaging modalities can be integrated to optimize visualization during interventions (ie, C-THV Paieon, New York, N.Y.; HeartNavigator Philips Healthcare, Andover, Mass) and ValveAssist (GE Healthcare, Little Chalfont, UK).[6] In the future, an electromagnetic navigation system may be integrated in imaging and guidance for TAVR.[16]

Radiation Safety

The most important aspect of radiation safety is education. The whole team must understand how to reduce the radiation dosage and exposure. Certain safety measures should be available during procedures. Hybrid ORs must have lead-lined walls and doors. Both portable and built-in shielding for personnel must be considered during design of a hybrid OR. Moreover, lead aprons must be attached to the table. Enough lead aprons must be hung in a dedicated space outside the hybrid OR for all personnel. Finally, the radiation exposure should be measured regularly for all personnel.[4]

PROCEDURES

Transcatheter Aortic Valve Replacement

Patient Selection and Indications

According to European and American guidelines, TAVR is recommended for patients with severe symptomatic AS who are inoperable or at high risk for needing surgical AVR and have a predicted post-TAVR survival of more than 12 months.[7,17,18] High-risk patients are generally defined as those with an STS score of 10% or European System for Cardiac Operative Risk Evaluation (EuroSCORE) of 20%.[19] According to the American Heart Association (AHA) and the American College of Cardiology (ACC), high risk is defined as STS predicted risk of mortality (PROM) 8% or higher; or two or more indices of frailty (moderate to severe); or up to two major organ systems compromised, not to be improved postoperatively; or possible procedure-specific impediment (Table 27.1).[17]

The approach to patient selection for TAVR is optimal with a multidisciplinary team (MDT)[20] that includes a primary cardiologist, cardiac surgeon, interventional cardiologist, echocardiographer, imaging specialists (CT or cardiac magnetic resonance [CMR]), heart failure and valve disease specialist, cardiac anesthesiologist, nurse practitioner, and cardiac rehabilitation specialists.[7] At minimum, cardiologists, cardiac surgeons, cardiac anesthesiologists, and an imaging specialist should be involved in daily clinical practice.

The following issues must be discussed during the patient selection process:

1. Indication for AVR, either surgical or TAVR
2. Risk assessment and indication for TAVR
3. Feasibility of the procedure for specific patient and choice of most proper access (eg, severe peripheral arterial disease)
4. Selection of specific valve type and size for the individual patient

TABLE 27.1 Risk Assessment for TAVR Candidates

	Low Risk (Must Meet All Criteriain This Column)	*Intermediate Risk (Any One Criterion in This Column)*	*High Risk (Any One Criterion in This Column)*	*Prohibitive Risk (Any One Criterion in This Column)*
STS PROM*	<4% *and*	4%–8% *or*	>8% *or*	Predicted risk with surgery of death or major morbidity (all-cause) *or*
Frailty	None *and*	One index (mild) *or*	>Two indices (moderate to severe) *or*	>50% at 1 yr *or*
Major organ system compromise†	None *and*	One organ system *or*	No more than two organ systems *or*	>Three organ systems *or*
Procedure-specific impediments‡	None	Possible	Possible	Severe

PROM, Predicted risk of mortality; *STS,* The Society of Thoracic Surgeons; *TAVR,* transcatheter aortic valve replacement.
†Not to be improved postoperatively.
‡Examples: tracheostomy present, heavily calcified ascending aorta.
Modified from Nishimura RA, Otto CM, Bonow RO, et al. 2014 AHA/ACC Guideline for the Management of Patients With Valvular Heart Disease: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Thorac Cardiovasc Surg.* 2014;148:e1–e132.

Other factors that may affect the decision-making process include availability, experience, and institutional commitment to managing very high-risk patients, technical skills, local results, referral patterns, and patient preference.

Indication for Aortic Valve Replacement: Surgical or Transcatheter

Diagnosis of AS should not differ according to whether or not a minimally invasive technique is chosen but should be made according to established guidelines.[17,21] Echocardiography and, to some extent, cardiac catheterization are the main diagnostic tools for AS. The echocardiographic criteria to define severe AS include decreased systolic opening of a calcified or congenital stenotic valve with an aortic valve area (AVA) of 1.0 cm^2 or less, indexed AVA 0.6 cm^2/m^2 or less, aortic velocity 4.0 m/s or higher, and/or a mean transvalvular pressure gradient of 40 mm Hg or higher. Symptomatic patients may have heart failure, syncope, exertional dyspnea, angina, or presyncope by history or on exercise testing. AVR is recommended for asymptomatic patients provided that left ventricular ejection fraction (LVEF) 50% or less (Fig. 27.2).[17] Stress echocardiography may be useful during the assessment of low-flow/low-gradient AS.[7] If stress results in increases in stroke volume and AVA larger than 0.2 cm^2 with little change in pressure gradient, it is not severe AS; with true severe AS, patients have a fixed valve area with increases in stroke volume and pressure gradient during a stress state[19] (see Chapters 3 and 21).

Risk Assessment and Indication for TAVR

The recommendations and the data regarding TAVR can be found in the registry experience or from randomized controlled trials.[22] Several multicenter registries, including SAPIEN valves (Edwards Lifesciences, Irvine, Calif) and CoreValves (Medtronic Minneapolis, Minn), have reported outcomes with TAVR. The patient selection criteria and the definitions of events and outcomes vary among these registries, which makes comparisons difficult[7]; however, they provide an overview of indications, complications, and mortality. These registries include the SAPIEN Aortic Bioprosthesis European Outcome (SOURCE) registry,[23] FRench Aortic National CoreValve and Edwards (FRANCE 2),[9] and the German Aortic Valve Registry (GARY).[24]

Placement of AoRtic TraNscatheER valves (PARTNER) trial was designed as a prospective, unblinded, randomized, controlled, multicenter pivotal trial evaluating the safety and effectiveness of the SAPIEN transcatheter aortic valve, in which two patient populations were involved: Cohort A were operable high-risk patients, and Cohort B were inoperable patients. All patients were followed during the hospitalization, at 30 days, 6 months, 1 year, and yearly thereafter. Recently, a group Cohort C was defined as a subset of the inoperable group with relatively poor survival and quality of life, despite TAVR. Comorbidities that defined Cohort C included frailty, malnutrition, cachexia, recent malignancy, stroke, dementia, and dialysis.[25] In Cohort B, there was a 50% decrease in mortality with improvement of all secondary end points. However, there was an increase in strokes,[26] bleeding, and vascular complications. The 30-day mortality in Cohort A was 3.4% and 5% in Cohort B. The risk of clinically apparent major stroke was 3.8% at 30 days and 5.1% at 1 year among the TAVR group compared with 2.1% and 2.4%, respectively, in the surgical group.

In the Medtronic CoreValve U.S. Pivotal Trial, patients were allocated into either an extreme-risk cohort (similar to Cohort B inoperable patients in the PARTNER trial) or a high-risk cohort (similar to PARTNER Cohort A). The incidence of complications used end-point definitions according to the Valve Academic Research Consortium (VARC), aiming for definition uniformity and standardization.[27]

The two most commonly used scores for risk assessment are the STS risk score[28,29] and the EuroSCORE and the related logistic EuroSCORE.[30] Both scores can be calculated online at: http://riskcalc.sts.org and http://www.euroscore.org, respectively. Both scores were used in the PARTNER clinical trials. The EuroSCORE II was recently developed and found to have better predictive capability compared with the logistic EuroSCORE for both surgical AVR and TAVR[31–34]; however, its use was questioned by one study.[35] A simple risk tool (the OBSERVANT Score) consisting of seven parameters for mortality prediction 30 days after TAVR was also developed.[36] Most of these scores were not developed specifically for TAVR, and specific factors that may affect TAVR decisions are not included, such as porcelain aorta, frailty, and TAVR access and approach. These risk scores must be used along with clinical judgment and the heart team's experience during the process of patient selection.

Five risk factors have special importance, either because of their impact on outcome or because they are not presented in risk models in spite of their prevalence. These factors are chronic kidney disease, coronary artery disease, chronic lung disease, mitral valve disease, and systolic dysfunction.[37] Some patients are generally eligible for surgical AVR, but because of local disease abnormalities they may be scheduled for TAVR (eg, severe calcification of ascending aorta, porcelain aorta, friable aortic atheroma, and previous radiation therapy to the mediastinum).[7]

Two other factors that may affect the decision on surgery are (1) very elderly with associated comorbidities, and (2) frailty and futility. Frailty, although it can have significant overlap with disability and comorbidity in old age, is a distinct syndrome with a vicious cycle. It includes decreasing muscle mass, decreasing energy expenditure, and malnutrition, which result in decreased physiologic reserves and resistance to stressors with increased vulnerability to adverse outcomes[38–40] (Table 27.2). Futility means that the clinical condition is too far advanced to be improved even with a successful procedure, and TAVR is not recommended for these patients.[17]

Recent updates to the STS risk score, including frailty as graded by the 5-meter walk test, porcelain aorta, previous radiation therapy, oxygen therapy, and liver disease as graded by the model for end-stage liver disease, were added to increase the reliability of the score with regard to TAVR.[41]

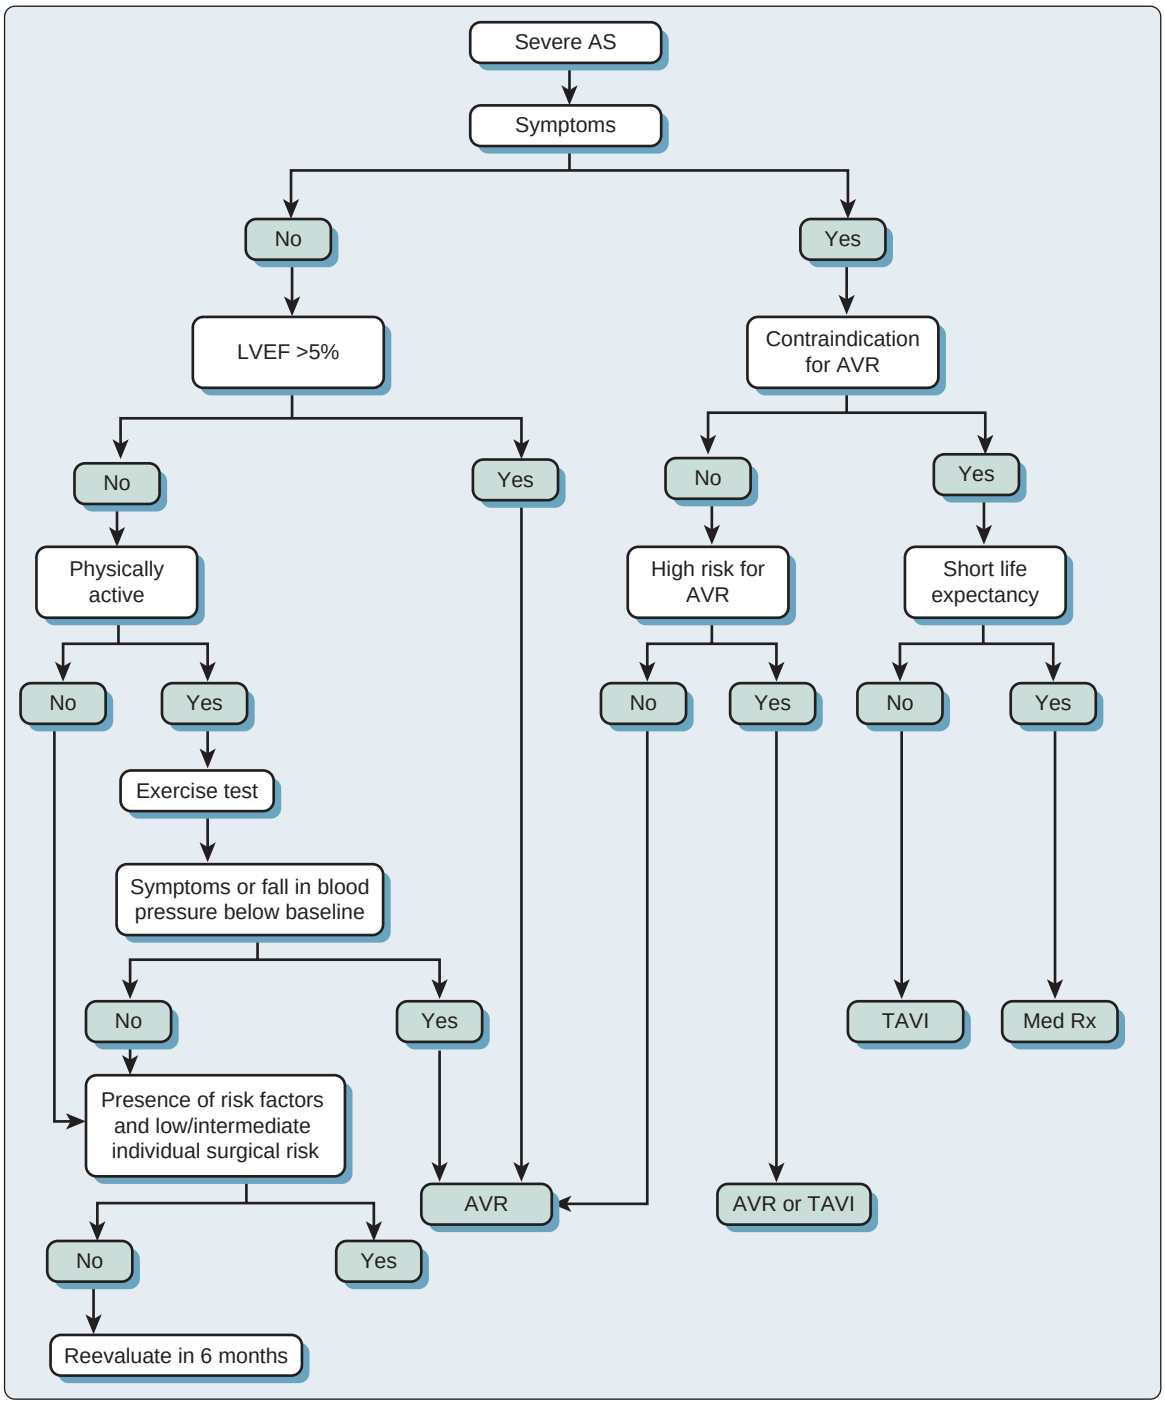

Fig. 27.2 Management of severe aortic stenosis. *AS*, Aortic stenosis; *AVR*, aortic valve replacement; *LVEF*, left ventricular ejection fraction; *TAVR*, transcatheter aortic valve replacement. *(Modified from Vahanian A, Alfieri O, Andreotti F, et al. Arnold and colleagues took a step forward when they considered postoperative poor quality of life as a poor outcome for the procedure. They demonstrated that the most important predictors of poor outcomes were poor functional capacity (as measured by the 6-minute walk test) and lower mean aortic valve gradients.[42,43] Risk assessment algorithms that incorporate hard clinical end points along with quality-of-life measures are likely to become instrumental in the assessment of patients referred for TAVR.[6]

The inclusion and exclusion criteria have been subjected to many modifications as a result of advances in technology and the specifications of next generation valves. Other clinical and anatomic contraindications also must be considered such as valve endocarditis, elevated risk of coronary ostium obstruction (asymmetric valve calcification, short distance between annulus and coronary ostium, small aortic sinuses), and untreated coronary artery disease requiring revascularization[18] (Box 27.1).

TABLE 27.2 Suggested Parameters or Tests to Evaluate Frailty in Patients Referred for TAVR

Frailty Tests or Assessment	*Description*
Grip strength	Dynamometer Abnormal: <30 kg in nonobese males and <18 kg in nonobese females
Gait speed	>7 s to walk 5 m
6-min walk	Abnormal: walk <128.5 m during 6-min walk
CAF	Grip strength, gait speed, instrumental activities of daily living questionnaire, standing balances test, serum albumin, brain natriuretic peptide and creatinine
MGA	Mini-mental state exam, basic and instrumental activities of daily living questionnaires

CAF, Comprehensive Assessment of Frailty[39]; *MGA,* Multidimensional Geriatric Assessment[40]; *TAVR,* transcatheter aortic valve replacement.

Feasibility of the Procedure for Specific Patients and Choice of Access

Access routes for TAVR include transfemoral, transapical,[44] transaortic (via left anterior minithoracotomy or ministenotomy), suprasternal (aortic/innominate),[45] transcarotid,[46,47] or axillary and subclavian.[48] Caval-aortic access also has been described for TAVR, wherein percutaneous entry is obtained into the abdominal aorta from the femoral vein through the adjoining inferior vena cava.[49] Recently, Cribier performed TAVR through the transseptal route in the absence of suitable iliofemoral access. All of these routes are retrograde except for transapical and transseptal approaches, which are antegrade[6] (Table 27.3).

The most common approaches are transfemoral and transapical. The alternative routes described earlier were investigated only in trials with relatively small patient numbers. In spite of good short-term outcome studies, larger sample sizes and longer follow-up times are needed for these alternative access approaches.[52]

The primary access route is transfemoral as long as the diameter of the femoral vessels are 6 to 8 mm or larger and the degree of atherosclerosis allows.[53] Transfemoral access was compared with transapical

TABLE 27.3 Different Approaches for TAVR

	Retrograde			Antegrade	
	Transfemoral	*Transaortic/Subclavian*	*Transcaval*	*Transseptal*	*Transapical*
Prosthesis	SAPIEN or CoreValve	SAPIEN or CoreValve	SAPIEN or CoreValve	SAPIEN or CoreValve	SAPIEN only
Access	Femoral artery	Aorta (mini-sternotomy) or subclavian artery	Femoral vein into IVC, then abdominal aorta	Femoral vein into IVC	Cardiac apex (mini-thoracotomy)
Type of anesthesia	Sedation (MAC) or general Anesthetic	General anesthetic	General anesthetic	General anesthetic	General anesthetic (less often: thoracic epidural)
Echocardiography	Transthoracic	Transesophageal	Transesophageal	Transesophageal	Transesophageal
Postoperative disposition	Variable, institution dependent: step-down, monitored (telemetry) Setting	Intensive care unit or PACU	Intensive care unit or PACU	Intensive care unit or PACU	Intensive care unit or PACU

IVC, Inferior vena cava; *MAC,* monitored anesthesia care; *PACU,* postanesthesia care unit; *TAVR,* transcatheter aortic valve replacement.

BOX 27.1 INCLUSION CRITERIA AND CONTRAINDICATIONS FOR TAVR

Inclusion Criteria

- Calcific aortic valve stenosis
- Echocardiography: Mean gradient >40 mm Hg or jet velocity >4.0 m/s and AVA <0.8 cm^2 or indexed EOA <0.5 cm^2/m^2
- High risk for conventional AVR assessed by one cardiac interventionist and two experienced cardiothoracic surgeons
- Symptomatic

Contraindications (Candidates Will Be Excluded if Any of the Following Conditions Are Present)

- Absolute
  - Absence of a heart team and no cardiac surgery on the site
  - Appropriateness of TAVR, as an alternative to AVR, not confirmed by a heart team
- Clinical
  - Estimated life expectancy <1 year
  - Improvement of quality of life by TAVR unlikely because of comorbidities
  - Severe primary associated disease of other valves with major contribution to the patient's symptoms, which can be treated only by surgery
- Anatomic
  - Inadequate annulus size (<18 mm, >29 mm) (when using the current devices)
  - Thrombus in the left ventricle
  - Active endocarditis
  - Elevated risk of coronary ostium obstruction (asymmetric valve calcification, short distance between annulus and coronary ostium, small aortic sinuses)
  - Plaques with mobile thrombi in the ascending aorta or arch
  - For transfemoral/subdavian approach: inadequate vascular access (vessel size, calcification, tortuosity)
- Relative
  - Bicuspid or noncalcified valves
  - Untreated coronary artery disease requiring revascularization
  - Hemodynamic instability
  - LVEF <20%
  - For transapical approach: severe pulmonary disease, LV apex not accessible
  - Mixed aortic valve disease (aortic stenosis and aortic regurgitation with predominant aortic regurgitation >3+
  - Hypertrophic cardiomyopathy
  - Severe incapacitating dementia
  - Renal insufficiency (creatinine >3.0 mg/dL) and/or end-stage renal disease requiring chronic dialysis
  - Severe pulmonary hypertension and RV dysfunction

AVA, Aortic valve area; *AVR,* aortic valve replacement; *EOA,* effective orifice area; *LVEF,* left ventricular ejection fraction; *RV,* Right ventricle; *TAVR,* transcatheter aortic valve replacement.

access and the results were the same according to the PARTNER trial and various other national trials. It seems that because of a "transfemoral first strategy," there may be a selection bias resulting in selection of nontransfemoral access routes for higher risk patients.[54]

Vascular complications are the most common complications with the transfemoral approach and are due to large caliber devices and the atherosclerotic disease of the patients. Peripheral vascular diseases with related vascular calcification, narrow arterial diameter, tortuosity and intramural thrombus or dissection are the most important factors. Planning access requires assessment of the luminal size and the degree of vessel calcification and tortuosity. The high-quality thin-slice CT scan with contrast that extends from the femoral artery to the subclavian artery is considered the key study in this context. Angiography and intravascular ultrasound may be adjuvants.[55] Limitations of the transfemoral approach will be fewer with the use of the newer generation lower-profile valves and reduction in the size of the delivery sheath. Subclavian access is an alternative approach for TAVR with less reported vascular injury, but rare brachial plexus neuropathies have been reported. Left subclavian artery access could be an unsuitable choice for patients who have undergone a previous CABG with left internal mammary anastomosis, because of the risk of myocardial ischemia during temporary occlusion of the artery.[7]

The transapical and direct aortic approaches are comparable. Both have the disadvantage of being a surgical technique that violates the chest wall and the advantage of avoiding the aortic arch with a theoretical reduction of stroke incidence. Moreover, because the distance from the entry point to implantation is short, implantation is easier and more accurate.[55]

The transapical approach has the risk of ventricular rupture and life-threatening bleeding. The concept of multimodal imaging plays an important role in preprocedural assessment, not only in helping determine the feasibility of the procedure but also in evaluating the access size and the size of the aortic annulus.[56] This includes angiography and cardiac catheterization, echocardiography, MDCT, and magnetic resonance imaging (MRI).[37] Some relative or absolute contraindications may be discovered during imaging, such as a bicuspid valve, left ventricular (LV) thrombus, significant mitral regurgitation with mitral annulus calcifications, a substantially high anatomic risk for coronary ostial obstruction (<10 mm), and infective endocarditis.[19]

Selection of Specific Valve Type and Size for the Patient

Because of the variety of the valves present on the market now, many cardiologists use the concept of "anatomy-dependent" valve selection. The close proximity to the coronary ostia, the width and height of the sinuses, the membranous ventricular septum with the His bundle, and the anterior leaflet of the mitral valve are important anatomic considerations.

Imaging techniques play a major role in:

- Identifying suitable prosthesis size.
- Measuring the distance of the coronary ostia from the aortic annulus to avoid occlusion by the valve stent (>11 mm).
- The diameter of the tubular aorta 45 mm from the aortic valve annulus in case of CoreValve use, which is designed to have a frame with hooks deployed in the supraannular aorta. This diameter must be less than 40 to 45 mm according to valve size.[7]
- Presence of atheroma in the thoracic aorta.
- Other valve dysfunctions, especially mitral regurgitation.
- Left ventricular outflow tract (LVOT) and septal hypertrophy
- Diameter of the femoral vessels

Prosthesis size: Slight oversizing is required for prevention of dislocation of these sutureless valves. Undersizing may lead to paravalvular regurgitation or valve embolization, whereas oversizing may lead to incomplete valve deployment or annular rupture. Contrast CT measurement is the ideal technique for aortic annulus sizing before TAVR; the annulus is larger than that measured by TEE by 1.5 ± 1.6 mm.[57]

Three-dimensional TEE measurements have been shown to be superior to 2D TEE measurements and correlate closely with those from MDCT.[58,59] TTE underestimates the annulus size by up to 15% or 1.36 mm.[7,59,60] The 3D TEE is also very accurate in measuring the true aortic annulus diameter via proper alignment of the short and long axes of the aortic valve[57] (Fig. 27.3). It should be used whenever CT is not available.[58] Sizing using cardiac MRI also may be an alternative to CT.[61] For example, patients with heavy annulus calcification, annulus eccentricity, and aorta-LVOT angle are more predisposed to have residual paravalvular leak after CoreValve implantation, but the CoreValve is preferable if the coronary ostia are very low and close to the annulus.[62] Operator experience is the main factor in valve selection.[6]

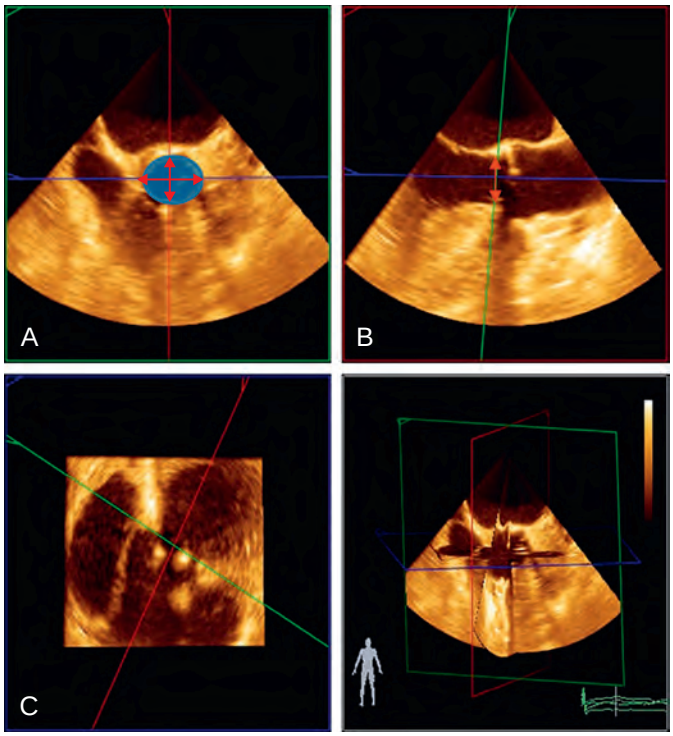

Fig. 27.3 Multiplanar reconstruction from a real-time three-dimensional transesophageal echocardiography of the aortic valve showing (A) the transverse, (B) the sagittal, and (C) the coronal axes. *Red arrows* indicate the annulus measurement.

In the absence of severe atherosclerosis and severe vascular tortuosity, femoral artery size is considered the main limiting factor in determining the most suitable route for TAVR. Sheaths allow access to the vessel without loss of blood when a hemostatic valve is used. Sheath diameter has decreased over time from 25-Fr in the first generation to 18-Fr in the third generation (or even 14-Fr in expandable sheaths [Edwards Lifesciences, Irvine, Calif]). Vessel diameter less than 6 mm (measured by angiography, ultrasound, or CT) presently is considered nonsuitable for the smallest sheath. The operator may puncture the vessel at a more proximal point (external iliac artery) to avoid smaller distal vessels. However, a puncture at or above the level of the inferior epigastric artery (branch of external iliac artery) is often noncompressible and increases the risk of retroperitoneal hemorrhage.[63]

The Edwards SAPIEN valve (initially the Cribier-Edwards valve) consists of a trileaflet bovine pericardium valve, pretreated to decrease calcification, mounted in a balloon-expandable stainless steel stent that can be implanted transfemorally or transapically. The CoreValve (now produced commercially by Medtronic, Irvine, Calif) has an autoexpandable nitinol stent containing a porcine pericardial valve. This valve has only been used by a retrograde approach, either via transfemoral, subclavian, or direct aortic access. Both valves were approved to be used commercially in Europe in 2007, while Edwards SAPIEN valve was approved in the United States in 2011 after the results of the PARTNER study.[64] The CoreValve was approved in the United States in 2014.[65,66] In Europe, the following valves also are approved and

commercially available: the ACURATE TA valve (Symetis, Ecublens, Switzerland),[67] the JenaValve (JenaValve Technology, GmbH, Munich, Germany),[68] and the transapical Medtronic Engager aortic valve system (Medtronic 3F Therapeutics, Inc, Santa Ana, Calif).

Recently, the randomized controlled trial CHOICE compared balloon-expandable versus self-expanding valves and found some advantages of the balloon-expandable valves with regard to device success and paravalvular leakage.[69] In a meta-analysis comparing the SAPIEN and CoreValve complications, increased postoperative permanent pacemaker implantation with the CoreValve was the only difference found between the two valves.[70]

Several newer transcatheter valves are in various stages of evaluation. The Lotus valve (Boston Scientific, Marlborough, Mass) is a repositionable transfemoral valve so the risk of postimplantation paravalvular leak is minimal. REPRISE I and II, dedicated to examining the Lotus valve, found it was safe and effective for high-risk patients.[71] The Direct Flow valve (Direct Flow Medical, Calif), the CENTERA valve (Edwards Lifesciences), SAPIEN XT and SAPIEN 3 valves (Edwards Lifesciences),[72] ACURATE TA transcatheter aortic valve (Symetis, Ecublens, Switzerland), JenaValve (JenaValve Technology, GmbH, Munich, Germany), and Medtronic Engager aortic valve system (Medtronic 3F Therapeutics, Santa Ana, Calif) are all second-generation valves. Some of these valves have already been included in clinical practice; however, experience and data remain limited.[19,67,68,73]

Logistical Considerations

The presence of a heart team is a prerequisite for establishing a TAVR program.[17,18,74] The German TAVR registry emphasized that the presence of on-site cardiac surgery, anesthesiologist, and CPB was essential regardless of the location in the OR, CCL, or hybrid OR.[75] They analyzed the location of emergency conversion from TAVR to open surgery and the mortality rate. They found a 25% mortality rate for surgeries performed in a hybrid OR in a CCL, 37.5% for patients transported from a CCL to an OR for surgery, and 75% for surgeries undertaken in a standard CCL.

During a TAVR procedure, patients may require conversion to emergency cardiac surgery if a complication occurs that cannot be managed conservatively. Although many TAVR patients are not candidates for conventional aortic valve replacements, rescue CPB should be instituted to allow the correction of reversible complications.[76] Further measures in case of major complications should be discussed with the patient before the procedure. These decisions must be documented in the medical notes and discussed with the whole medical team that is involved in the procedure.[51]

Some complications (eg, coronary obstruction, vessel injury) do not require open surgery but instead a lot of support for the interventionist from other team members such as anesthesiologists and radiologists. It is obvious that these complicated procedures need the MDT approach and a hybrid OR that provides an environment suitable for the team to ensure the safety and efficacy of the procedure and to manage complications that may arise.[77]

Multidisciplinary Team

Two important issues must be highlighted when evolving a TAVR program: First, it is not a solo procedure that can be done only by a group of physicians away from other team members. This team approach, which is known also as an MDT approach, is essential for a successful procedure. While the importance of full collaboration between interventional cardiologist and cardiac surgeon is obvious, it is even more critical to incorporate other key providers from other physician groups (eg, anesthesiology, radiology, noninvasive cardiology, intensive care) into the process (Fig. 27.4). Second, it is important to emphasize that TAVR therapy program is a process that starts outside the OR with patient evaluation and selection of suitability for this procedure and does not stop after the procedure, but continues in the postoperative period.[5]

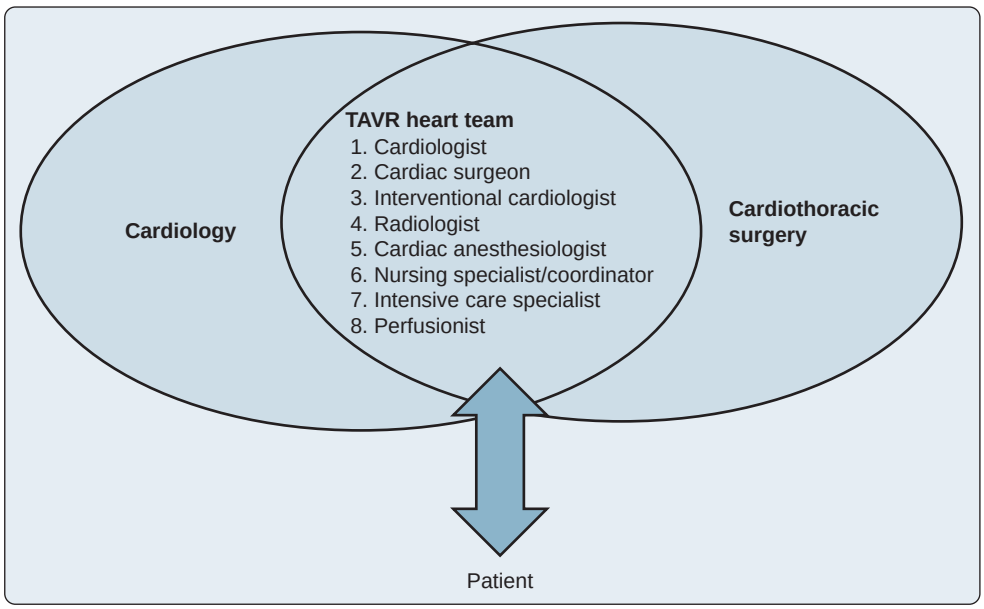

Fig. 27.4 Suggested components of the transcatheter aortic valve replacement *(TAVR)* heart team. *(Modified from Holmes DR, Jr, Mack MJ, Kaul S, et al. 2012 ACCF/AATS/SCAI/STS expert consensus document on transcatheter aortic valve replacement: developed in collaboration with the American Heart Association, American Society of Echocardiography, European Association for Cardio-Thoracic Surgery, Heart Failure Society of America, Mended Hearts, Society of Cardiovascular Anesthesiologists, Society of Cardiovascular Computed Tomography, and Society for Cardiovascular Magnetic Resonance.* J Thorac Cardiovasc Surg. *2012;144:e29–e84.)*

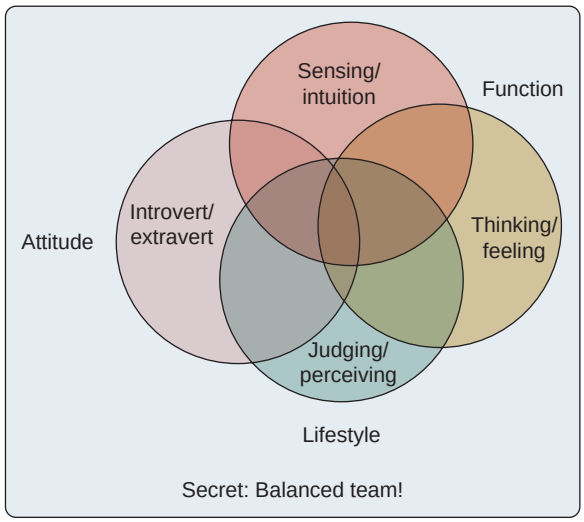

Fig. 27.5 Myers-Briggs Type Indicator.

Considering the different personalities of each team member may help to create a high-performing MDT. To accomplish this, the Myers-Briggs Type Indicator may be useful[78] (Fig. 27.5). A balanced team should have members with comparable personalities in terms of attitude and function to ensure free communication during the procedure. Of course, there must be one in the team who is the *primus inter pares* person (usually the interventionist). However, it is also important that everyone in the team feels free to communicate whenever they think that there is a problem.

Responsibilities for the different heart team members must be assigned before starting the procedure:

- Normally, instrumentation of the patient as well as anesthetic management belongs to the anesthesiologist.
- The intervention itself is performed by cardiologists, cardiac surgeons, or (ideally) both.
- Temporary transvenous pacemaker implantation can be done by the anesthesiologist from the jugular vein or by the interventionist from the femoral vein.
- Rapid pacing can be induced by the anesthesiologist or by the interventionist. No matter who is responsible, clear communication is mandatory.
- Echocardiographic imaging is done by the anesthesiologist or an echocardiographer.

Anesthetic Management

Anesthetic Technique

The decision whether the patient receives general anesthesia (GA) or local anesthesia (LA) of the access site with or without sedation or MAC depends on the route of access, institutional practice, and the patient's comorbidities. GA is still the mainstay in management of patients undergoing TAVR according to a recent survey.[79] In many institutions (especially in Europe), transfemoral TAVR is done under MAC with satisfying results.[80–82] Instead of LA infiltration, some have performed an iliohypogastric and ilioinguinal block during transfemoral TAVR.[83] LA infiltration was also used with the transaxillary approach.[84] The transapical TAVR is done under GA or, in rare cases, using thoracic epidural.[85] Otherwise, other access approaches are done under GA mostly because of lack of experience and familiarity to such procedures.

Advantages to using a MAC technique include avoidance of the circulatory depressant effects of GA, decreased use of vasoactive drugs, easy intraoperative central nervous system monitoring in case of embolic stroke, reduced procedural time, faster patient recovery, need for a lower level of postoperative care, and shorter hospital stay duration.[86] Even when LA or MAC is used, the anesthesiologist has to be prepared to switch to GA in emergency situations.

On the other hand, GA has its own advantages. The airway is secured, avoiding emergency airway intervention in case of an unfavorable hemodynamic situation. The use of TEE under GA is of particular importance in diagnosis and management intraoperatively. No randomized prospective studies have compared the techniques or found an advantage of one over the other.

No anesthetic drug is superior to another. In general, short-acting anesthetics with less hemodynamic effects are preferred to ensure early extubation after the procedure. Etomidate, propofol, remifentanil, sevoflurane, and desflurane are the most frequently used anesthetics.[51]

Procedure-Related Anesthetic Considerations

Monitoring

In addition to standard monitoring (ie, electrocardiography [ECG], pulse oximetry, end-tidal CO_2, anesthetic gas concentration, and noninvasive blood pressure), invasive monitoring is mandatory because of the complicated nature of the procedure, the patient's comorbidities, intraoperative cardiovascular compromise (especially with rapid pacing), and the possibility of life-threatening complications. Both arterial and central venous catheters should be inserted under LA or GA. Although a pulmonary artery catheter has been recommended,[7] there is still debate about whether it is needed in every patient. It may be useful in patients with moderate-to-severe pulmonary hypertension,[87] because pulmonary hypertension per se is an independent risk for mortality in TAVR patients.[88] In these patients, the use of elective femorofemoral CPB also may be considered.[89]At least one large-bore venous access catheter should be inserted for volume resuscitation. Urinary output and temperature monitoring are helpful.

Equipment

All equipment that may be used regularly during the procedure or during treatment of procedure-related complications must be available. This includes cell salvage, infusion pumps, pre-prepared crash carts, heating device, external defibrillator, external pacemaker battery, and intraaortic balloon pump.

Rapid Ventricular Pacing

Rapid ventricular pacing is a special and important issue during the procedure. It is essential to have no ejection with a cardiac arrest during balloon aortic valvuloplasty and during deployment of a balloon-expandable valve such as the SAPIEN valve. On the other hand, the longer profile of the CoreValve, which extends from the aortic annulus to the supracoronary aorta, allows its gradual release without need of rapid pacing.[66] The rapid pacing phase is usually brief and the heart recovers in seconds after stopping rapid pacing. Communication during this period is essential. A clear command "rapid pacing on" has to be followed by the clear reaction that rapid pacing has been started and the heart does not eject anymore. At the end of the maneuver the command "rapid pacing off" has to be followed by the reaction "rapid pacing is off" and the state of the circulation (ie, blood pressure and heart rate recovery).

Imaging Techniques and Guidance

The TAVR procedure creates many challenges throughout the whole process, in which multimodality imaging plays a major role and helps the heart team members to reach the right decision. Imaging is involved in patient selection, procedure planning, procedure performance, and in postoperative follow-up. It is difficult to determine a universal imaging protocol because of the wide variety of imaging modalities available in each institution and operator experience and preferences. The most common available imaging modalities are:

1. Echocardiography (TTE, TEE)
2. Conventional angiography
3. Intraoperative fluoroscopy

4. MDCT
5. Cardiac magnetic resonance

Preprocedural evaluation is the cornerstone in this process. These imaging modalities are used to evaluate the AS pathology, exclude TAVR contraindications (eg, severe aortic regurgitation, valvular vegetation, profound LV dysfunction), evaluate the aortic valve apparatus and dimensions, and evaluate the TAVR access anatomy (eg, iliofemoral vessels, aorta, subclavian vessels).

Transesophageal Echocardiography

TEE is one of two most important intraoperative imaging modalities used during TAVR. It stands side-by-side with fluoroscopy for a successful TAVR process. The radiation exposure to the patient and to the personnel is the major problem with fluoroscopy. In spite of that, it is used extensively because of its ability to better assess the guidewire and catheter locations and the valve stent position. On the other hand, TEE, in spite of being very useful in this context, is used intraoperatively only with patients under GA. Mini-TEE probes are available and can be used with patients under MAC.

The aortic valve has special anatomy that increases the imaging assessment difficulties, and it is important for the echocardiographer to have a good understanding of what is called the functional aortic annulus for good TAVR guidance. The functional aortic annulus contains the following components: the aortic annulus, the sinus segment with the sinuses of Valsalva and the origins of the coronary arteries, and the sinotubular junction where the sinus segment joins the tubular ascending aorta.[90,91] The definition of *aortic annulus* varies significantly among operators.[92] The aortic annulus has at least three definitions. It is either the ring formed by the anatomic ventriculoarterial junction, the ring formed by the hinge point at the attachment of the valve leaflet to the myocardium, or the ring formed at the top of the valve leaflets at the sinotubular junction[93,94] (Fig. 27.6). Actually, the most commonly used "hinge points" ring is a virtual ring, as there is no anatomic plane for this ring. Anatomically, it is located in the upper part of the LVOT, below the other two rings. It was found that the functional aortic annulus is not a spherical but an elliptical structure, with both major and minor diameters, which makes the measurements more difficult, with need for a multiplane, rather than one-plane (2D), assessment.[91] Three-dimensional imaging either by TEE or MDCT plays a major role to overcome this problem.

TEE should be used before, during, and after TAVR procedures to assess various factors.[12,51,95–97]

Preprocedural Assessments

- The severity of AS and associated aortic regurgitation if present
- Aortic valve system (cusps, annulus, root) morphology and abnormalities, which is recommended by the European Association of Echocardiography/American Society of Echocardiography guidelines[95]
- Aortic annulus size: the anterior-posterior aortic annulus diameter in systole at the hinge point of the cusps, either in the 2D long-axis view or 3D in the long-axis and the short-axis views using multiplanar reconstruction mode[51]
- LV size and function
- The aortic annulus to coronary ostia distance, which must be greater than 11 mm to avoid inadvertent coronary occlusion during implantation. Both 2D and 3D modes are used. For left coronary ostium, 3D multiplanar reconstruction must be used, while the right coronary ostium can be measured also in a 2D long-axis view.[51,98]
- Diameter of tubular aorta (a diameter >45 mm is a contraindication for CoreValve implantation)
- Presence of atheroma in thoracic aorta
- Other valve dysfunctions, especially mitral valve regurgitation
- LVOT and septal hypertrophy

Intraprocedural Assessments

- The ventricular puncture site in the transapical approach using the midesophageal two-chamber view
- The proper position of the wires, balloon, and valve delivery systems during and after the implantation. During the transapical approach it is important to ensure that the guidewire is not stuck in the mitral valve apparatus. The mitral valve chordae and the degree of mitral regurgitation must always be reevaluated as catheter advancement in these circumstances risks mitral valve injury and acute mitral regurgitation. Real-time 3D echo is superior in mitral valve apparatus visualization.
- The severity and the location (and sometimes the cause) of transvalvular and paravalvular regurgitation (PVR). The grading recommendation for PVR was recently revised.[99] It is either semi-quantitative or quantitative. The semiquantitative methods include the diastolic flow reversal in the descending aorta and the percentage circumferential extent of PVR. The quantitative parameters in TEE are the regurgitant volume (mL/beat), regurgitant fraction (as percentage), and the effective regurgitation orifice area (cm^2).[100]
- The valve after implantation concerning the pressure gradients, valve area and the dimensionless velocity index when applicable
- Global and regional LV and right ventricular (RV) function, especially after the rapid pacing phases[97]
- Possible complications (ie, new regional wall motion abnormalities, mitral regurgitation, pericardial effusion/tamponade, aortic dissection or trauma,[101] and coronary occlusion of the circumflex artery)[102,103]

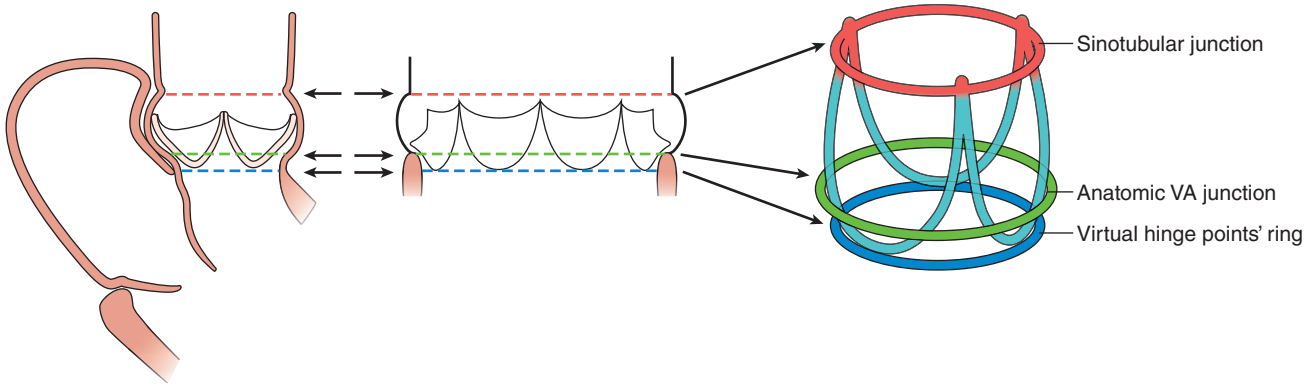

Fig. 27.6 The various rings associated with the aortic annulus. *VA*, Ventriculoarterial. *(Modified from Piazza N, de Jaegere P, Schultz C, et al. Anatomy of the aortic valvar complex and its implications for transcatheter implantation of the aortic valve.* Circ Cardiovasc Interv. *2008;1:74–81.)*

Postprocedural Assessments

- The aortic valve prosthesis function and position
- LV function and mitral regurgitation
- Any possible complication (eg, pericardial tamponade)[12]
- To follow up a paraprosthetic regurgitation, if present

A systematic, comprehensive echocardiographic protocol, incorporating the additional benefits of 3D TEE, is recommended by many experts and is shown to contribute to excellent outcomes of TAVR procedures.[104] Multiple studies have compared TEE (2D and 3D) with MDCT, especially in annulus sizing and aortic root dimensions, and they demonstrated significant measurement differences, where echocardiography usually underestimates the annular size.[61,105]

Conventional Angiography

Conventional angiography is used preoperatively to assess TAVR access (iliofemoral vessels, aorta, subclavian). Also, coronary angiography is done to exclude any significant coronary artery disease.[93] It carries the risk of contrast nephropathy.

Intraoperative Fluoroscopy

Valve positioning is currently based on fluoroscopy with or without (in patients receiving only MAC/LA) TEE guidance. Originally, the operator depends on the aortic calcifications that appear in the 2D view of the fluoroscopy for valve positioning. Some of the fluoroscopy operating systems can rotate fully around the patient and provide cross-sectional or 3D data in a few minutes. This 3D C-arm CT (eg, Dyna-CT, Siemens AG, Erlangen, Germany; and Vitrea, Vital Images [Toshiba], Plymouth, Minn)[11] can assist positioning for TAVR, especially with poor calcification at the annulus, by overlaying real-time 2D images and navigating the anatomy.[11] This technique has been compared with MDCT and found be comparable with regard to final valve-visualization angle.[11,14,15] This recent advance in imaging technology allows comprehensive real-time visualization and/or 3D reconstruction , which helps in optimal positioning of the prosthesis.

Other new imaging systems are also in use. They use either an aortogram acquired before device deployment (C-THV system, Paieon Inc., New York, N.Y.) or the CT data (3mensio valve, 3mensio Medical Imaging, Bilthoven, Netherlands; OsiriX, Pixmeo SARL, Bernex, Switzerland) to predict the optimal angiographic views. The Philips heart navigator system (Philips, Eindhoven, Netherlands) provides 3D reconstruction of the aorta and aortic valve by superimposing the CT data onto the angiographic projections. Small studies have shown the utility of these technologies, with better positioning of the valve.[106]

Digital Subtraction Angiography

DSA is used mainly to visualize the blood vessels and identify any abnormality without interference from background structures. An advanced visualization of the entire DSA flow (iflow) with color coding is another advancement in this field which allows the operator to visualize the entire vascular tree in just one image.

Multidetector Computed Tomography

MDCT is the "gold standard" method in assessment of complex aortic valve geometry. It can give almost all the information needed for TAVR. It is used in the assessment of the annular size and shape, degree of calcification, the distance between annulus and coronary ostia, and in planning for the precise coaxial alignment of the stent-valve along the centerline of the aortic valve and aortic root. In addition, the atherosclerosis of the iliofemoral and the thoracoabdominal aorta can be easily assessed.

Three-dimensional reconstruction of the heart is a very helpful realistic method that can be used at the desired phase of the cardiac cycle (eg, 30–40% of the systole) for valve area and annular assessment.[7] Four-dimensional reconstruction of the heart for the whole cardiac cycle can be done but at the expense of a high radiation dose.[107] Another risk that must be considered is the low-osmolar iodinated contrast agent causing contrast nephropathy. The noncontrast scan is not optimal, but the assessment of the vessel's size, calcification, and tortuosity is feasible.[7]

The elliptical shape of the aortic annulus gives the 3D CT reconstruction special importance, as it allows the measurement of both annular minimal and maximal diameters, which can be measured also by 3D TEE but not with 2D TEE.[61,108] A difference of 2 mm or more between the maximum aortic annulus and nominal prosthesis diameters by MDCT is considered as an independent risk factor for postoperative moderate-to-severe paravalvular regurgitation.[109]

Cardiac Magnetic Resonance

CMR also can give a comprehensive assessment of the aortic valve, annulus, aortic root, coronary ostia, aorta, and iliofemoral vessels. It has the advantage of avoiding radiation exposure and the iodinated contrast. On the other hand, it is time consuming, is contraindicated in patients with pacemakers and defibrillators, and carries the risk of nephrogenic systemic fibrosis if gadolinium is used to enhance CMR imaging.[110]

Although the 2D, ECG-gated, noncontrast cine CMR sequence across the aortic valve provides a good detailed assessment, the 3D whole heart acquisition with or without gadolinium-enhanced imaging gives more precise details for the left ventricle, aortic valve, aorta, and iliopelvic vessels. A navigator-gated, free-breathing, 3D noncontrast steady-state free precession sequence can be used to assess the vessels in patients with renal insufficiency.[7]

After TAVR, CMR can be used to assess the severity of aortic regurgitation. MRI also is used for cases with cerebral embolization.

Complications

In some patients, who have required relatively long rapid pacing because of multiple adjustments to balloon or valve positions before inflation, heart stunning has occurred and has not recovered without medical or mechanical support. Usually a small bolus of metaraminol (0.5–1 mg), phenylephrine (0.1–0.5 mg), or norepinephrine (10–20 μg) is sufficient for recovery. Epinephrine (10–20 μg) sometimes is necessary and can be injected through the central venous catheter or directly into the aortic root pigtail catheter used for contrast administration. This direct injection into the aorta is more effective, especially with a noncontracting heart. External cardiac massage must be initiated, without any delay, to obtain an acceptable cardiac output and coronary perfusion pressure. Failure of these measures must lead the team to move forward to mechanical circulatory support using emergency CPB. Institution of CPB must not take much time and the arterial and venous cannulas are inserted over the femoral guidewires already in situ for emergency situations. During this time, the situation must be assessed to discover any possible complication that led to the condition. Sometimes the only rescue maneuver is conversion to an open surgical operation through a sternotomy. Such a decision must be discussed with the patient before the operation takes place. Patients under LA usually have unpleasant feelings and nausea during the phase of rapid pacing and hypotension, which is distressing when this phase is prolonged. This can require changing to GA and rapidly securing the airway with an endotracheal tube, adding a major burden to the anesthesiologist during this critical situation. Additionally, the anesthesiologist must help to find the reason for the circulatory failure using TEE; however, this must not come before patient care and management.[51] The possible causes of severe acute hemodynamic collapse during the procedure that can be discovered by TEE include valve embolization, severe aortic regurgitation, severe mitral regurgitation, aortic rupture or dissection, LV or RV perforation, and hypovolemia.[104] Ventricular fibrillation is another rare complication that may arise after rapid ventricular pacing that mandates rapid defibrillation. External defibrillator pads should be attached to every patient before the procedure. Electrolytes levels, especially potassium, must be measured and corrected.

The two most common (rare, ≈1% of cases) complications that cause conversion to open surgery are valve embolization into the left ventricle and procedure-related aortic injury, including annular

TABLE 27.4 Complication Rates for TAVR

Complication	*Incidence Rate (%)*	*95% CI (%)*
Major bleeding	22.3	17.8–28.3
Vascular complications	All: 18.8 Major: 11.9	All: 14.5–24.3 Major: 8.6–16.4
Need for permanent pacemaker	13.9	10.6–18.9
Acute kidney injury (moderate to severe)	7.5	5.1–11.4
Aortic insufficiency (moderate to severe)	7.4	4.6–10.2
Stroke	All: 5.7 Major: 3.2	All: 3.7–8.9 Major: 2.1–4.8
Periprocedural MI (<72 h)	1.1	0.2–2.0

CI, Confidence interval; *MI,* myocardial infarction; *TAVR,* transcatheter aortic valve replacement.

Modified from Genereux P, Head SJ, Van Mieghem NM, et al. Clinical outcomes after transcatheter aortic valve replacement using Valve Academic Research Consortium definitions: a weighted meta-analysis of 3,519 patients from 16 studies. *J Am Coll Cardiol.* 2012;59:2317–2326.

rupture, aortic dissection, and perforation. In spite of active management of such complications, including the surgical team's using CPB, the mortality rate is still very high, ranging from 46% to 67%.[75,111,112] While it is highest in patients with aortic dissection or perforation (80%), it is about 33% following severe aortic regurgitation. For annular rupture, myocardial perforation, and prosthesis embolization, mortality rates are 67%, 50%, and 40%, respectively.

Coronary artery obstruction, which occurs in about 0.7% of cases, affects mainly the left main artery and requires emergency coronary intervention with a success rate of 82% and a 30-day mortality of 41%.[113] Another relatively common complication is vascular injuries; occurrences range from 1.9% to 17.3% of patients and mortality is increased by 2.4- to 8.5-fold.[63] These complications may require surgery, advanced endovascular stenting, ballooning, or intravascular ultrasound.

The common complications of TAVR are major bleeding, vascular injury, heart block, acute kidney injury, paravalvular leak, stroke, and postprocedural MI (Table 27.4).

Vascular Injury

As mentioned earlier, vascular complications (eg, rupture, perforation, dissection, hematoma, and pseudoaneurysm) were common (up to 27%) at the beginning of the era of TAVR, especially with the transfemoral approach because of relatively large valve delivery systems, lack of experience, and inadequate preoperative vascular system assessment tools. These complications have negative effects on morbidity and mortality.[100,115] On the other hand, in the PARTNER A trial, in spite of higher vascular complications (11%) for TAVR compared to 3.2% in the surgical group, there was no significant mortality difference. Over the past few years, the size of the valve delivery systems has been reduced and the precise assessment of the whole vascular system has become available.

Vascular injury must be considered if there is hemodynamic instability or a decrease in hemoglobin concentration at the end of the procedure. Good communication with the operator is essential in this situation.

Pericardial Hemorrhage

This life-threatening complication may arise at any time of the procedure. It occurs either by annular rupture or by wire perforation. The annular rupture and the ventricular or aortic wire perforation are very serious and usually require sternotomy and surgical repair. Venous bleeding by the guidewire or by the pacemaker wire can be managed by pericardial drainage and close observation.

Conduction System Abnormalities and Arrhythmias

As the atrioventricular node and bundle of His pass superficially through the interventricular septum, they are liable to be injured during aortic valve surgical procedures by mechanical trauma, tissue edema, or local inflammation. This dysfunction may be temporary or permanent, for which a permanent pacemaker must be implanted. The same problems occur during TAVR, especially with long valve stents that extend into the LVOT as with the CoreValve, low implantation of the valve, or oversizing. The incidence for a permanent pacemaker after implantation of a CoreValve ranges from 23.4% to 39%, whereas it is only 4.9% to 6% for the SAPIEN valve.[116–118] On the other hand, this pacemaker incidence is only slightly higher for the SAPIEN valve when compared with surgical AVR according to the PARTNER trial.[119] Preoperative predictors of the need for a postoperative permanent pacemaker are left bundle branch block with left-axis deviation, an interventricular septal dimension greater than 17 mm at end-diastole, increased baseline thickness of the native noncoronary aortic valve cusp (>8 mm),[118] or a preexisting right bundle branch block.[120] All patients must be closely monitored for 72 hours after the procedure because the conduction disturbances can occur up to 3 days after the valve implantation.

Valve Malpositioning

This includes either low (in LVOT) or high (in aortic root) valve implantation or valve embolization in the worst-case scenario. Low valve deployment in the LVOT may impinge on the anterior mitral leaflet, in addition to the high risk for postoperative heart block. On the other hand, high valve implantation in the aortic root carries the risk of coronary ostial obstruction leading to myocardial ischemia and potential cardiovascular collapse.

Coronary ostial occlusion occurs in 0.66% of patients[113] and is a life-threatening condition. Diagnosis is usually made by direct coronary angiography. Three-dimensional TEE can predict this problem by accurately measuring the distance between the aortic annulus and the left main coronary ostium.[121] Lifesaving coronary stenting has been attempted in 75% of patients, with a success rate of 82%. In spite of that, the 30-day mortality is very high (41%) with no case of stent thrombosis or reintervention.[113] To avoid delay in stenting for high-risk patients, either a prophylactic stent insertion[122] or at least a wire in the left coronary artery before valve deployment can be used.

Paraprosthetic aortic regurgitation can occur as a result of valve malpositioning, undersizing, extensive valve calcifications, or incomplete expansion of the valve (Fig. 27.7). Mild regurgitation is found in about 70% of patients after TAVR.[123] Moderate-to-severe regurgitation occurs in 11.7% of the patients[124] and is an independent predictor of mid- to long-term mortality.[125] Preoperative cardiac CT allows an accurate assessment of the degree of valve calcification and precise annulus sizing in order to minimize the risk of prosthesis mismatch.[126] This can also be predicted preoperatively using TEE by identifying the calcification of the commissure between the right coronary and noncoronary cusps and the area cover index.[56] Fluoroscopy/aortography or TEE can be used to diagnose the severity of the regurgitation. Management options for moderate and severe regurgitation include a second balloon dilation, snares, and valve-in-valve implantation. Second balloon dilation must be done carefully as it risks valve leaflet disruption. The concept of valve oversizing to reduce postimplantation regurgitation has not yet been investigated or approved.[95]

The rapid pacing technique is very important during valve deployment as any cardiac ejection during this phase may lead to valve malpositioning. Therefore, the temporary pacer must be adjusted to a nonsensing fixed mode with maximum output to minimize ventricular ejection risk.[51]

Embolization of the valve into the left ventricle or into the aorta is a complication that usually needs surgical intervention. It also has been managed by implanting a second device and leaving the dislocated valve safely in the descending aorta.[127]

Stroke

At the beginning of the TAVR era, neurologic complications were cumbersome. Recently, the incidence of stroke has declined from 7.8% to between 2.1% and 2.8%[129] but is still higher than in surgical AVR.

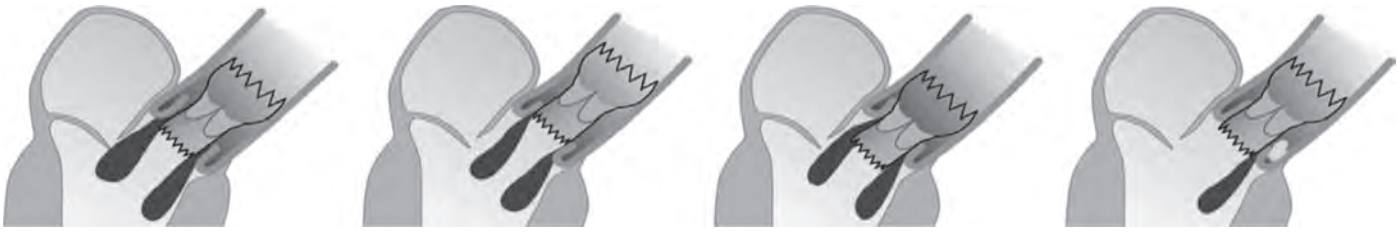

Fig. 27.7 Perivalvular leak can be caused by (A) inappropriate size (undersizing), (B) high or (C) low valve malpositioning, or (D) eccentric or bulky annular or leaflet calcification. *(Modified from Sinning JM, Vasa-Nicotera M, Chin D, et al. Evaluation and management of paravalvular aortic regurgitation after transcatheter aortic valve replacement.* J Am Coll Cardiol *2013;62:11–20.)*

Major stroke was found to occur similarly in TAVR and surgical AVR according to the PARTNER trial, but the central nervous system–associated morbidity was higher in TAVR patients.[130] Stroke in TAVR has many causes, including atherotic material from the ascending aorta or arch, calcific material from the native aortic valve, thromboembolism from the catheters used in the procedure, air microembolism during LV cannulation, prolonged hypotension, or dissection of brachiocephalic vessels.[51] Cerebral microembolism related to TAVR was evaluated with MRI, which demonstrated new foci of reduced diffusion. Manipulation of the aortic root and valve by guidewires and catheters, and during implantation of the prosthesis, are the critical phases in which embolism mostly occurs.[131]

A transcranial Doppler study of embolization during TAVR showed recordings of different rates of high intensity transient signals, yet there is no evidence that TAVR approach (transfemoral or transapical) or valve type is associated with more neurologic insults.[132]

A measure that may be taken to reduce stroke incidence is implantation of temporary carotid artery filters (embolization-protection devices) (debris/calcium-capture devices) at the beginning of the procedure using a radial artery approach with removal at the end of the operation (eg, the Claret Pro system, Claret Medical, Santa Rosa, Calif; the TriGuard, Keystone Heart Ltd, Herzliya, Israel; and the Embrella embolic deflector, Edwards Lifesciences).[106] However, no data support the clinical benefits of these devices in all cases.[19] They may be used in selected cases with a documented history of cerebrovascular disease and significant aortic valve calcifications.[133]

Silent cerebral ischemia occurs in 72% of patients after TAVR as demonstrated by imaging studies. Only 6.6% presented clinically.[131]

Renal Dysfunction

The PARTNER trial did not prove that TAVR has more postprocedural renal morbidity than surgical AVR.[119,130] In spite of that study, many patients required hemodialysis (1.4%) after TAVR. Acute renal injury occurs in 12% to 21% (8.3–57% in other studies) of patients and is mostly reversible. Diabetes mellitus, peripheral vascular disease, chronic renal failure, and the need for blood transfusions increase its incidence.[134,135] Acute kidney injury also occurs more often in surgical AVR patients who suffered preoperatively from chronic renal failure.[136]

Future Perspectives for TAVR

TAVR technology continues to improve the process and overcome the already known problems, as well as to find new applications for the procedure. The trend to smaller introducer systems has reduced vascular complications. New valve sizes are being produced to fit larger patients. Valve-in-valve TAVR,[137] TAVR in bicuspid aortic valve,[138] TAVR in medium- and low-risk surgical groups[139–141] and in younger patients,[19,142] and TAVR for aortic valve regurgitation[73,143] are under clinical investigation. Moreover, new access routes have been used with patients for whom none of known access routes are feasible.

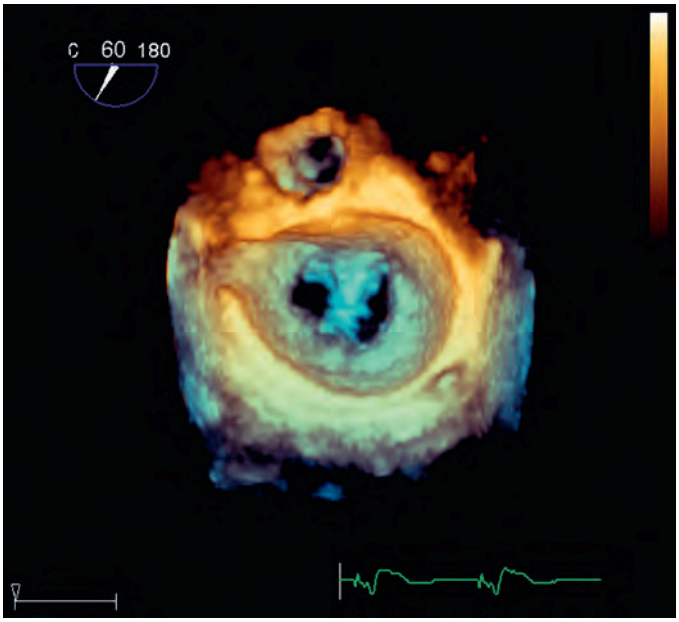

Fig. 27.8 Three-dimensional zoom double-orifice mitral valve after successful MitraClip implantation.

Transcatheter Mitral Valve Repair: MitraClip

Different transcatheter mitral valve repair techniques have been developed over the past few years addressing the leaflets, the mitral annulus, or the left ventricle.[144] These techniques usually mimic well-known surgical techniques.

The MitraClip (Abbott Laboratories, Abbott Park, Ill) is the most commonly used catheter-based mitral valve repair technique. It mimics the surgical edge-to edge technique first described by Alfieri and coworkers[145] and creates a double orifice mitral valve (Figs. 27.8 and 27.9).

Although residual mitral regurgitation is more common compared to surgical mitral valve repair, the reduction in functional class is not different to surgical mitral valve repair, even 4 years after MitraClip.[146]

Patient Selection and Indications

The MitraClip procedure should be considered in patients with chronic severe structural mitral regurgitation (Carpentier classification type II)[147,148] or chronic severe secondary or functional mitral regurgitation[147] in patients who are severely symptomatic (New York Heart Association [NYHA] functional class III or IV) with a prohibitive risk

for surgery or judged inoperable, favorable anatomy for a repair procedure, and a reasonable life expectancy (>1 year). Favorable anatomy with recommended echocardiographic criteria are described in detail in Table 27.5.[149]

Routinely used risk scores like the logistic EuroSCORE, EuroSCORE II, or STS-PROM overestimate the predicted mortality in these patients.[150] The procedure has been found to have a low rate of complications and in-hospital mortality.[151]

Access Routes

The procedure is performed via the left femoral vein. First, a steerable guide is placed through a transseptal puncture into the left atrium. Then, a clip delivery system together with the MitraClip device is introduced via the guide. After capturing both leaflets, the MitraClip is fixed to create the typical double orifice mitral valve.

Anesthetic Management

Usually this procedure is performed under GA to create optimal conditions for the interventionist and the echocardiographer,[152–154] although there have been some attempts to do this procedure in sedated patients.[155,156] Due to the patients' high-risk profile, invasive blood pressure and central venous catheters are mandatory, whereas the use of a pulmonary artery catheter is not recommended. Early extubation right after the procedure can be achieved in most patients. The procedure can be done in the CCL or in the hybrid OR.

Complications

Complications such as atrial perforation with pericardial effusion or tamponade are extremely rare and can be treated without the use of CPB. For a detailed list of complications, see Table 27.6.[157–168]

Imaging Techniques and Guidance

In contrast to TAVR, this procedure is primarily echo-guided. Angiography can be used for transseptal puncture and for visualization of the groin vessels. However, the guidance of the MitraClip system is performed by TEE (see Chapters 3 and 15). The main steps are:

- Transseptal puncture (Fig. 27.10)
- Introduction of the steerable guide catheter into the left atrium (Fig. 27.11)
- Advancement of the clip delivery system into the left atrium (Fig. 27.12)
- Steering and positioning of the MitraClip above the mitral valve (Fig. 27.13)
- Alignment of the clip (Fig. 27.14)

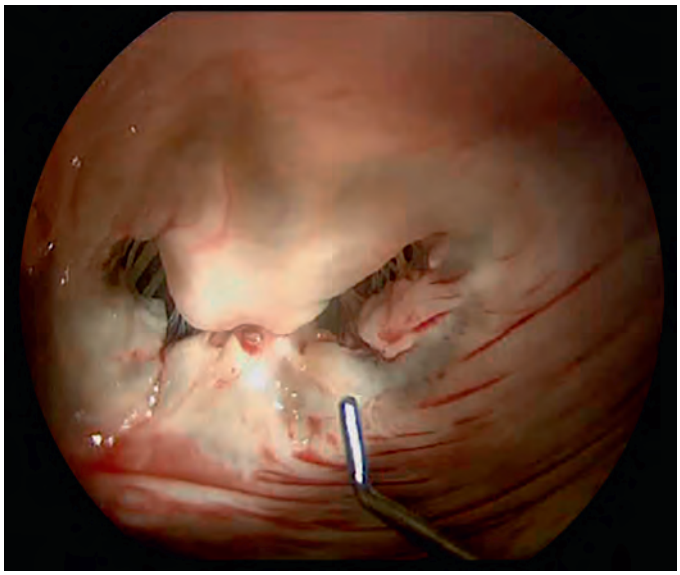

Fig. 27.9 Anatomic picture of double-orifice mitral valve 2 years after MitraClip implantation.

TABLE 27.5 Recommended Criteria for Echocardiographic Analysis of the Mitral Valve for Percutaneous Edge-to-Edge Repair

Criteria	*Assessment*
Mitral leaflet coaptation length	≥2 mm
Mitral leaflet coaptation depth	<11 mm
Flail gap	<10 mm
Width of flail leaflet	<15 mm
Mitral valve opening area	>4 cm^2
Leaflet thickness	≤5 mm
Considerable calcification of the mitral annulus	Should not be present
Marked valvular cleft or leaflet perforation	Should not be present
Marked restriction of posterior leaflet	Should not be present
Lack of primary or secondary chordae support	Should not be present
Calcification of the leaflets in the grasping area	Should not be present
Several significant regurgitant jets	Should not be present

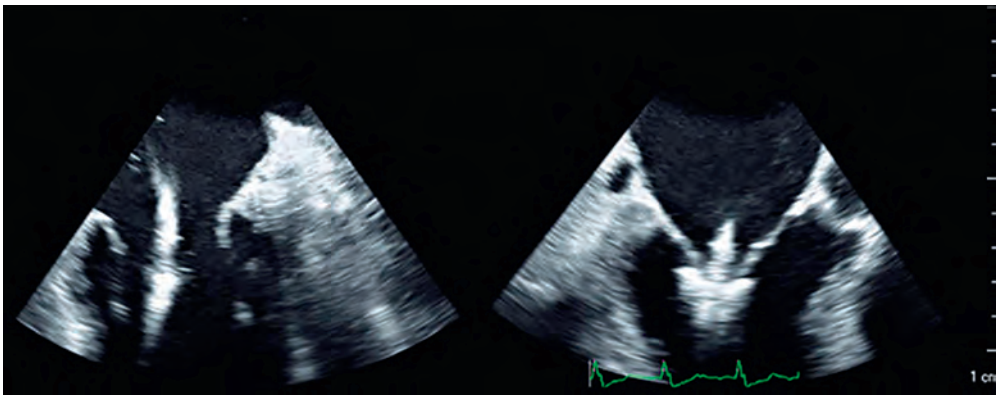

Fig. 27.15 Advancing and positioning of the clip in X-plane.

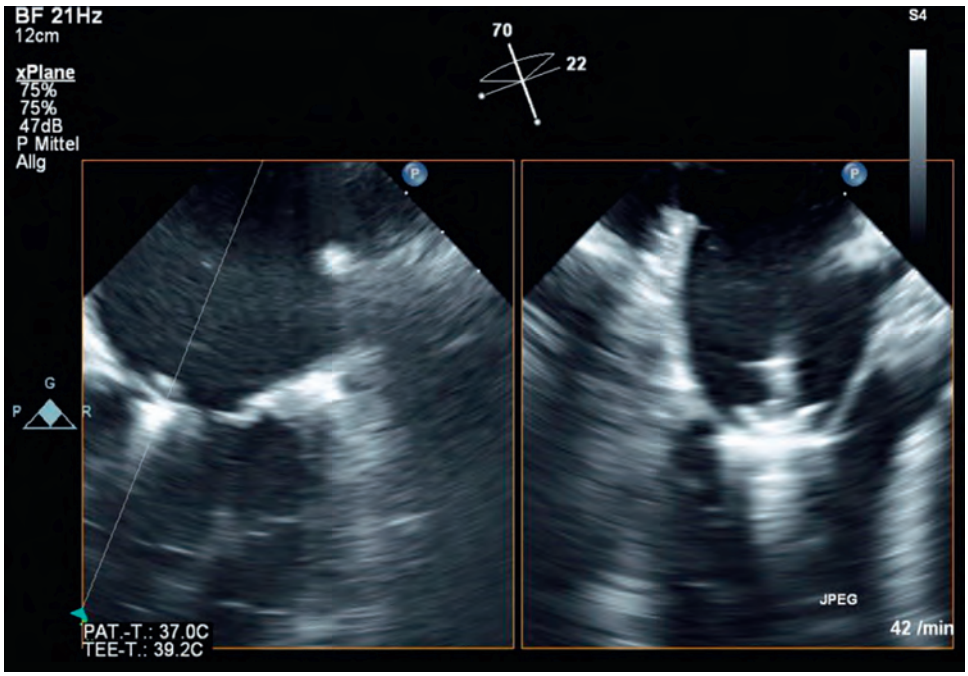

Fig. 27.16 Grasping the leaflets.

- Advancing of the MitraClip into the left ventricle (Fig. 27.15)
- Grasping the leaflets and assessment of proper leaflet insertion (Fig. 27.16)
- Control of leaflet insertion (Fig. 27.17)
- Functional control of the result (ie, residual mitral regurgitation, new mitral stenosis)
- Assessment of iatrogenic residual atrial septal defect after withdrawing of the steerable guide catheter.

For most of the main steps, real-time 3D TEE either in the wide sector zoom mode or in the X-plane mode is preferred over 2D TEE.[152,169,170]

Transcatheter Pulmonary Valve Replacement (Melody Valve)

The right ventricular outflow tract (RVOT) and the pulmonary valve and artery are subjected to many abnormalities of either congenital origin (ie, tetralogy of Fallot with pulmonary atresia and truncus arteriosus) or acquired origin (ie, Ross operation). These patients are often treated with surgical placement of a right ventricular–to–pulmonary artery (RV-PA) conduit. RVOT conduits develop stenosis, insufficiency, or both, over time due to the development of calcification, intimal proliferation, and graft degeneration; consequently, RV dysfunction by volume and/or pressure overload occurs. Such patients are subjected to multiple RVOT conduit reoperations. Bare metal stenting of stenotic conduits decrease RV pressures and is associated with immediate hemodynamic improvement[171] and potentially prolonged conduit life span.[172] Nevertheless, this treatment option comes at the expense of significant pulmonary regurgitation. Transcatheter pulmonary valve replacement (TPVR) provides a good option to treat such cases without the risk of reoperation.[173]

The first reported TPVR with a stent-mounted bovine jugular venous valve was in 2000.[174] The Melody transcatheter pulmonary valve (Medtronic, Minneapolis, Minn) has been used to treat RVOT conduit dysfunction for more than 10 years, with procedural success,

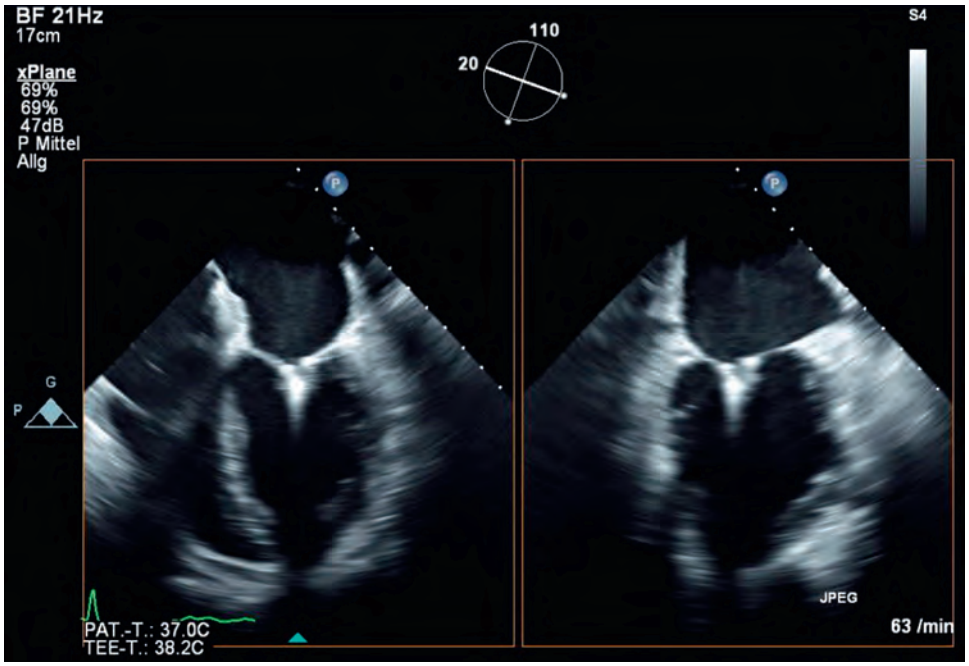

Fig. 27.17 Control of leaflet insertion with X-plane.

excellent short-term TPV function, and low reintervention and reoperation rates at 1 year.[175] It received approval from the U.S. Food and Drug Administration in 2010 as a Humanitarian Use Device.

The Melody valve is composed of a bovine jugular venous valve and a balloon-expandable stent. The valved stent is crimped on a balloon-in-balloon front-loading delivery system (Ensemble, Medtronic). For implantation, the inner balloon is inflated first, followed by inflation of the outer balloon. The utility of a balloon-in-balloon system increases stability of the stent on the balloon during the implantation. The device is available only in one size, while the delivery system comes in three sizes.[176] Larger long-term studies are needed to verify the promising short-term results.[177]

Patient Selection

The transcatheter pulmonary valve is implanted in patients suffering from long-term illness and multiple reoperations. Moreover, the RV pressure should be 65% to 75% of the systemic pressure as an indication for the intervention. Although there is an absence of clear-cut guidelines, these patients must have severe pulmonary regurgitation as assessed by echocardiography or MRI in addition to severe RV dilatation, RV dysfunction, severe symptoms, arrhythmias, or impaired exercise capacity with a peak oxygen uptake of less than 65% of predicted.[178]

Access Route

As in TAVR, the interventionist must consider the anatomic variations when choosing the access route. For sizing of the RVOT and pulmonary valve and artery, the same imaging techniques as in TAVR are used, except for TEE. Because of the limited size of the Melody valve, it is indicated only for patients older than 5 years who weigh more than 20 kg. The conduit RVOT diameter must be smaller than 16 mm, otherwise it cannot be dilated, and must be at least 22 mm, otherwise it is not likely to hold the valve in the landing zone.[179]

The femoral vein is the most common access site for these procedures. The transjugular route has was also been used in smaller patients (<30 kg) with interrupted inferior vena cava.[180] The possibility of additional complications such as injury to the thoracic duct, vagus nerve, carotid artery, and pneumothorax should not be ignored when pursuing this route.

Complications

Major intraprocedural complications have included dislodgement of the device, rupture of a homograft, compression of the main stem of the left coronary artery, obstruction of the origin of the right pulmonary artery (PA), and perforation of the left PA causing severe bleeding. Other complications have included limited perforation of a distal PA resulting in minor bronchial bleeding, partial homograft rupture, and entrapment of the delivery system in the tendinous cords of the tricuspid valve in two patients.[176] Stent fracture is more likely in patients with severely obstructed RVOT conduits[181] and is the most common complication during follow-up, occurring in 20% of cases, most of them having no symptoms. Symptomatic patients may undergo a reintervention by implantation of a second device (valve in valve).[176] If significant pulmonary regurgitation is discovered during the follow-up period, the possibility of endocarditis must be excluded.

During RVOT intervention, coronary compression must be ruled out by coronary angiography at the beginning of the procedure. Using biplane projections, the relationship between the coronaries and the PA can be judged. In unclear situations, a dynamic coronary artery compression test can be performed by simultaneous RVOT balloon angioplasty of the potential implantation site and coronary angiography. This test has been positive in 5% of the patients.[182]

This procedure is preferably done in a hybrid OR with an MDT for optimal complication management.

Anesthetic Management

Patients who undergo TPVR are usually young with chronic illness and a history of multiple reoperations. GA is the method of choice due to the possible length of the procedure. Insertion of arterial and central venous catheters is usually done following induction of anesthesia. It is important to monitor the patient's temperature during the procedure, because of the risk of hypothermia, and active warming is usually required. Rapid pacing is not required because of the low-pressure nature of the right ventricle. Following heparin, the activated

coagulation time at valve implant is targeted at 250 to 300 seconds. TEE evaluation of the pulmonary valve is technically difficult and usually not needed during the procedure. Real-time 3D TEE may be helpful and additive to fluoroscopy but is rarely used.[183]

MISCELLANEOUS PROCEDURES

The uses of hybrid ORs are rapidly expanding due to the wide variety of potential procedures that need both the hybrid OR layout and the heart team concept. Examples include the following procedures.

Hybrid Coronary Artery Revascularization

In addition to transcatheter valve replacement, coronary revascularization may take place in a hybrid OR. Surgical off-pump coronary artery bypass (OPCAB) can be done at the same time as PCI in patients with multivessel disease. This technique may be used in patients with a porcelain aorta, which prohibits proximal anastomoses and aortic clamping. The left internal mammary artery (LIMA) to left anterior descending artery (LAD) graft is performed as OPCAB surgery, in addition to PCIs for the rest of the diseased coronary vessels. The LIMA-LAD graft also may be done with a minimally invasive technique (MIDCAB), especially for patients with a previous sternotomy. These coronary surgical procedures can be combined with PCIs and/or transcatheter valve repairs or replacements.

Hybrid Arrhythmia Procedures

Catheter ablation around the pulmonary vein confluences with the left atrium is used to treat paroxysmal atrial fibrillation. Many techniques can be used ranging from catheter-guided ablation, minimally invasive procedures using video-assisted thoracotomy, or minimally invasive surgical thoracotomy. Combining the transvenous endocardial and the thoracoscopic epicardial approaches may be more effective. Intraoperative mapping allows additional endocardial touch-up when incomplete ablation is detected. The availability of the heart team with on-site CPB is necessary to manage some patients and to treat complications that may arise. Most of these cases are performed under GA with one-lung ventilation using a double lumen tube that gives the anesthesiologist the possibility of ventilating and deflating either lung during the procedure.[4] If mapping is to be done, GA is usually maintained using total intravenous anesthesia to avoid the possible effects of volatile anesthetics on the conduction system.[184]

Implantable Pacemaker and Defibrillator Implantations and Lead Extractions

In general, pacemaker implantation is done under LA with or without sedation. Complications such as pneumothorax, severe arrhythmias, atrial or ventricular perforation, and lesions of the tricuspid valve are rare, but serious, and may need immediate intervention. Therefore, a chest radiograph is mandatory after the procedure. If the patient has a complete heart block, a temporary external pacer is applied and used until permanent pacemaker is implanted.

The same LA/MAC technique can be used during the insertion of an implantable cardioverter-defibrillator (ICD), but with some added considerations (see Chapters 4 and 5). These patients usually have worse general conditions and lower ejection fractions, especially patients undergoing cardiac resynchronization therapy. After implantation, the defibrillating function of the ICD must be tested by inducing ventricular fibrillation, which is to be detected and terminated by the ICD. An arterial catheter should be inserted and external defibrillation pads placed before beginning the procedure. Heparin 5000 IU is usually administered before inducing ventricular fibrillation. During ICD testing, brief GA is needed using propofol or etomidate with oxygen delivered by mask or laryngeal mask airway. Other techniques using GA with endotracheal intubation also have been well tolerated by patients.[185] For procedural analgesia and sedation, propofol and short-acting opioids such as remifentanil have been used.

The number of patients subjected to lead extraction is increasing as a result of increased numbers of implantations. Lead extraction is a difficult procedure and is prone to severe complications due to the adherence of the leads to the myocardium. Ventricular perforation or severe tricuspid regurgitation may occur. Therefore, these patients receive GA with invasive blood pressure monitoring, large-bore intravenous cannula, and intraoperative TEE with the full heart team available if open surgery and CPB are urgently needed.[186]

Endovascular Procedures

Endovascular aortic repairs, either with thoracic (TEVAR), abdominal, or thoracoabdominal extents are also performed in a hybrid OR. Indications include aneurysms, acute and chronic aortic dissection, traumatic disruption, and penetrating ulcers. Hybrid debranching procedures may be done before the endograft implantation, as an open vascular bypass, to create a landing zone for implantation and prevent major vessel obstruction. Again, the presence of the complete heart team with anesthesiologists and perfusionists is mandatory.[4] TEVAR carries the risk of spinal cord ischemia and consequently permanent neurologic deficits. This can be diminished by early detection (using somatosensory or motor-evoked potentials and treatment by blood pressure augmentation (MBP >70 mm Hg) and cerebral spinal fluid drainage (intracranial pressure ≤10 mm Hg) using a subarachnoid catheter inserted at the beginning of the procedure[187] (see Chapters 18 and 23). Deliberate hypotension is usually required during the procedure. Rapid ventricular pacing is the gold standard because of its efficacy, predictability, consistency, rapid reversibility, and potential to assist in hemodynamic recovery after endovascular device deployment. Nitrovasodilators, adenosine, and balloon vena cava occlusion can also be used.[188]

Anesthetic Management

Although many procedures are often performed with MAC/LA, GA is needed during longer and more complex procedures. For success, anesthesiologists need to be familiar with the procedures and their specific complications. Close communication with the interventionist and the other members of the heart team is needed to increase the safety of the procedures. These patients usually suffer from multiple comorbidities, which must be identified and optimized during the preoperative assessment. During the operation, standard monitoring must be established with active warming methods. Invasive monitoring is required because unexpected or sudden changes in hemodynamics are likely to occur. Many interventions are performed under MAC/LA, but all general anesthetic drugs and equipment must be readily available.

Mechanical Assist Devices for Heart Failure

MARC E. STONE, MD | JOSEPH HINCHEY, MD, PhD

KEY POINTS

1. Mechanical circulatory support (MCS) for the failing heart has become a mainstay of the modern management of patients with both acute and chronic heart failure refractory to pharmacologic and other usual interventions.
2. Outcomes with MCS have improved so dramatically that the main focus of this arena has now shifted away from simple survival and toward mitigation of risk and minimization of adverse events.
3. Data taken from experience gained with the first generation of pulsatile devices may no longer be applicable in the current era of nonpulsatile support, but the valuable lessons learned continue to help shape management and clinical decision making.
4. In addition to the traditional indications for MCS (eg, short-term bridge to recovery and long-term bridge to transplantation), MCS is currently employed for a variety of both short- and long-term modern indications, including acute rescue of patients from acute low cardiac output situations (bridge to immediate survival), prevention of further myocardial damage following an ischemic event, prevention of deterioration in multisystem organ function, as a temporizing measure to buy time for recovery, as a bridge to the next step of management (bridge to next decision), as a bridge to improved candidacy (for transplantation), and, increasingly, as a final management strategy for end-stage heart failure (destination therapy).
5. Patient status at the time of implementation of rescue MCS is a key factor determining outcome. Deterioration from delayed implementation is associated with worse outcome.
6. The timing of implantation of a durable left ventricular assist device (LVAD) (eg, as a bridge to transplantation and/or as destination therapy) and perioperative optimization of the patient's nutritional status are key factors determining outcome.
7. Nonpulsatile support devices have supplanted the first generation of pulsatile ventricular assist devices worldwide, and outcomes have improved dramatically with the technology now available.
8. Extracorporeal membrane oxygenation is being incorporated more and more often into modern extracorporeal life support algorithms.
9. The implantable total artificial heart has undergone a resurgence of interest as a bridge to transplantation for patients with biventricular failure and in other scenarios where an LVAD alone would not be ideal.
10. A number of new MCS devices are in various stages of development and clinical trials.

The Current Era of Mechanical Circulatory Support

Mechanical circulatory support (MCS) for the failing heart has become a mainstay of current management of patients with both acute and chronic heart failure refractory to pharmacologic and other usual interventions. In fact, the successes realized to date have been so significant that the main focus of this arena has now shifted away from simple survival and toward mitigation of risk and minimization of adverse events. Undeniably, continued advances in device technology have made this possible, but when coupled with analyses of the enlarging patient management experience, we now have better understandings regarding optimal patient selection and timing of intervention,[1] the expectation of significant improvement in multiorgan function during ventricular assist device (VAD) support,[2–5] and the ways in which preexisting and demographic risk factors may result in complications.[6–9]

Although some of the data taken from the experience with the first generation of pulsatile devices may no longer be applicable in the modern era of nonpulsatile support, the valuable lessons learned help shape management and clinical decision making. All of these factors have now resulted in more widespread acceptance of VADs by physicians and patients as a management strategy, as well as an earlier use of VADs in the course of a patient's cardiac deterioration. As such, in addition to the traditional indications for MCS (eg, short-term bridge to recovery and long-term bridge to transplantation), MCS is currently employed for a variety of both short- and long-term indications, including rescue of patients from acute low cardiac output situations (bridge to immediate survival), prevention of further myocardial damage following an ischemic event, prevention of deterioration in multisystem organ function, as a temporizing measure to buy time for recovery, as a bridge to the next step of management, as a bridge to improved candidacy (for transplantation) and, increasingly, as a final management strategy for end-stage heart failure (destination therapy).

Equally important to the advances in MCS technology has been the formal sharing of outcomes data from centers nationwide through the Interagency Registry for Mechanically Assisted Circulatory Support

(INTERMACS), a North American registry database sponsored by the National Heart, Lung, and Blood Institute; the U.S. Food and Drug Administration (FDA); and the Centers for Medicare and Medicaid Services. INTERMACS was established in 2005 for adult patients receiving long-term MCS device therapy to treat advanced heart failure. A similar European-based database called EuroMACS exists in Europe. Additional databases collect pediatric MCS data (PEDIMACS) and data about adult heart failure patients with higher (less sick) INTERMACS levels (discussed later) still being medically managed (MEDAMACS).

INTERMACS collects clinical data about patients implanted with durable MCS devices at 1 week, 1 month, 3 months, 6 months, and every 6 months thereafter. Major outcomes after implant (eg, death, explant, rehospitalization, and adverse events) are updated frequently and also as part of the defined follow-up intervals. Additional end points include patients' level of function and quality of life, and the reported improvements in both of these areas have been compelling. These data have proven invaluable to appropriate risk stratification and patient selection, and as new devices are introduced, documentation of functional outcomes beyond simple survival assist in differentiating the value of MCS devices.

The sixth INTERMACS annual report, released in 2014, summarizes the enrollment and outcomes of more than 12,300 patients implanted with left ventricular assist devices (LVADs) between 2006 and 2013.[1] This latest INTERMACS report reveals the dynamic and expanding landscape of modern MCS:

- Patient accrual now exceeds 2000 VAD implants per year in the United States alone, and the number of implanting centers in the United States has grown to 158.
- At 1 year, overall survival with a durable MCS device now approaches 80%. This is a marked improvement over the 52% 1-year survival rate demonstrated with the pulsatile HeartMate VE in the REMATCH trial reported in 2001[10] and is a major advance when compared to the medically managed patients in that trial that demonstrated only a 25% 1-year survival rate.
- Overall survival rate at 2 years with a durable MCS device now approaches 70%, 3-year survival rate now approaches 60%, and 4-year survival rate now approaches 50%. Survival rate after destination therapy is now higher than 75% at 1 year and higher than 50% at 3 years.

Survival has improved dramatically in recent years, but this has been also been influenced by the earlier implantation in the course of a patient's cardiac deterioration. Classification in this regard is denoted by INTERMACS level, a scale of clinical condition ranging from 1 to 7. An INTERMACS 7 patient is simply in the advanced stages of heart failure, with the clinical condition of the patient worsening as the INTERMACS profile number gets lower. An INTERMACS 4 has symptoms at rest, an INTERMACS 3 is hemodynamically stable but inotrope-dependent, an INTERMACS 2 is clinically deteriorating with signs of end organ dysfunction despite the use of inotropes, and an INTERMACS 1 is in cardiogenic shock.

Based on the collective outcome data in the INTERMACS registry, guidelines for device implantation have developed. For early elective implantation of a durable LVAD, at numerically higher INTERMACS levels (5–7), the risks of adverse events may outweigh the benefits. Conversely, waiting until the patient is at too low an INTERMACS level (1 or 2) with multisystem organ failure is associated a low probability of ultimate rescue and poor survival. Consequently, at least in the United States, elective LVAD patients are being implanted with durable LVADs when at an INTERMACS level 3 (and in some cases 4), because this seems to be the best timing to balance the risks and benefits and to achieve the best outcomes.

Until 2009, MCS was used most often as a bridge to transplantation. Since 2010, use of destination therapy has grown exponentially, once the HeartMate II received approval as a destination therapy device. INTERMACS data show that destination therapy is now the most common utilization of MCS in the United States, accounting for 41.6% of all LVAD implants in the time period 2011–2013 (compared with 14.7% in 2006–2007). Bridge to candidacy (for transplantation) is now the second most common indication for VADs. The percentage of patients listed for transplantation at the time of VAD implantation has decreased to 21.7% in 2011–2013, compared to 42.4% in 2006–2007. Bridge to recovery and bridge to next decision with short-term VADs and/or extracorporeal membrane oxygenation (ECMO) currently constitutes only a very small percentage of the usage of this technology, compared with the long-term indications.

Mechanical Circulatory Support: Theory and Practice

Cardiogenic shock may be defined as the inability of the heart to deliver sufficient blood flow to meet the metabolic requirements of the body, despite the presence of adequate intravascular volume. Generally, cardiogenic shock entails sustained hypotension (SBP <90 mm Hg or 30 mm Hg below baseline), low cardiac output with high central filling pressures (eg, cardiac index <2.2 L/min/m^2 with pulmonary capillary wedge pressure >12 mm Hg) and signs of diminished tissue perfusion.

What distinguishes cardiogenic shock from the other forms of shock is the mechanical impairment of pump function. Once a patient develops mechanical pump failure and the intracardiac volumes and pressures begin to rise, the vicious cycles (Fig. 28.1) can result in an imbalance of myocardial oxygen supply and demand, worsening ischemia and resulting in further decreases in ventricular function. Cardiogenic shock may ultimately result if the cycle is not broken.

Manipulations and optimization of preload, afterload, heart rate, and contractility are generally the first-line treatment for acute heart failure. Facilitating recovery requires maintaining adequate myocardial oxygen supply, with the lowest feasible myocardial oxygen demand.

Pharmacologic therapies can potentially improve hemodynamics and stabilize the patient with mild or perhaps moderate cardiac failure. In severe failure, however, pharmacologic management with inotropes and vasopressors comes at the cost of increased myocardial oxygen demand and decreased perfusion to the peripheral and splanchnic circulations during attempts to attain acceptable central hemodynamics. For the myocardium, β-adrenergic stimulation may improve contractility of areas that are well perfused, but it will greatly increase myocardial oxygen demand, feeding into and fueling the vicious cycle.

Vasoconstriction may improve coronary and systemic perfusion pressures, but depending on which vasoconstrictor is used, α-adrenergic stimulation will increase both systemic and pulmonary vascular resistances, making it harder for failing ventricles to eject. This is especially problematic when there is right ventricular (RV) failure, because this will increase the workload of the already struggling right ventricle. Furthermore, intentional vasoconstriction often leaves the peripheral and splanchnic beds underperfused.

Afterload reduction with vasodilators is a common strategy to assist the failing heart because the physiologic principle of ventriculoarterial coupling holds that regardless of the poor intrinsic systolic mechanics of the failing ventricle, its overall function as a pump can be improved by decreasing the afterload against which it must pump. However, decreased afterload in the setting of developing cardiogenic shock results in hypotension and poor tissue perfusion that predisposes the patient to multisystem organ failure and a poor outcome.

This is where mechanical circulatory assistance can play an important role, effectively breaking the cycle and improving the balance between myocardial supply and demand as well as systemic perfusion. By decompressing the failing ventricle, the increased wall tension that is adversely affecting the supply-to-demand ratio is addressed, which potentially sets the stage for myocardial recovery. Concurrently, effective perfusion is resumed to the heart and the rest of the body, which can stave off multisystem organ failure.

Thus, by using a mechanical device to take over the pumping function of the failing ventricle, the ravages of cardiogenic shock can often be addressed with the one intervention, albeit an extremely invasive one, with potential advantages and disadvantages. Thus, the

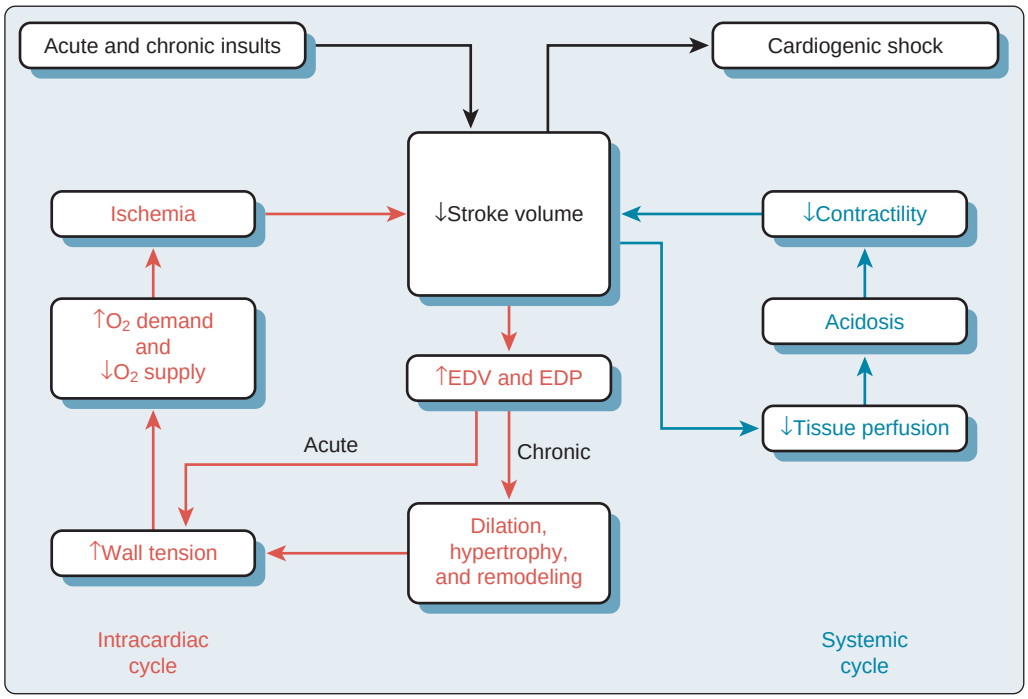

Fig. 28.1 Vicious cycles leading to cardiogenic shock. *EDP,* End-diastolic pressure; *EDV,* end-diastolic volume.

implementation of mechanical assistance is often approached in a stepwise fashion.

The Role of the Intraaortic Balloon Pump

The first step that specifically targets the problem is implementation of intraaortic balloon pump (IABP) counterpulsation. Despite the fact that it was introduced in 1968, the IABP still remains a very commonly used VAD (especially in the United States) because counterpulsation with a properly timed IABP simultaneously increases myocardial oxygen supply and decreases oxygen demand, and is often an effective treatment for left ventricular failure.

Fig. 28.2 demonstrates a deployed IABP. The device has been inserted percutaneously into the femoral artery and then advanced retrograde up the aorta to its correct position that is just distal to the left subclavian artery. Balloon inflation during diastole occludes the aorta and displaces arterial blood, abruptly increasing the aortic root pressure. This increases coronary perfusion pressure, which increases myocardial oxygen supply (assuming the patient has an adequate level of saturated hemoglobin). Abrupt deflation, just before the next systolic ejection decreases the pressure in the aorta in a sudden fashion, facilitating forward ejection from the heart by decreasing impedance to opening of the aortic valve. This results in increased stroke volume and decreased myocardial work and therefore less oxygen demand on the struggling left ventricle. It has been reported that a properly timed, optimally functioning balloon pump can increase cardiac output by 20% or perhaps 30%[11,12] and decrease afterload by as much as 15%. Of the two, it is generally believed that it is the decrease in oxygen demand that most benefits the failing ventricle supported by this device. In the setting of acute myocardial stunning (eg, as a result of an acute myocardial infarction [AMI]), such a decrease in oxygen demand can help to set the stage for myocardial recovery. In the setting of an acute deterioration of a chronically failing ventricle, the IABP may be used to stabilize hemodynamics as a bridge to intervention. Additional reported benefits of IABP counterpulsation include reduction in systemic acidosis and improvements in cerebral and renal microcirculatory perfusion. However, although a balloon pump is well known to improve cardiac function and overall hemodynamics, as mentioned earlier, it augments forward cardiac output by only 25% to 30% at maximum, and it will not augment anything if there is a complete absence of left ventricular output. As a sole intervention, the IABP cannot be expected to rescue a patient from catastrophic myocardial failure.

Appropriate timing of balloon inflation and deflation is key to realizing the hemodynamic benefits of the device. The usual trigger for balloon inflation is the R wave of the patient's ECG; however, an arterial pressure tracing and pacing spikes can also be used. Regardless of the trigger used, as illustrated in Fig. 28.3, inflation should always coincide with the dicrotic notch of the arterial tracing and should continue throughout diastole. Deflation should always occur just at end-diastole, immediately before the next systolic ejection. Inflation and deflation at any other point in the cardiac cycle must be manually corrected by adjustments in balloon timing. Fig. 28.4 shows and discusses potential timing errors. Helium is used as the inflation gas in the IABP because of its low viscosity and inert nature. Depending on the level of assistance required, the balloon can be triggered with each cardiac cycle (so-called 1:1 assistance), every other cycle (1:2), every third cycle (1:3), and so forth. Ratios of 1:2 or 1:3 are ideal for optimizing the timing of inflation and deflation.

Contraindications to the use of the IABP include clinically significant aortic insufficiency, aortic aneurysms, and significant friable atherosclerotic plaques in the aorta. However, the widespread availability of echocardiography to assess patients with cardiac problems, as well as the nearly routine use of transesophageal echocardiography (TEE) during IABP placement in the operative setting, can detect significant atherosclerotic disease in the arch and descending aorta and may help identify patients at high risk. While an ascending aortic dissection still contraindicates IABP use, a descending aortic dissection may no longer constitute an absolute contraindication to IABP use, because, in this era of echocardiography, TEE can be used to ensure the device comes to rest in the true lumen of the aorta.

Indications for the IABP have not changed, but routine IABP usage has recently become somewhat controversial, especially in Europe. It is estimated that 5% to 10% of patients will develop cardiogenic shock following an AMI, and early survival rates for these patients have always been reportedly on the order of 5% to 21%.[13] However, 75% of such patients who were unresponsive to pharmacologic interventions were

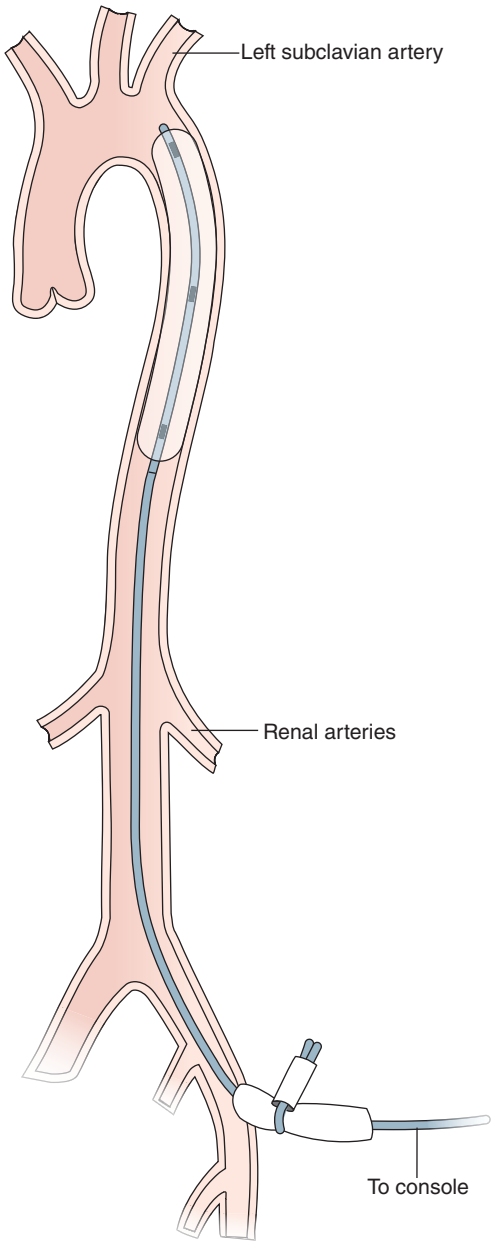

Fig. 28.2 The intraaortic balloon pump.

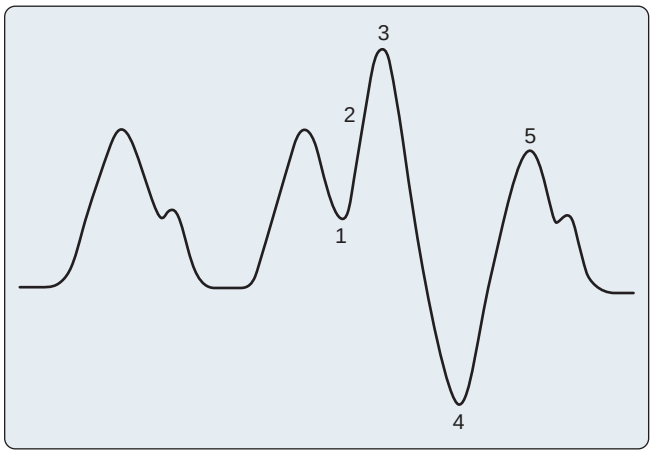

Fig. 28.3 A well-timed intraaortic balloon pump (IABP) inflation. The figure demonstrates an arterial pressure tracing taken from a patient with an IABP. The first pulse seen on the left is the familiar waveform of an arterial pulse. An IABP is triggered to inflate during the second pulse, generating a typical sinusoidal balloon inflation-deflation waveform. The third pulse represents an assisted ejection due to the action of the IABP. Characteristics of the typical balloon waveform include the following: *1,* The balloon inflation point coinciding with the location of the patient's dicrotic notch (representing aortic valve closure at the end of systole). *2,* A steep slope of increasing pressure indicating rapid balloon inflation. This creates a rapid rise in aortic root pressure to reach. *3,* The assisted diastolic peak pressure perfusing the coronary arteries while the IABP is inflated. This increased in coronary perfusion pressure creates the increased myocardial oxygen supply associated with IABP action. *4,* A steep slope of pressure decline indicates a rapid balloon deflation, resulting in a decrease in end-diastolic aortic root pressure. This localized decreased afterload decreases impedance to opening of the aortic valve at the beginning of systole, and creates the decreased myocardial oxygen demand associated with IABP action. *5,* The assisted systolic peak pressure of the next beat perfusing the body. The systolic pressure attained by this ejection was accomplished with less myocardial work thanks to the IABP. Depending on the level of assistance required, the balloon can be triggered with each cardiac cycle (so-called 1 : 1 assistance), every other cycle (1 : 2), every third cycle (1 : 3), and so forth.

well known to exhibit hemodynamic improvement with IABP therapy alone,[14] and early survival rates in these patients were reported to approach 93% when treated with IABP counterpulsation.[15] Although decades of nonrandomized studies and clinical observational trials reported such benefit of IABP use, until recently, limited data were available from randomized trials regarding the outcomes of patients with AMI cardiogenic shock in whom IABP counterpulsation was employed.

In the era of thrombolysis as a primary management of AMI, the IABP enjoyed a class I recommendation in international guidelines, but in current international guidelines (Box 28.1), in the era of percutaneous coronary interventions (PCIs), the recommendation for routine IABP use in the setting of AMI cardiogenic shock has now been downgraded from class I to class IIa in the 2013 American Heart Association (AHA) guidelines and to a class IIb recommendation in European guidelines, on the basis of registry data and a small number of retrospective meta-analyses and randomized trials that failed to demonstrate a mortality benefit from use of the device.[16–19] However, a number of serious concerns and criticisms (eg, regarding patient selection and timing of intervention) have been raised about the methodologies and protocols used in these trials (and thus in trials analyzed in the meta-analyses), and their negative conclusions have been questioned at the international level because several modern-era trials and analyses have demonstrated outcome benefits from IABP use in the AMI cardiogenic shock population.[20–23]

A summary of available published data at the time of this writing regarding the routine use of the IABP to treat patients with AMI cardiogenic shock is as follows:

1. There are no strong data to support the routine use of the IABP in the management of AMI with or without cardiogenic shock, certainly when the device is deployed after PCI.
2. Conversely, no strong data support the avoidance of the use of an IABP in a timely manner in appropriately selected patients who might benefit from the hemodynamic optimization it can provide. Overall, minimal harm has been demonstrated from its use, specifically regarding the incidence of stroke, bleeding, peripheral ischemic complications, and sepsis.[19]
3. There are data suggesting that the routine inclusion of an IABP before high-risk PCI decreases the number of procedural complications[22] and the need for rescue.[24]
4. There are data suggesting that long-term mortality is improved by timely inclusion of an IABP when placed before PCI to ameliorate myocardial ischemia, decompress the ischemic LV, and assist forward flow.[20,22]

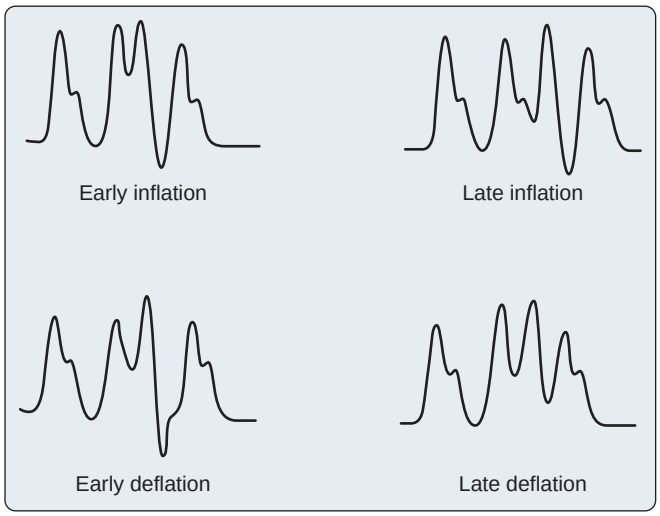

Fig. 28.4 Intraaortic balloon pump (IABP) timing errors. *Early inflation,* before the dicrotic notch (ie, before systolic ejection is completed) immediately forces the aortic valve closed, resulting in prematurely terminated systolic ejection. This results in decreased stroke volume for that cardiac cycle and increased preload for the next cardiac cycle. Not only does this reduce an already impaired cardiac output, but acutely increased end-diastolic volumes stress the failing ventricle by increasing wall tension, which can increase myocardial oxygen demand, impair perfusion, and lead to ischemia. Thus early inflation must be corrected because it increases myocardial oxygen demand and decreases myocardial oxygen supply. *Late inflation,* after the dicrotic notch, fails to augment coronary perfusion pressure optimally. Thus myocardial oxygen supply is not maximally enhanced. *Early deflation* allows time for aortic root pressure to return to baseline before systolic ejection and therefore fails to decrease impedance to opening the aortic valve. Thus myocardial oxygen demand is not decreased. Recall that it is the decrease in myocardial oxygen demand that most benefits the failing ventricle and allows for increased stroke volume with less myocardial work. *Late deflation* can be identified by a failure of the pressure to fall back to baseline or, ideally, below baseline, before the next systolic ejection. Late deflation impedes systolic ejection like an aortic cross clamp. The ventricle is forced to develop such a high pressure to open the aortic valve that ventricular wall tension is significantly increased, which increases myocardial oxygen demand, impairs perfusion, and can lead to ischemia.

Clearly, the IABP remains useful for stabilizing and improving the hemodynamics of selected patients with low cardiac output. It cannot, however, substantially augment forward cardiac output in patients with severe LV failure. This is where more formal MCS comes into play. Despite the absence of strong data and only a class IIb recommendation in current American College of Cardiology (ACC)/AHA guidelines regarding MCS for acute situations (see Box 28.1), the immediate survival of acute cardiogenic shock of any origin will be minimal if nothing is done and disappointingly low (<20%) if medical management alone is instituted.

Implementation of Mechanical Circulatory Support

When the patient with a failing ventricle has failed to improve substantially following all the usual attempts to optimize and maximize, including an IABP, signs that the patient likely needs formal MCS include the following:

- Hypotension (mean arterial pressure [MAP] <60 mm Hg or systolic blood pressure [SBP] <90 mm Hg)
- Cardiac index <2 LPM/m^2
- Pulmonary capillary wedge pressure (PCWP) or right atrial pressure (RAP) >20 mm Hg
- Systemic vascular resistance (SVR) >2000 dyne-sec/cm^5
- Oliguria, low mixed venous oxygen saturation, and rising lactate.

BOX 28.1 2013 ACCF/AHA STEMI GUIDELINES FOR THE USE OF IABP AND VADS

Class I

1. Emergency revascularization with either PCI or CABG is recommended in suitable patients with cardiogenic shock due to pump failure after STEMI irrespective of the time delay from MI onset. (Level of evidence: B)
2. In the absence of contraindications, fibrinolytic therapy should be administered to patients with STEMI and cardiogenic shock who are unsuitable candidates for either PCI or CABG. (Level of evidence: B)

Class IIa

1. The use of IABP counterpulsation can be useful for patients with cardiogenic shock after STEMI who do not quickly stabilize with pharmacologic therapy. (Level of evidence: B)

Class IIb

1. Alternative LVADs for circulatory support may be considered in patients with refractory cardiogenic shock. (Level of evidence: C)

ACCF, American College of Cardiology Foundation; *AHA,* American Heart Association; *CABG,* coronary artery bypass graft; *IABP,* intraaortic balloon pump; *MI,* myocardial infarction; *PCI,* percutaneous coronary intervention; *STEMI,* ST-segment elevation myocardial infarction; *VAD,* ventricular assist device.

From O'Gara PT, Kushner FG, Ascheim DD, et al. 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: executive summary: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines: developed in collaboration with the American College of Emergency Physicians and Society for Cardiovascular Angiography and Interventions. *Catheter Cardiovasc Interv.* 2013;82(1):E1–E27.

It cannot be overemphasized that fixing numbers will not inevitably improve outcome. Even if somewhat acceptable central hemodynamics can be created pharmacologically, it is very important to consider evidence of poor organ and peripheral perfusion, such as oliguria, low mixed venous oxygen saturation, and rising serum lactate as indications of the need to support the circulation in a more formal way.

Moreover, it is critically important that the failure of the usual maneuvers to adequately stabilize the patient be promptly recognized, because experience of the past few decades has shown that the timing of implementation of MCS is the most important factor in patient outcome.[25]

One cannot wait to initiate support until there is profound cardiogenic shock with deterioration in major organ function. Some recovery may be possible with restoration of adequate perfusion, but it's very difficult to predict, and study after study has shown that patient status at the time of implantation is the primary determinant of outcome. *The longer one waits, the worse the outcome.*

To provide formal MCS, the heart and great vessels must be cannulated and connected to a pump. Fig. 28.5 shows the classic cannulation strategies in the heart and great vessels that, until recently, were the only options, regardless of which manufacturer's device was selected to provide the support. Novel potential cannulation strategies of specific devices are discussed later in the chapter.

While diversion of blood to the pump provides the stroke volume that is ejected, it also facilitates decompression of the failing ventricle, which is critical, because decreased ventricular wall tension dramatically reduces myocardial oxygen demand, interrupting the cycle of worsening ventricular failure. It should also be noted that currently available VADs do not provide any oxygenation or removal of waste from the blood but simply act as pumps that can promote perfusion of the arterial circulation downstream from the failing ventricle. It is possible with some devices, however, to introduce an in-line membrane oxygenator and extracorporeal carbon dioxide (CO_2) removal system for patients with concomitant respiratory failure.

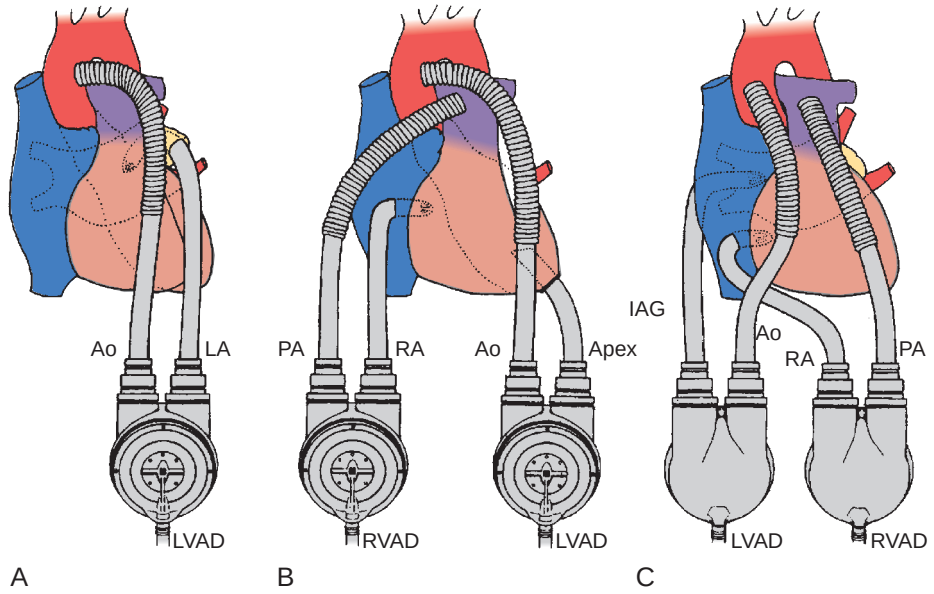

Fig. 28.5 (A–C) Classic cannulation strategies for mechanical circulatory support. *Ao,* Aorta; *IAG,* interatrial groove; *LA,* left atrium; *LVAD,* left ventricular assist device; *PA,* pulmonary artery; *RA,* right atrium; *RVAD,* right ventricular assist device.

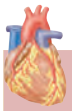
Once the decision to provide MCS has been made, an appropriate device is selected. A number of different devices may be available, and the device selected for a given patient depends primarily on the following factors:

1. The anticipated duration of support required (different devices have different intended durations of use rooted in their engineering, and there are also considerations of FDA approval of the various devices)
2. Whether uni- or biventricular support is required (some devices are intended to support just the left ventricle, although some can be configured to support either, or both simultaneously)
3. The degree of pulmonary dysfunction such that ECMO is required
4. The urgency of the situation (some devices can be deployed rapidly, perhaps even at the bedside, whereas others require transfer to the operating room for sternotomy and cardiopulmonary bypass [CPB])
5. The availability of the device

Before MCS implantation is performed, numerous individual patient factors must be considered, because MCS is fraught with pitfalls, complications, and ethical considerations.

As patient management experience in the field has grown and the outcomes have improved with more advanced devices, there has been an interesting shift away from the question, who needs a VAD? to the more pertinent question, who probably should not receive one? The only absolute contraindications to even temporary VAD use are prognostic factors that would preclude survival even with the restoration of perfusion to the vital organs and peripheral tissues. Thus, the potential for recovery is the paramount consideration. On many occasions, however, the myocardial insult is at least initially the primary problem, and more relative contraindications to VAD support will need to be considered.

Box 28.2 lists a number of commonly encountered considerations and relative contraindications to VAD support that include a variety of anatomic issues and other patient factors that create management issues, make VAD placement or use difficult, make complications more likely, or make meaningful recovery unlikely. Although the advent of modern devices and management strategies has rendered some of these relative contraindications essentially moot, all must be considered and addressed.



BOX 28.2 CONDITIONS OR COMORBIDITIES THAT MAKE VENTRICULAR ASSIST DEVICE PLACEMENT OR USE DIFFICULT, MAKE THE PATIENT MORE LIKELY TO HAVE MAJOR COMPLICATIONS, OR MAKE MEANINGFUL RECOVERY UNLIKELY

Absolute Contraindication

- The patient will not survive regardless of the restoration of adequate systemic perfusion

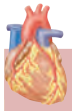
Relative Contraindications or Issues That Need to Be Addressed

- Patient is not a transplant candidate (unless destination therapy or bridging to improved candidacy is the intention and a durable LVAD is being implanted)
- In situ prosthetic valves
- Clinically significant aortic insufficiency
- Clinically significant tricuspid insufficiency
- Mitral or tricuspid stenosis
- Congenital heart disease
- Intracardiac shunts
- Previous cardiac surgery
- Poor nutritional status
- Extremes of body surface area
- Advanced systemic disease (severe COPD, malignancy, ESLD, ESRD, sepsis, progressive neurologic disorder, etc)

COPD, Chronic obstructive pulmonary disease; *ESLD,* end-stage liver disease; *ESRD,* end-stage renal disease; LVAD, left ventricular assist device.

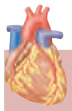
Short-Term Support

INTERMACS data reveal that short-term MCS support constitutes a relative minority of the usage of this technology, but the use of a VAD as a bridge to recovery remains critical to the survival of patients with acute, refractory, severe cardiac failure. However, the traditional conception of short-term use of a VAD only as a bridge to recovery has now been expanded to include concepts such a bridge to immediate



BOX 28.3 COMMON CLINICAL SCENARIOS IN WHICH SHORT-TERM MECHANICAL CIRCULATORY SUPPORT MAY BE INDICATED

- Stunned myocardium following open heart surgery
- Acute myocardial infarction
- Following a failed heart transplantation
- Cardiogenic shock due to acute myocarditis
- Stress-induced cardiomyopathy
- Following a cardiac catheterization lab misadventure
- In the setting of right ventricular failure in the patient already supported by left ventricular assist device



BOX 28.4 POTENTIAL OUTCOMES FROM URGENT IMPLEMENTATION OF SHORT-TERM MECHANICAL CIRCULATORY SUPPORT

- The patient is neurologically intact and multisystem organ function is acceptable; the heart recovers after a period of time and support is weaned to off.
- The patient demonstrates severe neurologic deficits and/or multisystem organ failure; support is withdrawn.
- The patient is neurologically intact and multisystem organ function is acceptable but the heart does not recover; the patient is bridged to either transplantation or destination with a durable mechanical circulatory support device.

survival, bridge to next decision, bridge to a bridge, and bridge to surgery (sometimes at another center). It is common for MCS to be implemented to allow for patient transport to a transplant center, often referred to as a *hub* from an outside hospital or *spoke*.

In general, short-term VAD use is intended for rescue from acute refractory ventricular failure, from which the myocardium is expected to recover.

Thus, as listed in Box 28.3, common scenarios in which temporary VAD insertion may be indicated include ventricular failure due to stunned myocardium following open heart surgery, AMI, following a failed heart transplantation, cardiogenic shock due to acute myocarditis, stress-induced cardiomyopathy, following a cardiac catheterization laboratory complication, and in the setting of RV failure in the patient already supported by an LVAD.

Possible Outcomes From Short-Term VAD Support

An understanding of the limited number potential outcomes from the short-term use of MCS (Box 28.4) helps guide decision making and illustrates some of the current indications for MCS.

1. MCS with a short-term VAD (or ECMO, discussed later) is implemented as a component of an acute rescue strategy; the patient does well on support (eg, the patient is neurologically intact and multisystem organ function is acceptable), and the heart recovers. In this scenario, MCS has been successfully used as a bridge to recovery. Depending on the specific cause of the acute cardiac failure, this could take anywhere from a few days to a few weeks. At that point, MCS flows can be weaned down and the cannulas explanted. It must be appreciated, however, that rates of successful weaning from short-term support were quite low as recently as the late 1990s (eg, 25–30% immediate survival). Over the past decade, however, experienced centers with well-defined protocols for patient selection and optimal timing of intervention have demonstrated survival rates exceeding 50% in the postcardiotomy cardiogenic shock population. Survival following AMI cardiogenic shock that requires VAD support remains in the range of 30%, depending on the device that was used and other critical factors, especially the status of the patient at the time of intervention. Again, the key factor seems to be the time frame in which intervention is implemented; postcardiotomy cardiogenic shock is generally managed immediately, while the management of AMI cardiogenic shock seemingly has a more variable time frame before intervention.
2. Short-term MCS is implemented, but the patient manifests severe neurologic damage and/or progresses to multisystem organ failure before the heart has a chance to recover. Progressive multisystem organ failure and severe neurologic damage are not uncommon in this population, regardless of the restoration of systemic perfusion by a device. In such cases, support is often withdrawn. This reality is one of the reasons why patient selection is so critical and also why it has become popular to use temporary ECMO to determine which patients will recover and likely survive before implanting a formal VAD, even for short-term use. In this case, the use of ECMO would be an example of bridge to next decision.
3. A short-term VAD is implemented as a bridge to recovery; the patient survives and is neurologically intact, but the heart never recovers. If the myocardium does not recover after a period of short-term support, then a decision must be made as to whether the patient is an acceptable transplant candidate. If so, the short-term VAD may be switched to a different device capable of providing long-term support as a bridge to transplantation. In this case, the short-term VAD has been used as a potential bridge to immediate survival and then as a bridge to a bridge. If not transplant-eligible, the patient must be evaluated for permanent implantation of an approved VAD as a permanent management strategy, also known as *destination therapy*. In some cases, the long-term durable LVAD implanted as a bridge to transplantation may be an approved device used in destination therapy. The current generation of durable LVADs has afforded new options for patients with myocardial failure.

Available Devices for Short-Term Support

Before 1992, when the Abiomed BVS 5000 became clinically available, standard centrifugal pumps were used to provide either uni- or biventricular short-term mechanical circulatory assistance. Currently, this type of very basic device would be used for pediatric applications (with small-caliber cannulas to limit flow) or for ECMO; clinicians are beginning to incorporate ECMO more frequently into resuscitative efforts as a bridge to next decision. Such a strategy has been termed *extracorporeal life support*, in which a patient with refractory cardiogenic shock with uncertain outcome is placed on ECMO for a few days. In this fashion, a less expensive centrifugal device is used to determine if there is reasonable likelihood of survival, before committing the patient to a more formal (and much more expensive) VAD. As experience grows, ECMO utilization is likely to increase in these circumstances, concurrent with the availability of more advanced devices that are replacing standard centrifugal pump head technology.

CentriMag

The CentriMag (Thoratec Corporation, Pleasanton, Calif; Fig. 28.6) is a small centrifugal pump with a magnetically levitated impeller that is now being used widely in the United States, in Europe, and in other parts of the world to provide short-term support for almost any modern indication. As with other short-term devices, the pump head itself remains paracorporeal during support, connected to cannulas in the heart and great vessels, so it can be used for left-sided, right-sided, or biventricular support.

Earlier short-term support devices were usually pulsatile and made of polyurethane and other suboptimal materials; they included artificial valves and had a high rate of thrombosis. In contrast, the CentriMag produces nonpulsatile continuous flow, and its design has demonstrable advantages. The impeller of the CentriMag is magnetically levitated and hydrodynamically suspended in the patient's blood;

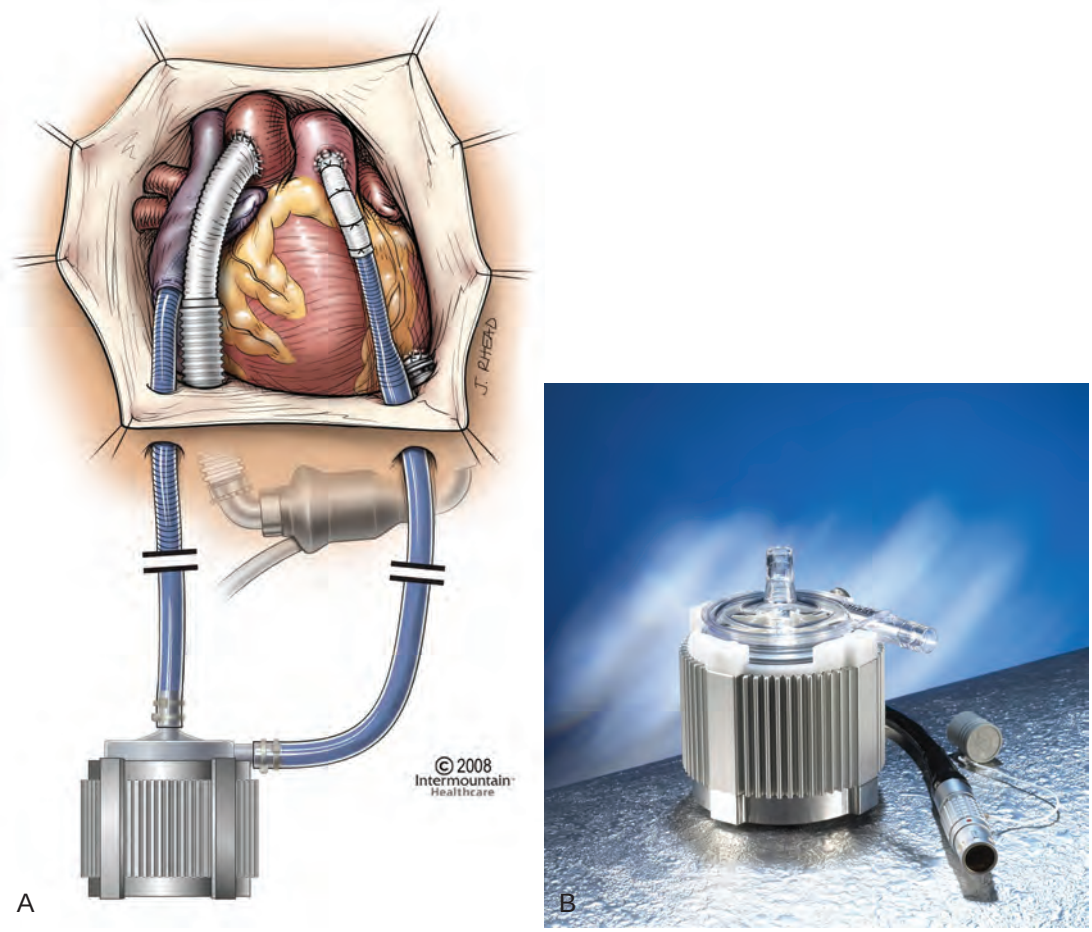


Fig. 28.6 (A) and (B) The Thoratec CentriMag. *(Courtesy of Thoratec Corporation, Pleasanton, Calif.)*

there is no central bearing, and without a bearing, less heat is produced. As a result, there is less hemolysis and therefore less inflammatory response, less peripheral vasoconstriction, and less microvascular occlusion related to plasma free hemoglobin. There may also be a lower incidence of thromboembolic events, and the derangement of liver function tests generally seen after a few days with a standard centrifugal pump head are reportedly not seen to nearly the same extent with the CentriMag.

Despite its small size, the pump itself can provide flow rates of up to 9.9 liters per minute (LPM) and can pump through a membrane oxygenator if ECMO is desired. This versatility coupled with its superior performance profile has made the CentriMag the device of choice for short-term support in many experienced institutions.

At the time of this writing, the CentriMag is FDA cleared for 30 days as a right ventricular assist device (RVAD), but only for 6 hours as an LVAD. It should be understood, however, that the off-label use of the CentriMag as an LVAD for periods longer than 6 hours is common. A smaller version called the PediVAS is approved for 6 hours of use as either an LVAD or an RVAD.

Recent publications of experiences using the CentriMag for biventricular support as a bridge to next decision report 30-day survival in the range of 44% to 73%.[26–28]

Bridge to Immediate Survival: Concepts and Devices

A key determinant of the overall success of bridge to recovery is the rapidity with which the failing ventricle can be decompressed and resumption of adequate systemic perfusion ensured. One of the recognized limitations of currently available devices as a bridge to recovery following an acute myocardial insult is that they must be implanted in a cardiac operating room, often utilizing CPB. Even assuming the immediate availability of the operating room, the device, and the necessary surgical, anesthesia, perfusion, and nursing personnel, delays are inevitable. Poor patient selection aside, it is conceivable that a factor contributing to the low rates of successful bridge to recovery seen in the past was delay in treatment due to operating room and personnel availability. During this interval, the failing ventricle was invariably pressure and volume overloaded, while the splanchnic beds and peripheral tissues were underperfused.

Deploying a rescue device rapidly at the first recognition of refractory ventricular insufficiency (whether acute, or acute on chronic) in the emergency room, the cardiac catheterization laboratory, or an intensive care unit without the need for sternotomy and CPB is theoretically a superior option. Additionally, commonly encountered complications of CPB, such as perioperative bleeding, and the sequelae of the systemic inflammatory response would be minimized. Once immediate survival is ensured, such a strategy/device can conceivably be switched to another that is capable of providing a longer period of support. Considerations such as these led to the development of innovative short-term assist devices and continue to drive the use of time-honored strategies in new ways.

Extracorporeal Membrane Oxygenation

ECMO can be rapidly deployed in experienced centers as a lifesaving intervention to provide temporary cardiopulmonary support as a bridge to immediate survival, a bridge to recovery, and/or as a bridge to support by a longer term support device. Developed from

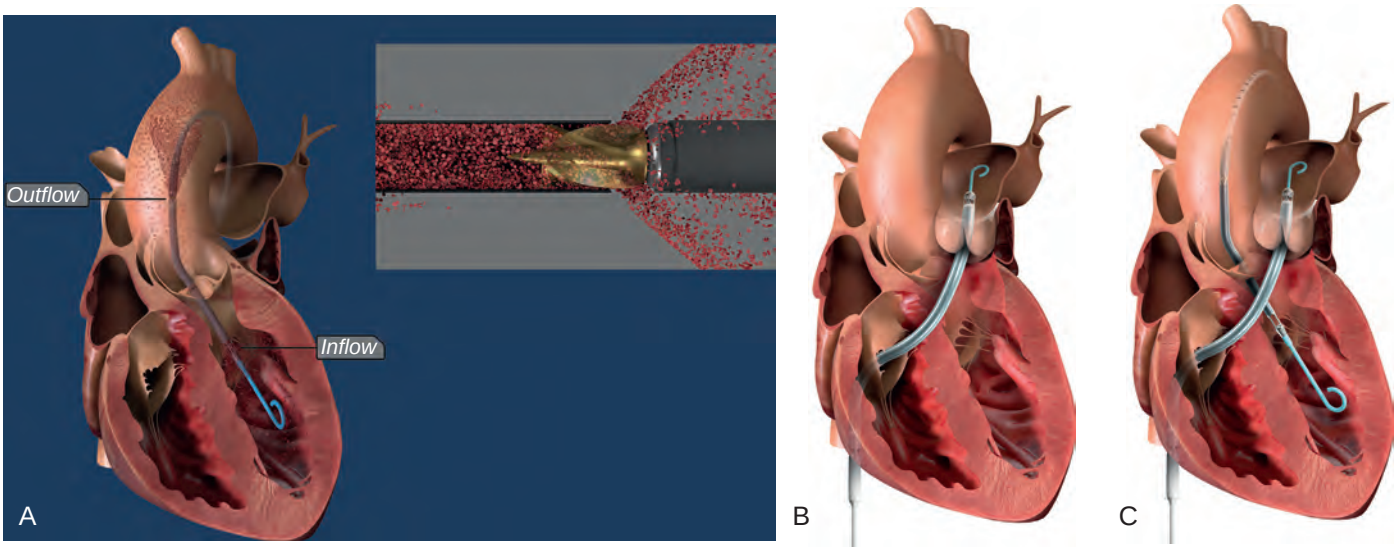

Fig. 28.7 (A–C) The Impella family of support devices. *(Courtesy of Abiomed Inc., Danvers, Mass.)*

CPB technology in the 1970s, a simple ECMO circuit generally uses only a centrifugal pump head, a membrane oxygenator, and a heat exchanger. Survival to hospital discharge has always been the best for full-term neonatal patients with respiratory failure, but experience suggests that appropriately selected adults can also benefit. Clearly, similar considerations govern patient selection for ECMO as for acute implementation of MCS in general (as discussed earlier), with a high likelihood of recovery being the key consideration prior to initiating the therapy. Patients with poor clinical prognosis beyond their respiratory or cardiopulmonary failure, those with multisystem organ failure, and those who have already been intubated and mechanically ventilated for several days at the time of proposed intervention are not likely to demonstrate optimal outcomes from ECMO.

Where respiratory failure is the principal issue and the heart is able to provide adequate output to potentially meet circulatory needs, venovenous (VV) ECMO can provide the necessary oxygenation and ventilation of the blood. In this strategy, venous blood is drained from a caval cannula (introduced through either the femoral or the jugular route), pumped through a membrane oxygenator, and returned to the venous circulation (usually at the level of the right atrium).

Patients with both respiratory and cardiac pump failure are best supported by venoarterial (VA) ECMO, in which venous blood is oxygenated, ventilated, and pumped back into the arterial circulation. Such a strategy is essentially providing CPB. Although cannulations for VA ECMO can be peripheral (eg, femoral vein to femoral artery) or central (eg, right atrium to aorta), central venous cannulation generally provides optimal decompression of the cardiac chambers, which is important for myocardial recovery.

Thus, both VV and VA ECMO provide respiratory support, but only VA ECMO provides MCS. Potential complications of ECMO include all of those inherent to extracorporeal circulation, including bleeding (due to the requisite anticoagulation during support) and limb ischemia distal to peripherally inserted cannulas.

Echocardiography plays an important role in determining the type of ECMO needed (VV vs VA) to ensure proper positioning of cannulas, to assess the extent of ventricular decompression, to monitor potential myocardial recovery, and to aid in subsequent decision making.

Current AHA guidelines for cardiopulmonary resuscitation[29] give ECMO a class IIb recommendation (may be considered, benefit may outweigh risk) for clinical scenarios where recovery is possible. A position article, published in 2011 by the European Extracorporeal Life Support (ECLS) Working Group, outlines the indications, contraindications, and various aspects of patient management regarding ECMO.[30]

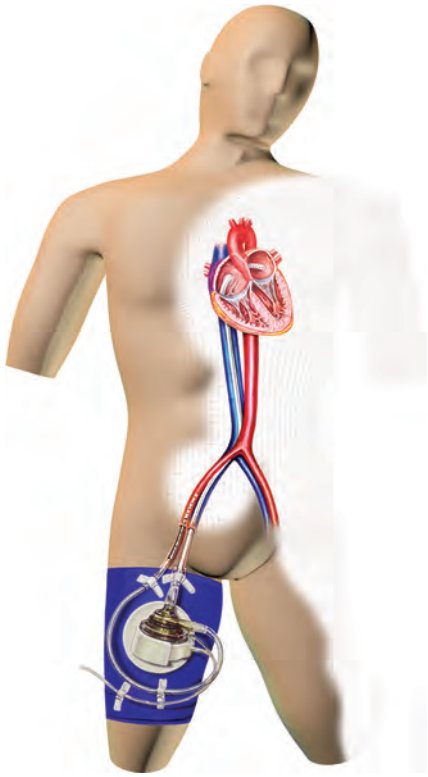

Fig. 28.8 TandemHeart. *(Courtesy of CardiacAssist Inc., Pittsburgh, Penn.)*

Impella and TandemHeart

The Impella (Abiomed, Danvers, Mass; Fig. 28.7) and the TandemHeart (CardiacAssist, Pittsburgh, Pa; Fig. 28.8) percutaneous VADs (pVADs) represent potential bridge-to-immediate-survival devices. Both are designed to support the failing LV, and both are rapidly deployable percutaneously at the time of diagnosis of acute ventricular insufficiency in the emergency room, cardiac catheterization laboratory, or intensive care unit. There is no need for sternotomy and CPB, which has clear potential advantages (as discussed earlier).

Despite the enormous potential of these devices when employed early as a lifesaving intervention, the most frequent use of both

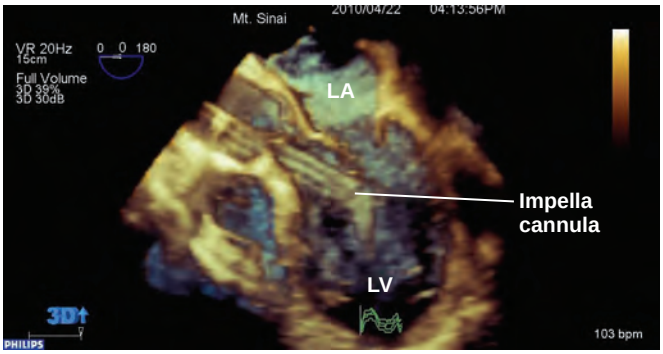

Fig. 28.9 The proper positioning of the inflow cannula of the Impella VAD (ventricular assist device) entering the left ventricle (LV) in a retrograde fashion through the aortic valve. *LA,* Left atrium.

devices has been in the catheterization and electrophysiology labs as an extra margin of safety for high-risk patients undergoing high-risk percutaneous interventions and hemodynamically challenging electrophysiologic interventions (eg, ablation of ventricular tachycardia or fibrillation pathways); the least frequent use has been as a bridge to immediate survival or recovery.

Unfortunately, similar to the initial experience with VADs themselves, when such devices first became available, they were implemented for rescue only as a last resort, once patients had already developed profound cardiogenic shock and organ dysfunction refractory to pharmacology and IABP counterpulsation. Not surprisingly, this led initially to suboptimal results. Outcomes, however, are reportedly improving, and such devices may ultimately demonstrate benefit over ECMO or long-term VADs in the setting of isolated LV or RV failure without pulmonary dysfunction, major valvular abnormality, or biventricular failure. Accordingly, clinical experiences with these devices for acute rescue now appear in the peer-reviewed, published literature. There seems to be an advantage of these devices over the IABP in terms of the level of support provided and the output they can generate, but with a higher risk of bleeding, and the clinical situations in which they might be optimally employed are still being elucidated.

Impella

The Impella pump system is a family of microaxial continuous flow support devices that can be used to support the left, right, or both ventricles. Clinical trials intended to establish the efficacy and optimal utilization of each Impella device are ongoing.

Percutaneously deployable members of the Impella family include the LP 2.5 (provides 2.5 LPM of flow as an LVAD), the LP 5.0 (provides 5 LPM of flow as an LVAD) and the recently approved RP (provides 4 LPM of flow as an RVAD). Other members of the Impella family include directly implantable versions for both left and right ventricular support (LD and RD). All of these devices are FDA cleared, and theoretically all hold the international class IIb recommendation for VAD use in the AMI cardiogenic shock population.

As illustrated in Fig. 28.7, the percutaneous Impella LVAD devices can be inserted from the femoral or subclavian arterial approach retrograde across the aortic valve into the left ventricle to pump blood into the ascending aorta, actively unloading the LV. Relative contraindications to this approach include significant aortic valvular disease or significant atherosclerotic burden in the aorta (eg, mobile plaques or vascular stenosis). The Impella RP is inserted via the femoral vein through the right atrium and into the pulmonary artery, unloading the failing right ventricle and ensuring pulmonary blood flow as an RVAD.

Although reasonably easy to deploy with fluoroscopy or TEE guidance (Fig. 28.9), the majority of use of the LP 2.5 has been in the cardiac catheterization lab or electrophysiology lab as an extra margin of safety for high-risk patients undergoing PCIs and arrhythmia ablations. This is because 2.5 LPM of flow is generally insufficient to rescue by accommodating the circulatory needs of a full grown adult with cardiogenic shock. A recently published analysis of the outcomes with LP 2.5 support in 120 adult patients with acute MI cardiogenic shock at 14 tertiary care centers in 5 European countries demonstrated that although lactate levels came down within 48 hours of device support (demonstrating the positive effects of low flow support), 30-day survival rate remained fairly low (36%).[31] Similar to the situation with the IABP, criticisms of the methodologies used in the practices and studies included patient selection and the timing of intervention.[32]

As discussed earlier, since the mid-1990s, it has been understood that patient status at the time of implementation of MCS is the primary determinant of outcome. Early and sufficient MCS leads to the best possible outcomes. Cardiologists and emergency physicians are the providers who must make the decision to employ MCS when patients present with acute symptoms, typically in the emergency department setting. Cause of the cardiogenic shock and appropriate patient selection are critical factors as well. The outcome of a young person with acute myocarditis cannot be compared to an older person with coronary artery disease, long-standing heart failure, and varying levels of multisystem deterioration. Furthermore, it is also important to consider that simply preventing imminent death is not the same thing as prolonging a high quality of life. Goals of care are important to these decisions.

By comparison to the LP 2.5, the Impella 5.0 can produce a physiologically relevant amount of forward flow, and there is a rapidly growing experience with the use of that device as a bridge to immediate survival, a bridge to recovery, and a bridge to surgery. In contrast to the experience with the LP 2.5 in the setting of AMI cardiogenic shock, a 2013 publication reported the results of a multicenter assessment of the Impella 5.0 as a rescue device for postcardiotomy LV failure.[33] Survival rates were very encouraging, with 30-day, 3-month, and 1-year survival rates of 94%, 81%, and 75%, respectively. It is important to consider that in MCS for postcardiotomy, LV failure is associated with superior outcomes when compared with MCS for AMI cardiogenic shock. This is likely related to shorter intervals separating diagnosis and active management. A recent publication also reported the utility of the Impella 5.0 as a bridge to improved candidacy for transplantation with a durable long-term LVAD.[34]

The TandemHeart

The TandemHeart pVAD (CardiacAssist, Pittsburgh, Pa) uses a full-sized centrifugal pump and a percutaneous cannulation strategy that results in reasonable decompression of the failing LV and rapid resumption of systemic perfusion. As illustrated in Fig. 28.8, with this device, a long percutaneous venous inflow cannula is advanced retrograde from the femoral vein through the RA and across the interatrial septum into the LA. Up to 5 LPM of continuous, nonpulsatile outflow from the centrifugal device (strapped to the patient's leg) is directed into the femoral artery to maintain systemic perfusion. It should be noted that the concept of using LA to femoral artery bypass with an interatrial septal cannula was first described by Dennis and colleagues in the 1960s.[35]

The TandemHeart holds a CE mark in Europe and is FDA cleared in the United States for up to 6 hours of use as an LVAD. In current guidelines, the TandemHeart holds a class IIb recommendation for the management of AMI cardiogenic shock. Although this device was envisioned to be a comparatively rapidly deployable bridge to immediate survival device, the need for a transseptal puncture guided by fluoroscopy and/or echcardiography may limit the ease of implantation, and it would be impossible to implement this device during cardiopulmonary resuscitation.

The superiority of the TandemHeart to provide MCS when compared to a balloon pump was reported in a number of studies, but there is a paucity of published data regarding outcomes with the TandemHeart LVAD by itself. The main complications with the TandemHeart appear to be bleeding at the cannulation sites and limb ischemia. Cannula dislodgment is also a potential issue. The TandemHeart is currently the subject of a multicenter pivotal trial called TRIS (TandemHeart

to Reduce Infarct Size) looking at myocardial salvage in AMI patients, and experience with the use of the TandemHeart as an RVAD is growing.

A 2013 study compared outcomes of 79 patients in acute cardiogenic shock supported by the TandemHeart, the Impella 5.0, and conventional VA ECMO.[36] Overall, in-hospital mortality, rates of successful weaning, rates of successful bridging to a bridge with a longer term device and incidence of limb complications did not differ between the devices. Younger age was the only predictor for improved in-hospital survival, and cost considerations favored ECMO. The manuscript also discussed the advantages and disadvantages of each support strategy. A consensus statement published in 2015 also reviewed and discussed the utility of percutaneous MCS devices.[37]

Fig. 28.10 depicts a logical decision-making algorithm for MCS in the setting of severe refractory cardiogenic shock, but what works well in one institution may not be generalizable to another. Thus, each institution should ideally develop its own algorithm, taking available devices, resources, and experiences into account.

Long-Term Support

As revealed by the INTERMACS data, long-term, durable devices are being implanted in thousands of people each year who otherwise would succumb to heart failure. A number of long-term VADs are available at the time of this writing, but only the HeartMate II (Thoratec Corporation, Pleasanton, Calif; Fig. 28.11) and the HeartWare HVAD (HeartWare, Framingham, Mass; Fig. 28.12) are approved for use and currently in regular use in the United States. Efficacious devices exist in other countries (eg, the Berlin Heart INCOR, Berlin Heart, Berlin, Germany, Fig. 28.13). Several new durable devices are still under investigation in the United States (eg, the HeartMate III, Thoratec Corporation, Pleasanton, Calif; Fig. 28.14). Additionally, some previously used or approved devices may still be employed infrequently in specific centers, but a complete discussion of all potentially available devices is beyond the scope of this chapter. The total artificial heart is indeed in use in the United States and is discussed in detail later.

HeartMate II

The HeartMate II (HM II) is by far the most commonly used long-term LVAD in the United States at the time of this writing. Approved as a bridge to transplantation in 2008 and for destination therapy in 2010, the device is a small axial flow pump, about the size of a D-battery, with a rotating impeller shaped like an Archimedes screw. It has an internal volume of 63 mL and a maximum output of 10 LPM against a mean pressure of 100 mm Hg. This is a continuous flow device that initially results in a mostly nonpulsatile circulation, but pulsatility returns in most patients once the ventricle starts to recover. According to the manufacturer, more than 16,000 patients worldwide have been implanted with the HeartMate II, with the longest duration of support greater than 8 years. Out of all the patients implanted with this device for the purpose of bridge to transplantation, 87% have received a heart transplantation.[1]

Given that the HM II has been the most frequently used, durable LVAD in the United States since the time of its FDA approval for all long-term MCS indications, the 2014 INTERMACS data (presented earlier) are essentially the current data for the HM II.

Figure 28.11 shows how the device is configured internally. The only visible external component is a driveline that exits the skin of the abdomen, usually on the right somewhere convenient between the upper and lower quadrants. The device draws blood from the LV apex and pumps the blood continuously into the ascending aorta. This does not prevent the left ventricle from ejecting through the aortic valve, and the amount of support provided by the device depends on several factors, including intrinsic myocardial function, preload, and afterload. These issues have relevance for the management of a patient on such a support device, as discussed later.

HeartWare HVAD

The HeartWare ventricular assist device (HVAD) is a small intrapericardially positioned continuous flow centrifugal pump, with a bearingless, hydrodynamically suspended, magnetically driven impeller. Technically, the HVAD is a third-generation device because it is bearingless. Typical for a centrifugal pump, rotational speeds of 2000 to 3000 rpm can produce upward of 10 LPM of flow. There are the usual external system controller and power supply that are connected to the device by a tunneled driveline. The configuration of the HVAD is depicted in Fig. 28.12.

The HVAD was CE marked for clinical use in Europe in 2009, was approved by the Australian TGA in 2011, and received FDA approval as a bridge to transplantation in the United States in November 2012 following its demonstration as noninferior to other implantable devices in the ADVANCE trial.[38] In this trial, 140 patients implanted with the HVAD were followed for 180 days or until transplantation or death, and their outcomes compared with 544 patients implanted with other commercially available devices. Of the 140 in the investigational group, at 180 days, 62% were still supported by their original device, 29% had been transplanted, 5% had required device exchange (2% for pump thrombosis), and 4% had died. Overall the 1-year survival rate was 85%.[39]

The HVAD, because of its small size, has also been used as an implantable RVAD. Experience with the use of the HVAD for RV support (while limited at this time) is steadily increasing.[40–42] The HVAD is already approved as a device for use in destination therapy in Ontario (since 2012), and it is anticipated that data from the ENDURANCE trial and the ENDURANCE supplemental trial, which began enrolling patients in late 2013, will establish the HVAD as a device for that use in the United States.

A recent analysis of real-world experience with the HeartWare HVAD over 4 years in the UK revealed a 75% survival rate at 1 year and 66% at 2 years.[43] It should be noted, however, that European patients are generally implanted at lower INTERMACS levels (higher acuity) than in the United States, which may account for the lower rate of survival when compared to the ADVANCE trial conducted in the United States. Interestingly, a multicenter trial conducted at four Canadian centers (where patients were implanted at INTERMACS levels 1 and 2, as they tend to be in Europe) reported an 86% 1-year survival rate. In this trial, 39% were successfully bridged to transplantation, but a 3% incidence of pump thrombosis was seen. It is worrisome that a 36% incidence of adverse neurologic outcome was reported.[44]

Complications of Mechanical Circulatory Support

As outcomes have improved, simple survival of mechanically supported patients has become less of an issue, and the primary focus of MCS research has shifted toward optimizing outcomes through limiting adverse events. Unfortunately, no single risk-stratification method or scoring system has yet been devised to predict the various adverse events inherent to the MCS population. For example, although the preimplant Sequential Organ Failure Assessment (SOFA) score was recently reported to reliably predict survival after 6, 9, 12, 24, and 36 months of support, the SOFA score did not predict other long-term adverse events (eg, stroke, bleeding, infection, need for pump replacement).[45] It is also important to understand that because of the distinct mechanical underpinnings, materials, and functional specifications of modern devices, all data, predictive indices, and risk-stratification scores generated during the era of first-generation pulsatile devices cannot be extrapolated to the current generation of nonpulsatile devices.

Overall, there has been a major decrease in the rates of specific adverse events with the continuous flow devices compared to the first generation of pulsatile devices, according to INTERMACS and other data sources. Conversely, only minor decreases in the total burden of adverse events have been reported in the current era compared to the previous era. Although the rates of some classic problems have

decreased significantly (eg, mediastinal bleeding, RV failure, perhaps stroke), the rates of some important ones (eg, renal failure and respiratory failure) have not changed. Moreover, new complications have appeared that did not exist with the first generation of pulsatile devices, such as arteriovenous malformations in the gastrointestinal tract, von Willebrand syndrome resulting in gastrointestinal and intracerebral bleeding, and pump thrombosis, among others.

New information is rapidly emerging, and certain modern complications of VAD support have now been linked with certain preexisting factors and/or aspects of modern MCS technology.

- Gastrointestinal arteriovenous malformations are now understood to result from the nonpulsatile flow produced by modern MCS devices, much as they are known to form in patients with severe aortic stenosis (Heyde syndrome).[46–50]
- Acquired von Willebrand syndrome (from the loss of high-molecular-weight von Willebrand monomers) is now understood to result from the shear stresses imposed by the continuous flow devices.[51–55]
- Pump thrombosis has been seen with surprisingly high frequency with both the HM II and the HVAD. As outlined in a 2014 *New England Journal of Medicine* publication, starting in approximately March 2011, the rate of confirmed HM II pump thromboses at 3 months after implantation rose from approximately 2.2% to 8.4% by January 2013.[56] This was alarming, because previously, the median time from implantation to identification of any significant incidence of pump thrombosis had been 18.6 months. To date, any single reason for this increase remains elusive. In all likelihood, this is a multifactorial problem. In addition to design changes to the HM II introduced in 2010 (a new gelatin sealing of the grafts), as reviewed by Lindenfeld and Keebler,[57] additional potential causes of the increased rate and number of HM II thromboses may have

included inadequate anticoagulation and/or antiplatelet therapy during VAD support, overestimation of the actual level of anticoagulation present,[58] the use and dosage of erythropoiesis stimulating agents,[59] abnormal angulation of the inflow and or outflow cannula,[60] strategically decreased rates of flow, heat production by the bearing, infection, atrial fibrillation,[61] and RV failure. For the HVAD, the addition of titanium sintering to the inflow conduit (which should encourage the ingrowth of a nonthrombogenic neointima, as was present in the first-generation, pulsatile HeartMate I) in 2011 appears to have decreased the incidence of HVAD thrombosis seen during early clinical experience with the device.

Hemolysis and increasing LDH levels are now recognized as premonitory signs of thrombosis. These can be monitored, and pharmacologic strategies may be employed in many cases as alternatives to device exchange or transplantation.

Additionally, new associations are being established between adverse events and potentially modifiable risk factors. For example, stroke has recently been linked to vitamin D deficiency[62] and also to elevated systolic blood pressure during support.[63]

Total Artificial Hearts

From the original pneumatically driven devices with their massive external control consoles to the totally implantable computer-controlled AbioCor implantable replacement heart (Abiomed, Danvers, Mass), a mechanical total artificial heart (TAH) that could permanently replace the failing human heart has been the subject of intensive research and development for decades.

The first TAH was a pneumatically driven biventricular pump developed by Dr. Domingo Liotta and colleagues in the 1960s. This device (the Liotta TAH) was first implanted in a 47-year-old patient with severe heart failure by Dr. Denton Cooley on April 4, 1969, and was used for 64 hours as a bridge to heart transplantation.[64] The patient died of Pseudomonas pneumonia 32 hours after his transplantation, but the Liotta heart proved that a mechanical device could be successfully used clinically to sustain a patient, and in fact, the original intention of such a device was the permanent replacement of the failing heart. The second human implantation of a TAH was also performed by Dr. Cooley. In July 1981, the Akutsu III TAH was successfully used for 55 hours as bridge to transplantation in a 36-year-old patient with end-stage heart failure.[65] The Jarvik-7 TAH was first implanted as a permanent replacement heart (destination device) in August 1985 in a 61-year-old man with primary cardiomyopathy and chronic obstructive pulmonary disease.[66] Although the patient survived only 112 days, the duration of his survival was encouraging. The first successful bridge to transplantation with the Jarvik-7 TAH occurred in August 1985.[67]

New approaches to the surgical treatment of end-stage heart failure. In: Kaplan J, Reich D, Lake C, Konstadt S, eds.* Kaplan's Cardiac Anesthesia. *5th ed. Philadelphia: Elsevier; 2006:867–890.)*

The SynCardia Temporary Total Artificial Heart

From 1991, the Jarvik-7 was known as the CardioWest TAH. Now known as the SynCardia temporary total artificial heart (TAH-t; SynCardia Systems Inc., Tucson, Ariz), the current incarnation of this device is in use today as a bridge to transplantation in more than 100 centers in North America, Europe, Asia, and Australia/New Zealand, with nearly 50 more centers currently in the process of certification worldwide.

The TAH-t is a pneumatically driven, orthotopically placed, biventricular pump weighing less than 0.5 pounds that can produce in excess of 9 LPM of pulsatile flow. Metal tilting-disk prosthetic valves within the device mandate anticoagulation during support. FDA approval of this TAH as a bridge to transplantation came in 2004, and a CE mark was granted for its use in Europe in 2006.

This device has seen a major resurgence of interest in the past few years as an implantable support device for patients with end-stage biventricular failure (instead of biventricular support with paracorporeal VADs), as a bridge to retransplantation in patients experiencing rejection and failure of a transplanted heart (instead of reimplanting an LVAD), and when there is LVAD failure (in lieu of device exchange).

According to the manufacturer, more than 1400 implantations have now been performed, with the longest duration of support at approximately 4 years. The rate of successful bridge to transplantation with this device has been reported at approximately 75% to 80% for over a decade,[68,69] but it remains to be seen if such success will continue to be manifested as the number of implants grows beyond the confines of clinical trials. As with other devices used to provide MCS, stroke and infection are encountered, but data regarding rates of these complications are not currently available from the INTERMACS database. A recent update publication in the *Texas Heart Institute Journal* reported that "most" (4%) of the strokes associated with the TAH-t occur essentially in the perioperative period, and the rate of fatal infections with this device is approximately 2%.[69] As it produces pulsatile flow, acquired von Willebrand syndrome, and bleeding complications from arteriovenous malformations (now commonly observed with continuous flow VADs) may not be seen with the TAH-t. Again, a large real-world experience with this device has just begun.

Originally powered and controlled by a massive control console ("Big Blue"), the availability of a small, wearable controller weighing less than 15 pounds (the Freedom portable driver) now allows for easy ambulation and hospital discharge. An even smaller controller will soon be available, as will a smaller version of the TAH itself (with 50-mL ventricles), for use in small adults and children. Ironically, although it was originally conceived of and used as a destination device, the TAH-t is only now currently the subject of a formal destination therapy trial.

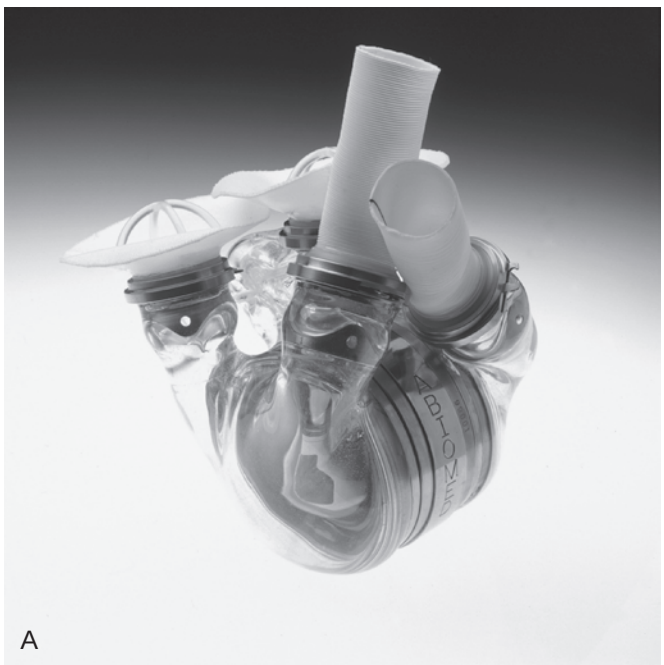
AbioCor Implantable Replacement Heart

The AbioCor implantable replacement heart (Abiomed, Danvers, Mass; Fig. 28.15) potentially represents a major advance in artificial heart technology because it is truly totally implantable; there are no percutaneous cables, conduits, or wires. The device is motor driven, so a source of compressed air to drive the pumping action is not required, allowing patients complete mobility without the need for even a portable or wearable controller. The device itself weighs approximately 2 pounds and is orthotopically implanted, as illustrated in Fig. 28.15.

The AbioCor is indicated for patients not eligible for transplant who are younger than 75 years old and have end-stage, biventricular failure. Transcutaneous energy transfer is used (in lieu of a percutaneous cable) to supply the motor-driven hydraulic pumping of the artificial ventricles with power and system control. Artificial unidirectional valves within the device mandate anticoagulation during support.

A relatively small number (14) of implantations of this device at the University of Louisville and three other centers in the early 2000s demonstrated a moderate amount of success (survival of over 1 year was achieved, but there were high rates of stroke and infection and a few device failures).[70]

The FDA initially denied application for approval of this device in 2005 citing "quality of life vs quantity of life" issues, but the AbioCor



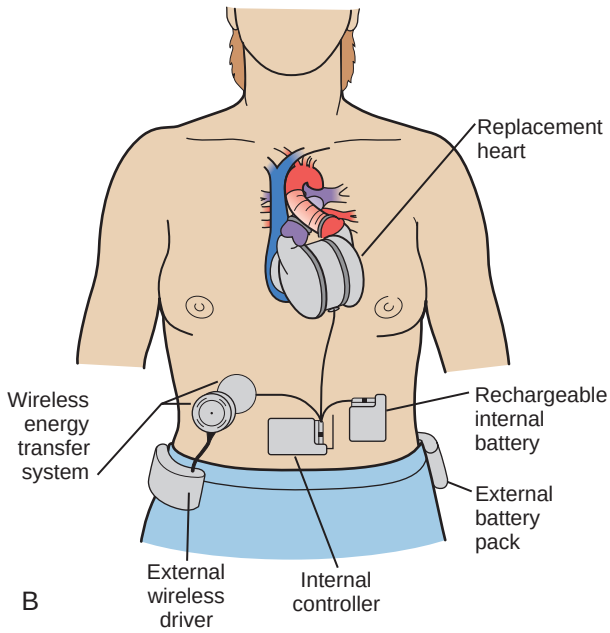


Fig. 28.15 (A) The AbioCor implantable replacement heart. (B) Orthotopic implantation of the AbioCor implantable replacement heart. The native failed heart is removed, and the AbioCor is implanted orthotopically, anastomosed to cuffs of native atria and the great vessels. Transcutaneous energy transfer technology eliminates the need for percutaneous wires. *(Courtesy of Abiomed, Inc., Danvers, Mass.)*

eventually received FDA approval in 2006 under the Humanitarian Device Exemption Program,[71] largely as a result of the testimony of patients and families of those supported regarding the ability of the supported patients to be present to "share significant life events" with their families.[72] A very small number of implants apparently followed as part of a postmarket study, but there have been no recent publications about this device, and it is essentially no longer even available.

Future of the Total Artificial Heart

As reviewed by Gerosa and associates in 2014,[73] a number of innovative TAHs with advanced technologies are under development worldwide that seek novel solutions, portending advancements in the permanent replacement of the failing human heart.[74–79]

Perioperative Anesthetic Considerations for VAD Support

The anesthetic approach to the patient requiring VAD implantation depends entirely on the urgency of the situation. Patients requiring emergent VAD support are in extremis and health professionals can do little but provide supportive care until the patient can be placed on CPB. In contrast, patients presenting for elective VAD implantation as a bridge to transplantation or as destination therapy have end-stage heart failure and, when medically optimized, can appear remarkably well despite significantly depressed cardiac function. Some patients presenting for elective LVAD insertion have suffered an acute decompensation of long-standing heart failure and will have been admitted preoperatively to an intensive care unit with pharmacologic therapy (eg, milrinone, nesiritide, dobutamine) and intraaortic balloon counterpulsation therapy in an attempt to stabilize and optimize hemodynamics.

Regardless of their outward appearance, all patients requiring VAD support decompensate easily from even the most transient of hemodynamic aberrations (eg, tachycardia, bradycardia, hypercarbia, loss of sinus rhythm, sudden alterations in volume status, hypotension) and thus must be approached with caution.

Patients Presenting for Elective LVAD Implantation

Severely depressed cardiac function is the key consideration in the management of all patients presenting for LVAD insertion. The majority will have a dilated cardiomyopathy that is accompanied by mitral regurgitation, diastolic dysfunction, a dilated tricuspid annulus with functional tricuspid regurgitation, and varying degrees of pulmonary hypertension. Renal insufficiency, cerebral vascular disease, and mild coagulopathy due to hepatic congestion are not uncommon. As coronary artery disease has become one of the most common causes of heart failure (31.8% of all patients currently listed for heart transplantation),[80] ongoing ischemia is a potential concern. Many of these patients will have undergone previous cardiac surgery (eg, coronary artery bypass grafting, valve repair/replacement, ventricular reshaping, correction of congenital heart disease), adding the attendant risks of repeat sternotomy to the anesthetic concerns. Finally, it is common for this population to have a pacemaker and/or implantable cardioverter-defibrillator that must be managed perioperatively.

Issues Related to Outpatient Medications

Patients presenting for elective LVAD implantation have generally been managed with medications that reduce afterload, promote diuresis, prevent arrhythmias, control heart rate and antagonize the adverse myocardial remodeling that accompanies chronic, progressive heart failure. Typically employed agents include angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers, aldosterone antagonists, amiodarone, β-blockers, diuretics, and digoxin. While effective for the preoperative optimization of this population, agents with long elimination half-lives, such as ACE inhibitors and amiodarone, result in significant vasodilation that will need to be addressed and countered pharmacologically in the period after bypass. Where feasible, it is generally recommended to withhold diuretics in the immediate preoperative period in an attempt to lessen the relative hypovolemia and electrolyte depletion seen with these commonly used agents. There is currently no consensus about whether or not to withhold ACE inhibitors preoperatively.

Preoperative Nutritional Optimization

It is widely understood that preoperative malnutrition predisposes the general surgical population to an array of postoperative complications, including delayed wound healing and increased risk of infection. Nutritional status has also been established as an important determinant of survival in patients with heart failure, and in VAD patients there is growing evidence that nutrition, as measured by traditional surrogates, such as serum albumin and body mass index, is a critical determinant of postimplantation survival. In a study by Lietz and colleagues, poor preoperative nutrition status was identified as one of several predictors of poor postimplantation outcomes as part of a risk-stratification score.[7] More recently, preoperative hypoalbuminemia was reported as an independent risk factor of mortality in a large cohort of patients with nonpulsatile devices.[81] Interestingly, postoperative correction of albumin levels also correlated with a significant survival advantage in this study.

Postoperative indicators of suboptimal nutritional status, such as low prealbumin levels, have also been shown to correlate with increased mortality in this population.[82] Based on these findings, aggressive optimization of nutritional status has become an important component of patient management before and after operations. In patients refractory to conventional approaches to nutritional augmentation, enteral and/or parenteral feeding should be considered. Of note, parenteral nutrition, despite its traditional association with increased risk of infection, has been shown to be a safe and effective alternative to enteral nutrition preoperatively for VAD patients and may prove in the future to be a standard component of perioperative nutritional optimization in patients refractory to other methods.[83]

The Immediate Preoperative Period

It is prudent to provide supplemental oxygen (via nasal cannula or face mask) and monitor vital signs during the preoperative period, especially if anxiolytic medications are given. The potential for hypoventilation always exists with sedation, and this population will not generally tolerate sudden decreases in sympathetic tone, hypoxemia, and the potentially increased pulmonary vascular resistance that may accompany a sudden respiratory acidosis. Preinduction insertion of an intraarterial catheter for blood pressure monitoring is of critical importance for patients with severely depressed cardiac function.

Induction and Maintenance

The anesthetic plan must take into account the severe degree of cardiac dysfunction and potential preexisting organ insufficiency. The failing heart is at least partially compensated by a heightened adrenergic state, and anesthetic induction agents that markedly blunt sympathetic tone should be avoided as they may result in rapid cardiovascular decompensation or collapse. Additionally, management goals for patients with heart failure should also include the avoidance of anesthetic agent–induced depression of cardiac function and of hemodynamic conditions that increase myocardial demand, such as tachycardia and increased ventricular afterload. In summary, the induction strategy should aim to strike a balance between adequate depth of anesthesia and maintenance of stable hemodynamics.

Etomidate (0.2 mg/kg IV) is an ideal induction agent for patients with heart failure because it does not cause a significant reduction in SVR nor does it decrease myocardial contractility. An induction

technique based on a high-dose opioid (eg, fentanyl 50–100 μg/kg) and a neuromuscular blocking agent will likely result in several hours of hemodynamic stability. The resultant bradycardia with high doses of opioids, however, could result in further decreases in cardiac output. Additionally, amnesia is usually inadequate with narcotics alone and ventilatory support will be required for several hours after the procedure has ended. Thus, high-dose opioid techniques are less frequently used currently.

Ketamine remains an extremely useful alternative agent in patients with severely decreased ventricular function. A ketamine induction (1–2.5 mg/kg IV or 2.5–5 mg/kg IM) followed by a maintenance infusion (50–100 μg/kg/min) will usually provide excellent hemodynamic stability while ensuring adequate analgesia and amnesia. Before administering ketamine, a small dose of midazolam (eg, 1–2 mg IV) is often given to theoretically lessen the potential postemergence psychomimetic side effects that may occur in some patients and an antisialagogue (eg, glycopyrrolate 0.2 mg IV) is generally employed. Studies conducted in laboratory animals have shown ketamine to exert a relatively profound direct myocardial depressant effect, which is ordinarily balanced by its indirect sympathomimetic properties. In the setting of advanced heart failure, however, where partial compensation is achieved through chronic activation of the adrenergic system and downregulation of myocardial β-adrenergic receptors, there is a theoretical risk of unmasking and seeing primarily the direct depressant effects of ketamine on the heart with doses adequate for induction.[84,85]

Thus, a standard balanced technique consisting of small doses of midazolam, etomidate as the induction agent, moderate doses of opioid (eg, total fentanyl dose 10–20 μg/kg), a neuromuscular blocking agent, and potent volatile inhaled agents as tolerated is often used in well-optimized patients. As a general rule, however, high doses of all the potent inhaled volatile agents are poorly tolerated in this population because they all interfere with calcium handling and cyclic nucleotide secondary messengers in the myocardium. By comparison with the other currently available agents, sevoflurane appears to cause less myocardial depression and decrease in SVR, although low concentrations of isoflurane are commonly used without difficulty. In addition to direct myocardial depression and vasodilation, the inhaled anesthetic agents may also adversely affect myocardial automaticity, impulse conduction, and refractoriness, potentially resulting in reentry phenomena and dysrhythmias. Dysrhythmias are especially likely when the delivered concentration of an agent is abruptly increased.

As perioperative bleeding is a common problem following VAD implantation, an antifibrinolytic agent (eg, ε-aminocaproic acid or tranexamic acid) is used during these cases.

Monitoring

In addition to standard American Society of Anesthesiologists monitors (eg, ECG, end-tidal CO_2, temperature, pulse oximetry, and blood pressure), an intraarterial catheter, a pulmonary artery catheter, and TEE are routinely employed during LVAD implantation.

Before LVAD implantation, TEE is used to detect anatomic pathologies that will:

- impede optimal LVAD filling (eg, mitral stenosis, severe tricuspid regurgitation, severe RV dysfunction),
- decrease the potential for optimal LV decompression (eg, aortic regurgitation), and
- cause complications once the LVAD is functioning (eg, patent foramen ovale, atrial septal defect, intracardiac thrombus, ascending aortic atherosclerosis, mobile ascending aortic plaques).

During LVAD implantation, TEE is used to:

- ensure proper inflow cannula position (in the center of the left ventricle, pointing toward the mitral valve; often the midesophageal two-chamber view at a 90-degree angle best reveals the cannula position, but three-dimensional imaging can also be helpful) (Fig. 28.16), and

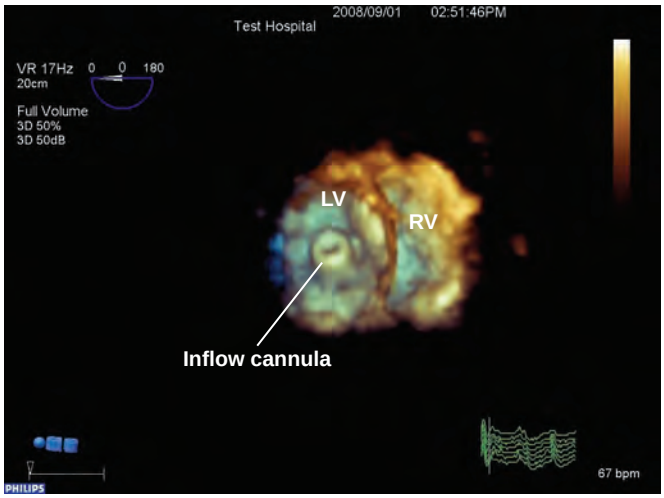

Fig. 28.16 The cannula orifice should be centrally located entering the apex of the ventricle, aligned to the left ventricular inflow tract (mitral valve orifice), not abutting any ventricular structures. *LV,* Left ventricle; *RV,* right ventricle.

- ensure adequate de-airing of the device (and the heart) before and after engagement of support.

The Postimplantation Period

Hemodynamics can initially be quite labile once LVAD support is engaged until intravascular volume is restored, vasomotor tone is reestablished in both the systemic circuit and the pulmonary beds, and RV function is optimized. Thus, despite a properly functioning device, inotropic and vasoactive agents are often required to enable separation from CPB. Certain management strategies appear to be more advantageous than others, and an understanding of the physiology of the LVAD-supported state greatly aids in decision making.

Potential Effects of LVAD Support on Right Ventricular Function

Data from the era of the pulsatile VADs consistently reported the response of the right ventricle to LV unloading by an LVAD to include an increased RV preload, increased RV compliance, decreased RV afterload, and overall decreased RV contractility.[86–92] It has also been established that preexisting or perioperative RV disorders (eg, regional ischemia, poorly compensated chronic ventricular failure, inflammatory insults) can predispose the patient to profound deterioration of RV function when LVAD support is engaged.

To understand RV decompensation in the post-LVAD implantation setting, several key physiologic principles must be appreciated, namely, ventricular interdependence, series circulatory effects, and ventriculoarterial coupling (Box 28.5). First, the concept of *ventricular interdependence* centers on the continuous nature of the muscle fibers between the free wall of the right ventricle and the left ventricle and the presence of a common interventricular septum (IVS), which results in anatomic and mechanical coupling of the ventricles.[93] Second, the concept of *series circulatory effects* holds that it is the output of the right ventricle that fills the LVAD and that the LVAD output in turn becomes the preload of the right ventricle. Third, the concept of *ventriculoarterial coupling* holds that no matter how impaired the intrinsic systolic mechanics of the ventricle are, the chamber can always function better as a pump if one reduces the afterload against which it must pump. Additionally, one must appreciate the unique anatomic and physiologic properties of the right ventricle as they relate to pump function.

BOX 28.5 KEY PHYSIOLOGIC PRINCIPLES IN VENTRICULAR ASSIST DEVICES

- Ventricular interdependence
- Series circulatory effects
- Ventriculoarterial coupling

Ejection of blood from the right ventricle is accomplished by two separate simultaneous actions: (1) compression of the chamber caused by contraction of the single layer of transverse fibers that make up the free RV wall, and (2) a twisting caused by sequential contraction of the two layers of obliquely oriented septal fibers.

In the absence of normal septal twisting, RV ejection must be produced only by contraction of the basal wall that contains a single layer of predominantly transverse fibers. This compression may not always provide enough contractile force to ensure adequate cardiac output, especially if pulmonary vascular resistance is increased. It has long been known that normal septal function can compensate for loss of the RV free wall with respect to overall RV systolic performance, but the RV free wall cannot always compensate for loss of septal function, and RV failure appears to be a problem primarily when the septum becomes dysfunctional.

Perhaps the most obvious effect of LV decompression by an LVAD is the potential shift of the IVS to the left, but bowing of the IVS to the left creates what has been called an *architectural septal disadvantage* because the distortion of the normal architecture of the IVS results in the otherwise obliquely oriented septal muscle layers assuming a more transverse orientation with respect to one another, with subsequent loss of normal septal twisting. Numerous investigators have demonstrated the critical contribution of the IVS to RV pump function,[86,94–98] and it has long been demonstrated that as long as septal function is unimpaired, contraction of the RV free wall is of little consequence where overall RV pressure development and volume outflow are concerned.[99,100]

Another consequence of deforming the septum is dysfunction of the electrical conduction system due to stretching of the conducting pathways. Intraventricular conduction delays resulting in dyssynchronous contraction of the ventricle lead to a decrease in overall systolic function. Additionally, it is clear that stunning of the IVS is common following prolonged CPB despite the best of myocardial protective efforts, and there can be residual adverse electrophysiologic effects of cardioplegia that can persist through the early period after bypass. One or both of these factors can act to increase the degree of septal dysfunction. Thus, decompression of the left ventricle plays a big role in the baseline predisposition to RV failure, because it causes septal shift leftward, which can result in septal dysfunction, but this is not the only factor predisposing to RV failure during LVAD support.

The LVAD and right ventricle exist in series, as codependent pumps in a circuit. Given that the right ventricle may be mechanically disadvantaged because of septal dysfunction of various causes when LVAD support is engaged, it may not tolerate even modestly increased preload. Potential sources of increased RV preload during LVAD support include high LVAD outputs, requisite perioperative transfusions of blood and blood products, and the potential for increased tricuspid regurgitation if the level of LV decompression results in septal displacement. Potential causes of increased tricuspid regurgitation include (1) deformation of the tricuspid annulus, and (2) distraction of the subvalvular apparatus attached to the IVS, resulting in failure of apposition of the leaflets.

Despite the predisposition to RV dysfunction based on ventricular interdependence and the potential problems that may come from the series circulatory effects, it appears that the beneficial effect of decreased RV afterload due to LVAD action still tends to outweigh any impairment of intrinsic RV systolic mechanics. An overall improvement in RV pump function is generally seen during LVAD support in patients with normal pulmonary vascular resistance. This illustrates the principle of *ventriculoarterial coupling,* in which a conceptual separation of RV systolic mechanics from overall RV pump function reveals the critical importance of RV afterload.

As discussed in detail earlier, and as might be surmised from the success of Fontan physiology, RV pumping function is probably dispensable in the LVAD-supported patient, so long as the pulmonary vascular resistance is normal.[101] Pulmonary vascular resistance, however, is not always normal after LVAD implantation. In many patients, pulmonary vascular resistance rises due to pulmonary vascular endothelial injury from inflammatory mediators resulting from prolonged exposure to extracorporeal circulation, as well as from perioperative blood and platelet transfusions. Other causes include the routine ones that are encountered in the care of critically ill patients, such as hypoxemia, hypercarbia, acidosis, hypothermia, large tidal volumes, pain, and catecholamine infusions. Fig. 28.17 demonstrates the potential consequences of increased RV afterload.

Furthermore, the potential roles of perioperative events and management cannot be discounted in the etiology of potential RV failure during LVAD support. Numerous factors potentially influence the outcome of the patient, including the timing of LVAD insertion in the course of the patient's heart failure, surgical misadventures, stunning of the right coronary artery distribution during CPB, and hypotension in the post-CPB period compromising coronary perfusion. While ischemic insults or other injuries to the RV free wall do not appear to have great influence on the development of RV failure when LVAD support is engaged, ischemic insults to the septum will likely have profoundly negative consequences.

The quality of perioperative care is also a major determinant of success in LVAD implantation, and it is imperative that staff caring for patients immediately after LVAD implantation be well versed in the relevant physiology and associated risks. While relative hypovolemia is a common issue in the LVAD-supported patient, large rapid volume loads are a potential problem for a right ventricle that is already mechanically disadvantaged, and fluid management must be approached judiciously. Perhaps the biggest concern is increased pulmonary vascular resistance. As described earlier, once the septum becomes deformed from LV decompression, the transversely oriented fibers can only generate enough pressure to eject into a low resistance pulmonary vascular bed. Thus, between the physiology of the LVAD-supported state and potential perioperative events and requisite postoperative care, there are many reasons why the right ventricle is at increased risk of failure during LVAD support.

Intravascular Volume Status

LVADs are dependent on adequate volume in the LV chamber. Most elective LVAD patients will have started out volume overloaded and with a massively dilated left ventricle. With the nonpulsatile devices, if the amount of blood removed from the ventricle by continuous VAD action exceeds the amount of blood present in the left ventricle, *suckdown* occurs; that is, the continuous flow VAD sucks the ventricle empty, which results in decreased output and hypotension. Thus, the goal for perioperative fluid management is to maintain a euvolemic, if not slightly hypervolemic, state (which may help minimize vasopressor requirements), assuming the unsupported and potentially dysfunctional right ventricle is able to handle the volume load. An empty left ventricle also shifts the IVS to the left, changing the geometry of the right ventricle, which decreases its function (septal architectural disadvantage discussed earlier) and decreased RV function is another important reason for an inadequate preload to an LVAD. Furthermore, the effect of surgical positioning and/or retractors must be monitored so as not to obstruct venous return to the right ventricle, and high intrathoracic pressures (eg, from excessively large tidal volumes) should be avoided once the chest is closed for the same reason. Overall, LVADs generally function well as long as there is sufficient intravascular volume (and RV function) to fill the pump, but management must

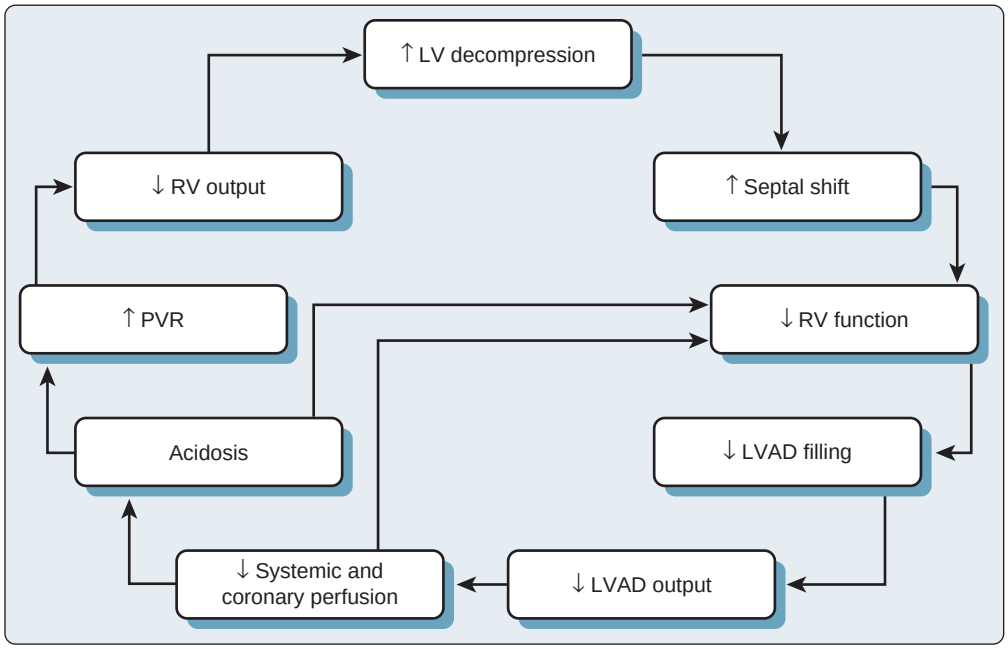

Fig. 28.17 The potential consequences of increased right ventricular *(RV)* afterload. *LV,* Left ventricular; *LVAD,* left ventricular assist device; *PVR,* pulmonary vascular resistance.

be individualized. The HM II control console (Fig. 28.18) provides several parameters that are helpful in this regard.

Afterload and Contractility

In general, the profound vasodilatation that often follows LVAD implantation requires administration of vasoconstrictors to maintain adequate perfusion pressures. A major goal following LVAD implantation is to maintain pulmonary vascular resistance as low as possible; thus, vasopressin may have advantages over norepinephrine because of vasopressin's lack of pulmonary vasoconstrictive effects.[102] Physicians must be cautious, however, because markedly increased SVR may sometimes impair forward flow from certain LVADs. The current generation of axial flow devices are not likely to be affected, but the output from the new miniaturized centrifugal devices can be sensitive to afterload. Inotropic agents are also typically required to support the function of the right ventricle. A typical pharmacologic regimen that may be required includes milrinone (0.3–0.75 µg/kg per minute), vasopressin (2.5-5 units/h), nitric oxide (20–40 parts per million) and epinephrine (0.05–0.25 µg/kg per minute). As noted earlier, norepinephrine may be disadvantageous if significant pulmonary hypertension is present due to the imperative to keep RV afterload as low as possible. Where refractory vasodilatory shock is manifest, a bolus of methylene blue (0.5–2 mg/kg IV) may be of help in restoring vasomotor tone. In severe cases, a continuous infusion of methylene blue (0.5 mg/kg per hour) may be required.

Bleeding

Anecdotally, and for a number of potential reasons, intraoperative or postoperative bleeding does not seem to be as severe with the modern devices as it once may have been with the large pulsatile devices, but coagulopathy following VAD implantation remains common despite the routine use of antifibrinolytic agents, and the transfusion of platelets, cryoprecipitate, and fresh frozen plasma (FFP) is often necessary to restore hemostatic competence. However, practitioners must be cautious, because rapid infusion of large volumes can precipitate RV failure. Moreover, significant risk of transfusion-associated lung injury (TRALI) exists with the transfusion of platelets

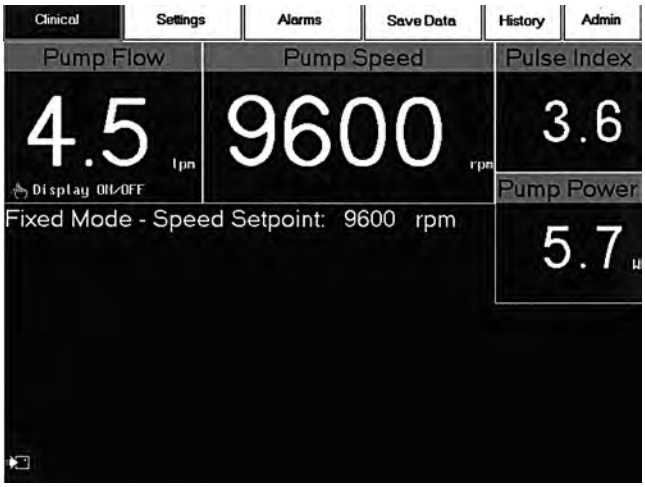

Fig. 28.18 The HeartMate II control console. *(From Reed AP, Yudkowitz FS, eds.* Clinical Cases in Anesthesia. *4th ed. Philadelphia: Elsevier; 2014.)*

and FFP. Where available, thromboelastography can be extremely useful to help guide the judicious transfusion of blood products. Factor concentrates such as prothrombin complex concentrates (PCC) represent a compelling alternative to FFP, both from the perspective of avoiding volume overload and TRALI. When compared to FFP, PCCs have been shown to restore target factors and reverse factor-dependent coagulopathy more rapidly, with negligible additional volume, and lower risk of TRALI.[103,104]

Another source of coagulopathy uniquely associated with LVAD implantation involves the dysfunction of von Willebrand factor (vWF). Sheer forces generated by some VAD devices promote cleavage of vWF multimers by the metalloprotease ADAMTS13, leading to an acquired vWF deficiency and increased tendency for gastrointestinal bleeding, wound site bleeding, and epistaxis. Recent data from a population of nearly 1000 HM II patients demonstrated an overall 38% incidence

and prevalence of bleeding, with gastrointestinal bleeding in 29% of those implanted as destination therapy and 13% of those implanted as bridge to transplantation.[105] Thus, strategies to control bleeding in these patients should ideally include the use of vWF-containing concentrates, factor VIII concentrates, antifibrinolytics, and desmopressin (DDAVP).

The Postimplantation Role of Transesophageal Echocardiography

After LVAD placement, TEE is used to:

- Ensure adequate LV decompression (but not complete obliteration of the LV cavity)
- Ensure RV function does not deteriorate (may need RVAD as well)
- Ensure tricuspid regurgitation does not worsen (may need annuloplasty)
- Reevaluate for patent foramen ovale (must be closed if detected)
- Assist with diagnosis of new patient problems that arise in the postoperative period (eg, hypovolemia, tamponade, cannula misalignment or obstruction)

Anesthetic Considerations for SynCardia Total Artificial Heart Implantation

Preoperative considerations and pre-CPB management are largely as discussed earlier for LVAD implantation. Patient receiving an elective TAH (eg, as a bridge to transplantation) generally have biventricular failure, which, if chronic, has likely resulted in hepatic pathophysiology, portending poor hemostatic potential and poor nutritional status. Patients receiving a TAH in the setting of a failing heart transplant or a malfunctioning LVAD require all of the considerations associated with reoperative cardiac surgery.

The Role of Transesophageal Echocardiography Before Cardiopulmonary Bypass for Total Artificial Heart Implantation

Given that the native ventricles and heart valves are removed during implantation, the role of the pre-CPB TEE is somewhat limited, but certain baseline findings may need to be addressed before engaging support by the device and/or may play a role in the period after implantation.

- As the native atria will remain once the device is in place (the inflow cuffs of the SynCardia device are anastomosed to the ventricular side of the mitral and tricuspid annuli), atrial septal defects must be sought (and closed).
- The inferior vena cava should be imaged and measured at the point where it enters the right atrium, and the flow profile should be noted.
- Flow profiles in all four pulmonary veins should be imaged and noted.
- Atherosclerotic burden in the aorta should be characterized and taken into account, so as to assist in guiding anastomosis of the aortic outflow graft.
- The left atrial appendage (which will be ligated during the implantation) should be imaged.
- Although the mitral and tricuspid leaflets and all of the subvalvular apparatus will be excised during the implantation, the annuli will remain, so it is reasonable to assess the annuli for vegetations and calcifications.

Post-CPB management centers on optimization of volume status and vascular resistances and restoration of hemostasis. Perfusion pressures are directly dependent on volume status and the vascular resistances, but the TAH requires appropriate optimization of the parameters of its function. Such parameters include the drive pressures, the pump rate, and the percentage of time spent in systole.

- Drive pressures should be set slightly higher than the systemic and pulmonary pressures (eg, set at 100–150 mm Hg and 60-80 mm Hg, respectively), but the pressures should not be so excessive as to cause bleeding from fresh suture lines on the great vessels. The drive pressures are adjusted to achieve full ejection. Often, the left-sided drive pressures are set relatively higher than those for the right to unload the pulmonary veins.
- Pump rate is adjusted as needed, but an initial rate of approximately 125 beats per minute is not unusual.
- Percent systole is generally initially set to 50% and then adjusted as needed to achieve complete filling.
- Vacuum is generally not used to assist filling until the chest is closed (to avoid entraining air through fresh suture lines).

To understand how to optimize the patient supported by a SynCardia TAH, familiarity is required with the waveforms on the controller for filling and ejection. The standard device ventricles can accommodate 75 mL, but the fill volume is normally set to 50 to 60 mL so the device can accommodate occasionally increased venous return. Regarding the waveforms, an abrupt drop to zero flow during diastole represents complete filling, and an abrupt end-systolic rise in pressure represents complete ejection. If the flow does not drop to zero during the diastolic phase, then filling of the ventricles is incomplete, and augmentation of intravascular volume is indicated. Alternatively, next steps are to decrease the beat rate and/or slightly decrease the percent systole (eg, 50% down to 48%). Once the chest is closed, the amount of vacuum can be increased to assist filling, but vacuum stronger than –20 mm Hg may increase hemolysis. If no abrupt rise in end-systolic pressure is noted during device systole, then ejection is incomplete, and next steps are increasing the drive pressure and/or decreasing the relevant vascular resistance with an appropriate vasodilator (eg, nicardipine or nitroprusside for the left side; nitric oxide, milrinone for the right side).

As with other RVADs, pulmonary edema has been reported with this device, sometimes requiring ECMO.[106] It should be understood that the origins of such pulmonary edema may be multifactorial; hydrostatic pressure in the pulmonary bed as a result of RVAD action certainly plays a role, but alveolar integrity may also be compromised.

Following implantation of a TAH, TEE is used to:

- Ensure adequate de-airing of the device
- Detect flow acceleration in the pulmonary veins or inferior vena cava, which may represent relative occlusion due to kinking or twisting as a result of the positioning of the device
- Visualize the proper functioning of the tilting disk mechanical valves in the device
- Visualize the outflow into the great vessels

These images and assessments should be performed again following chest closure, as the position of the device may have changed.

Following chest closure, device settings may need to be adjusted to ensure full filling and emptying.

Conclusion

This chapter has summarized the phenomenal advances realized in the past decade in the arena of MCS. As patients with heart failure comprise one of the fastest growing segments of our aging population, and as outcomes continue to improve with advancing technology and patient-care experience, MCS will undoubtedly continue to play a pivotal strategy in prolonging a high quality of life for patients who would otherwise succumb to end-stage heart failure.

Reoperative Cardiac Surgery

AMANDA J. RHEE, MD | JOANNA CHIKWE, MD

KEY POINTS

1. Reoperative cardiac surgery presents greater risk than first-time surgery because patients are usually older, have more comorbidities, and have more advanced cardiovascular disease. Also, resternotomy can be hazardous due to adhesions of cardiac structures to the sternum. Bypass conduits may not be unavailable due to prior use, and the frequency of valve replacement versus valve repair is higher.
2. A thorough history, clinical evaluation, and review of imaging must be performed—with particular thought to weighing the risk of surgery against the possibility of medical management with multidisciplinary expertise—before making the decision to proceed.
3. Preinduction anesthetic preparations include placement of defibrillator pads, pacemaker or defibrillator adjustments, and placement of invasive monitoring in the setting of the possibility of peripheral cannulation strategies and alternative cardiopulmonary bypass techniques such as cooling before sternotomy.
4. Coagulopathy can be strategically managed using point-of-care testing to guide blood and blood product transfusion.
5. Emergency reexploration is a high-risk situation in which expeditious surgical intervention is required, usually in the setting of bleeding with pericardial tamponade. Transfusion should be anticipated, hemodynamics supported, and heparin ready to administer in anticipation of possible cardiopulmonary bypass.

In contemporary practice, 3% to 4% of coronary artery bypass graft (CABG) operations and approximately 10% of valve surgery procedures are reoperations.[1,2] Reoperative cardiac surgery carries an incremental risk of mortality and major morbidity compared with first-time or primary cardiac surgery because patients are usually older, with additional comorbidity and more advanced cardiac disease, and because of specific technical challenges presented by prior cardiac surgery.[3] The surgical approach to incision and cannulation in coronary and valve surgery reoperations often differs significantly from the approach used in primary cases, and adverse intraoperative events that require immediate changes to the planned strategy are common and often predictable.[4–6] Preoperative assessment and planning with the surgical team is therefore particularly important because optimal patient care may require the modification of several aspects of standardized cardiac anesthetic approaches. The incidence of emergency reexploration ranges from 1% to 5% after cardiac surgery, and the primary challenges relate to effectively managing major cardiopulmonary instability and ensuring safe and efficient surgery, either in the operating room or outside the operating room setting.

This chapter deals with two different aspects of reoperations in cardiac surgery. The first is repeat cardiac surgery performed at an interval of more than 1 month after a cardiac operation, in which the presence of adhesions, prior cardiac surgery, and patient comorbidity require a highly tailored approach to anesthesia and operative intervention. The second is emergency reexploration, usually within the first few hours to days after cardiac surgery, which may occur in the operating room or in the intensive care unit (ICU).

Reoperative Cardiac Surgery

Indications for Reoperative Cardiac Surgery

The indications for reoperative cardiac surgery are based on the same principles as for primary cardiac surgery. However, the incremental hazard of resternotomy, the lack of bypass conduits, the greater age and comorbidity of this patient group, and the likelihood of valve replacement rather than repair are additional considerations. Consequently, the threshold for recommending surgery rather than medical or transcatheter approaches is higher for reoperative patients. The large majority of patients with symptomatic coronary artery or graft stenoses after CABG surgery are most effectively treated by percutaneous coronary intervention (PCI).[1] Very symptomatic patients with significant lesions to a left anterior descending graft are generally considered to gain symptomatic and prognostic benefit from reoperative coronary artery surgery. The main indications for reoperative valve surgery include prosthetic valve dysfunction (for which the results of transcatheter valve-in-valve implantation are still preliminary) and endocarditis, which is a contraindication to transcatheter valve replacement. Paravalvular leaks are increasingly addressed by percutaneous placement of occluder devices. Late reoperation for isolated severe tricuspid regurgitation is associated with particularly high mortality and major morbidity because of the high prevalence of preoperative moderate-to-severe right ventricular dysfunction, pulmonary arterial hypertension, and multiorgan dysfunction in this population.

Preoperative Assessment

History

Patients undergoing reoperative cardiac surgery are generally older have more comorbidity and more advanced cardiovascular disease than patients undergoing first-time surgery.[3] The decision to operate usually depends on correlating a precise account of the nature, timing, and severity of symptoms with the findings from diagnostic studies and balancing the benefits of intervention against the incremental risk of mortality and morbidity posed by reoperation. The presence of any significant comorbidity is a major consideration in calculating the patient's predicted risk of death or major complications.

Risk calculators, such as The Society of Thoracic Surgeons online Risk Calculator (accessible at http://riskcalc.sts.org/stswebriskcalc/#/calculate), are very helpful adjuncts. Patients who are not capable of many of the activities of daily living at baseline due to noncardiac disability may not be appropriate candidates for reoperative intervention, and a careful functional history is needed to evaluate this possibility. Additionally, the medical history should establish details of all prior cardiovascular procedures, including date and type of PCI; any previous cardiac surgery, including incisions; history of difficult intubation or adverse reaction to anesthesia, respiratory failure, or tracheostomy; coagulopathy and blood transfusions; and postoperative sepsis and organ dysfunction. All efforts should be made to obtain prior hospital records, particularly operative notes, so that the precise details of previous procedures, including cannulation sites, cardiotomies, prosthesis sizes, and any intraoperative complications can be accurately known. Although the balance of risks generally favors continuing antiplatelet medication until surgery in non-reoperative patients, this may not be the case in patients scheduled for reoperative surgery, who will be at greater risk of postoperative coagulopathy and bleeding. It may be appropriate to admit patients preoperatively in order to discontinue oral anticoagulation and transition to a shorter-acting regimen, such as a heparin infusion.

Clinical Examination

One of the most important risk factors for poor outcomes is frailty.[4] Although this is not well defined, and consequently is not included in most risk models, it is a relatively easy, albeit subjective, judgment often made by looking at a patient. Quantitative evaluation of frailty through shuttle tests, muscle mass measurements, and strength gauges has been used in clinical trials but is not commonly performed in clinical practice. Physical examination of all patients referred for cardiac surgery includes a careful inspection of the entire chest and abdomen. Patients may omit to mention distant cardiac and thoracic surgery procedures, and these may become evident only from incisions, which can be inframammary, posterior thoracotomy, or axillary. All incisions, including conduit harvest sites, pacemaker or defibrillator insertion sites, and potential sites of peripheral cannulation for cardiopulmonary bypass (CPB) in upper and lower extremities should be assessed for signs of distant or recent infection, poor healing, and vascular complications such as stenosis or aneurysm formation. Important clinical signs that may not have been documented in the history or prior investigations and are easy to elicit include chronic or paroxysmal atrial fibrillation; hypertension or hypotension; peripheral edema; sensory and motor neuropathy, particularly in elderly or diabetic patients; cognitive impairment; and poor dentition, which necessitates a dental examination in any patient for whom valve surgery is planned. Evaluation of the airway includes inspection of the suprasternal notch and trachea for evidence of prior tracheostomy.

Imaging

With the exception of young adult patients without risk factors for acquired or congenital coronary artery disease, all patients should have recent cardiac catheterization including coronary angiography to assess the patency and anatomy of native vessels and any CABG. In young patients, computed tomographic (CT) coronary angiography usually provides sufficient information about coronary anatomy. Coronary angiograms should be reviewed to determine whether grafts are close or even adherent to the sternum. The presence of patent coronary bypass grafts is a potential hazard during sternal reentry and mediastinal dissection because manipulation of them may result in embolization, occlusion, or hemorrhage that could precipitate myocardial ischemia and ventricular fibrillation. Additionally, the presence of patent bypass grafts may dictate operative choice of incision, cannulation, and myocardial protection strategies (see later discussion) (Fig. 29.1).

Cross-sectional imaging, typically CT, is particularly helpful in planning cardiac reoperation because it reveals the relationships among important structures including the aorta, right atrium, right

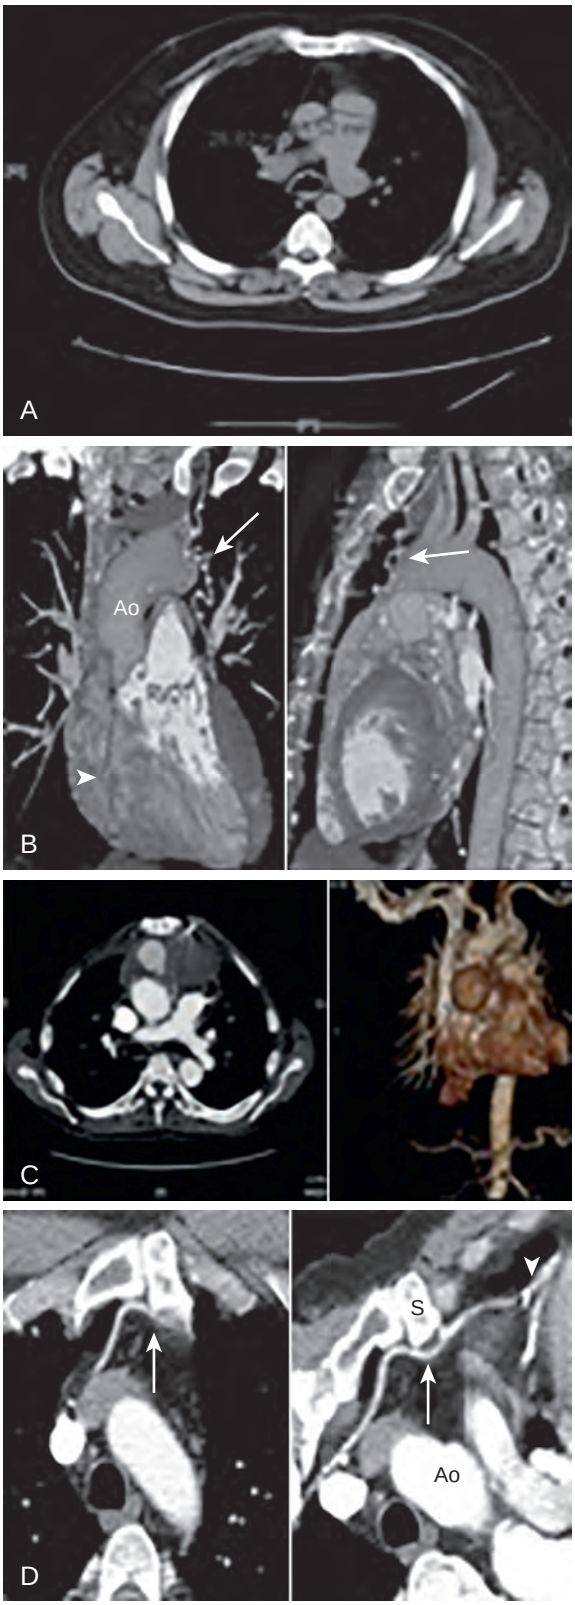

Fig. 29.1 Cross-sectional imaging of reoperative cardiac surgery patients illustrates anatomy that indicating the risk posed by resternotomy. (A) Low-risk resternotomy: Aorta and pulmonary artery are of normal caliber and well away from the sternum. (B) Moderate-risk resternotomy: Patent left internal mammary artery graft *(arrow)* is lying lateral to and distant from the sternum. There is a normal-caliber aorta *(Ao)* distant from sternum. (C) High-risk resternotomy: Right ventricle is adherent to sternum. (D) Patent left internal mammary artery graft crosses midline close to sternum *(arrow)*. *(From Akujuo A, Fischer GW, Chikwe J. Current concepts in reoperative cardiac surgery.* Semin Cardiothorac Vasc Anesth. *2009;13:206–214.)*

ventricle, pulmonary artery, innominate vein, and any bypass grafts to the planned incision. Noncontrast CT provides helpful visualization of calcification and aneurysmal segments along the entire arterial tree from aortic root to femoral vessels that may dictate choice of cannulation site. The presence of large amounts of prosthetic material indicates potentially severe adhesions. Intravenous contrast may be employed in CT angiography to demonstrate the course of bypass grafts more clearly; contrast is required to assess patency, and it provides detailed information on the presence of peripheral vascular disease, which is particularly relevant if peripheral arterial cannulation is planned or the patient is likely to need an intraaortic balloon pump.

Echocardiography is necessary to quantify right and left ventricular function, the presence of pulmonary hypertension, and the nature and grade of any valvular dysfunction. Transesophageal echocardiography (TEE) is particularly valuable in the detailed assessment of prosthetic valve endocarditis and failed valve repair or if transthoracic echocardiographic windows are poor. The presence of moderate aortic insufficiency precludes mitral valve approaches under fibrillatory or beating heart conditions without aortic cross-clamping. It also implies that antegrade cardioplegia will not be delivered reliably via the aortic root and will lead to ventricular distention if the heart fibrillates on CPB before cross-clamping or circulatory arrest, resulting in inadequate myocardial protection.

In patients for whom a thoracotomy approach is planned, preoperative lung function testing, including arterial blood gas sampling, will provide an indication of whether single-lung ventilaton will be tolerated, particularly in the post-CPB period, when lung function is worse than baseline. Preoperative evaluation of central venous access with ultrasound is helpful in patients with a history of multiple central venous catheters, transvenous pacemakers, or dilaysis shunts and in those with prothombotic disorders because they are at increased risk of stenosis or occlusion of the brachiocephalic venous circulation.

Before Induction

Days Before Induction

Reoperative patients require the same laboratory tests as patients undergoing first-time surgery. The presence of renal or hepatic dysfunction at baseline means that particular attention must be paid to maintenance of adequate systemic flows, perfusion pressure, and venous drainage on CPB. Patients with preoperative anemia and thrombocytopenia, particularly if they have low body surface areas, are more likely to require blood products than if they were undergoing first-time surgery. In reoperative patients, the hemostatic benefits of stopping antiplatelet drugs (particularly dual antiplatelet therapy) before surgery outweigh the risks of acute coronary ischemia.[5] In patients with or at high risk of acute coronary syndromes, short-acting antiplatelet drugs can be used as a bridge to surgery.[7,8] Intravenous heparin should be stopped 4 to 6 hours before the planned surgery time and eptifibatide (Integrilin) infusions at least 12 to 24 hours beforehand. Withholding long-acting vasodilators, particularly angiotensin-converting enzyme inhibitors, for 48 hours before surgery may reduce the risk of postoperative vasoplegia.

Immediately Before Induction

Adhesive external defibrillator pads must be attached to the patient before induction. It is advisable to review placement of these pads with the surgical team, who may need access to the left chest wall. The external defibrillator pads are retained throughout the case for several reasons: Internal paddles usually cannot be used because of dense adhesions; electrocautery of adhesions close to myocardium may directly induce ventricular fibrillation; and damage to patent bypass grafts during mediastinal dissection can cause severe myocardial ischemia leading to ventricular fibrillation. As in primary cases, delivery of external defibrillator energy to the heart may be enhanced by optimal lung inflation.

A significant proportion of reoperative patients have cardiovascular implantable electronic devices that should be checked preoperatively by an individual familiar with the device to ascertain its functionality and to devise a plan for intraoperative management (see Chapter 5). The defibrillator function mode of an implantable cardioverter-defibrillator should be disabled for the duration of surgery using the appropriate programming computer. Otherwise, defibrillation shocks (which can precipitate asystole or ventricular fibrillation) may be triggered by electrocautery. The devices should be interrogated again and appropriate defibrillator and pacing settings restored postoperatively, before the removal of temporary epicardial pacing wires. The external defibrillator pads should remain in place for the entire period that the permanent devices are disabled.

In reoperative cases in which CPB times may be prolonged, with associated vasoplegia or low cardiac output states, arterial pressure tracings from distal arteries are often damped and may be unreliable. The presence of two arterial catheters is particularly valuable in reoperative patients who are at increased risk of vasoplegia, low cardiac output, or malperfusion; one of these catheters should be placed in a large proximal artery (either femoral or axillary) to provide a reliable indication of central arterial pressure. Alternatively, monitoring of central arterial measurements via the aortic cannula, an aortic vent or cardioplegia cannula, or placement of a small-bore needle or catheter directly into the aorta can be performed at key intervals such as onset and weaning from CPB. The plan should be discussed with the surgical team because cannulation and the operative strategy will dictate the available location and utility of these catheters. If axillary artery cannulation is planned, the ipsilateral radial artery provides helpful assessment of distal hyperperfusion or hypoperfusion once CPB is commenced, but a catheter in the contralateral arm (radial or axillary) or a femoral catheter must be placed for assessment of the systemic arterial pressure. If femoral cannulation is planned for CPB, then an ipsilateral femoral arterial catheter should not be placed (because it will be in the way) unless the surgeon requests such a placement to facilitate percutaneous femoral cannulation. If a radial artery conduit harvest is planned, the ipsilateral radial artery should not be catheterized and venous access should be avoided in the ipsilateral arm to optimize maintenance of a sterile surgical field during radial artery harvest.

Anesthesia

Balanced and high-dose narcotic techniques can be used in the reoperative setting. Particular attention must be paid to patients who are at high risk of cardiovascular collapse during induction, such as those with unprotected critical left main (or left main equivalent) coronary artery stenosis, severe aortic stenosis, or cardiac tamponade. If these types of patients decompensate, their obstructive anatomy means that they will rarely respond well to standard cardiopulmonary resuscitation. Emergency sternotomy, internal cardiac massage, and institution of central CPB are usually not possible because of adhesions that prevent safe, rapid access to the mediastinum. Therefore, in selected reoperative patients thought to be at particularly high risk of cardiovascular decompensation during induction of anesthesia, it may be appropriate to place arterial and central lines in the awake patient and then perform preparation and draping for sternotomy and/or rapid femoral cannulation with the surgeon scrubbed before anesthesia is induced.

In view of the potential for massive hemorrhage and the difficulty in achieving rapid surgical access, large-bore venous access, such as with a 9-French (or larger) central venous introducer, is essential to guarantee the capability for rapid volume infusion. This should be obtained with superficial vascular ultrasound guidance, manometry, and/or confirmation of the wire during the Seldinger technique in the right atrium by TEE. Lung separation with a double-lumen endotracheal tube or a bronchial blocker may be indicated for thoracotomy approaches.

Once the patient has been intubated tracheally and monitoring catheters have been inserted, all prior chest and abdominal incisions, previous drain sites, extrathoracic cannulation, and conduit harvest

TABLE 29.1 Risk Stratification of Low, Medium, High, and Very High Risk Sternotomies, With a Summary of Operative Strategy Tailored to Address Risks

Preoperative Assessment of Risk		*Intraoperative Strategy*
INCREASING RISK OF MAJOR INJURY	Low-risk resternotomy: • Prior cardiac surgery without patent coronary bypass grafts • Aorta and mediastinal structures a safe distance from the sternum (Fig. 29.1A)	• Resternotomy, dissection of adhesions, standard aortocaval cannulation; initiate bypass; proceed with residual adhesiolysis and cardiac surgical procedure • Optional: Expose peripheral cannulation sites before stenotomy
	Moderate-risk resternotomy: • Patent coronary bypass grafts that lie >1 cm from the sternum, including patent left internal mammary artery (IMA) to left anterior descending coronary artery routed lateral to the sternum (*arrow* in Fig. 29.1B)	• As above • Optional: peripheral arterial cannulation, with 5000 units of heparin given and arterial line flushed intermittently by perfusion; resternotomy and division of adhesions as above • If major vascular injury occurs, venous cannulation can be performed peripherally, and centrally and after full heparinization cardiopulmonary bypass (CPB) is commenced.
	High-risk resternotomy: • Patent left IMA graft crossing midline close to sternum, right ventricle adherent to sternum (Fig. 29.1C), normal aorta in close proximity to sternum • Third- or fourth-time resternotomy	• Peripheral and arterial cannulation with full heparinization before resternotomy • Optional: Institute CPB, stop ventilation, and drain venous return into pump reservoir to decompress right side of heart
	Very-high-risk resternotomy: • Patent left IMA graft crossing midline adherent to sternum (Fig. 29.1D) and large area of myocardium at risk, aortic tube graft or aneurysm adherent to sternum	• Peripheral and arterial cannulation with full heparinization, institution of CPB, cooling before resternotomy • Optional: circulatory arrest under moderate hypothermia during sternotomy

Adapted from Akujuo A, Fischer GW, Chikwe J. Current concepts in reoperative cardiac surgery. *Semin Cardiothorac Vasc Anesth.* 2009;13:206–214.

sites should be reconfirmed by the surgical team. Femoral and axillary cannulation sites should be marked, and the patient should be prepared and draped so that extrathoracic cannulation sites (axillary and femoral), conduit harvest, and permanent pacemakers and defibrillators can be accessed from within the sterile field. An antifibrinolytic agent should be administered intravenously before incision to mitigate the incremental risk of postoperative bleeding in reoperative patients.

Before Incision

The strategy and order of sternotomy, heparinization, cannulation, and institution of bypass may be very different in a reoperation because the safest sequence of these steps is dictated by the risk posed by resternotomy (Table 29.1).[6] Many institutions mandate a surgical time-out and checklist before incision in which the patient, key personnel, and operative plans are identified. This is a useful point at which to reconfirm the planned sequence of steps. Cross-matched blood should be checked and made immediately available before incision. The CPB circuit should be fully primed, and the bypass lines should be brought up to the field before sternotomy, during which time the perfusionist, attending anesthesiologist, and circulating nurse must be present.

Incision

The sternal skin incision is usually made in the standard fashion, and then the sternal wires are untwisted, cut, and either bent to the sides or removed entirely. This can theoretically result in laceration of vascular structures in close proximity underneath, including the right ventricle. Some surgeons elect routinely to perform an initial dissection under the sternum using thoracoscopic guidance. In cases in which an aneurysmal aorta is thought to be densely adherent to the posterior sternal table, a small transverse incision may be made in the second or third left intercostal space to allow the aorta to be dissected free before median sternotomy.

The anterior sternal table is divided with an oscillating saw. Under an optional period of apnea, the posterior table is then divided along its entire length with either the oscillating saw or a heavy blunt-tipped scissors. This part of the sternotomy poses the most risk to underlying structures. Injury to these structures is particularly problematic because hemorrhage and hemodynamic instability may prevent completion of the sternotomy—in which case the surgeon will have insufficient surgical access to address the injury effectively. To minimize the risk of this scenario, surgeons commonly try to decompress the mediastinal structures by asking the anesthesiologist to hold ventilation and, in the case of patients who have been cannulated and heparinized, asking the perfusionist to exsanguinate the patient into the pump temporarily. On rare occasions, the safest option is to commence CPB using peripheral cannulation, cool the patient, and arrest the circulation before skin incision and sternotomy (see Table 29.1). This last option would usually be reserved for cases in which there is a very high risk of laceration of the ascending aorta on sternotomy.

Electrocautery is used to dissect the heart away from the left sternal edge and then the right sternal edge. Excessive retraction of the sternum before this dissection is fully completed can result in right ventricular rupture. Other possible complications during this initial dissection are ventricular arrhythmias, including fibrillation as a result of electrocautery in proximity to the myocardium and injury to a patent left internal mammary artery (IMA) graft resulting in myocardial ischemia and a high likelihood of ventricular dysfunction and/or ventricular fibrillation.

Subsequent mediastinal dissection is targeted at obtaining access to central cannulation and aortic cross-clamp sites, specifically the aorta, and the right atrium. A "no touch" technique is used for bypass grafts to avoid distal embolization and myocardial ischemia. The most common injuries during this phase of dissection are to the right atrium, which is frequently thin walled and densely adherent at sites of prior cannulation and atriotomy. Such injuries can usually be addressed with primary suture closure, but occasionally institution of CPB is mandated to effect a repair.

For patients undergoing a mitral, a tricuspid, or (occasionally) an aortic valve procedure, a right thoracotomy may be less hazardous than a median sternotomy. In these cases, after the intercostal muscles have been divided, the right lung is deflated before the pleural space is entered. This technique is used to reduce the risk of injury to structures lying adjacent to the sternum. The disadvantage with a right thoracotomy approach is that access to the lateral border of the heart, the ascending aorta, and the aortic valve is limited. Although it is effective and safe in many patients, retrograde arterial perfusion from femoral arterial cannulation has been associated with a higher risk of stroke than antegrade arterial perfusion from the ascending aortic or axillary cannulation, particularly in elderly patients and those with aortic atherosclerosis.[9,10]

Cannulation

Arterial and/or venous cannulation for CPB can be peripheral, central, or a combination of both. The choice depends on the risks posed by

sternal reentry and the presence of peripheral arterial disease (see Table 29.1), as well as the presence of multiple sites of previous and planned surgery on the aorta and right atrium, which may limit the room available for central cannulation.[10] For example, the presence of multiple patent graft anastomoses to the aorta may favor peripheral arterial cannulation. For patients who are at high risk of catastrophic injury to mediastinal structures, arterial (and in certain cases venous) cannulation may be carried out peripherally before sternotomy. The choice of cannulas should take into account the patient's body surface area: If the venous cannula is too small, the perfusionist will be unable to adequately drain the venous return, and if the arterial cannula is too small, the perfusionist will be unable to provide adequate arterial flow without excessive line pressures. Should the peripheral vessels be too small to permit adequately sized cannulas, it is usually possible to subsequently add additional cannulas centrally, if needed, to improve the adequacy of systemic perfusion.

The right or left axillary artery and vein may be exposed by a 5-cm incision in the deltopectoral groove. Use of the axillary artery for arterial cannulation offers less risk of limb ischemia and cerebrovascular events than use of the femoral artery, which is less well collateralized and provides retrograde arterial flow.[10] The most common complication of axillary artery cannulation involves trauma to the branches of the brachial plexus that are intimately involved with the artery. Injury to the artery itself, causing ischemia, dissection, and hyperperfusion, is also possible. The risks of ischemia and dissection are minimized by cannulating a T-graft sewn to the axillary artery rather than cannulating the artery directly. Institution of CPB via the T-graft may be associated with hyperperfusion of the ipsilateral arm. This can be avoided by maintaining the ipsilateral radial arterial pressure no higher than the contralateral radial or femoral arterial pressure once CPB has commenced; this is done by adjusting tension on a Silastic sling (vessel loop) placed in the surgical field around the axillary artery just distal to the cannulation site.

The femoral artery may be accessed with a modified Seldinger technique or, more commonly, under direct vision, usually via a 4-cm incision in the inguinal skin crease. The main complications of a Seldinger approach to femoral arterial cannulation are retrograde dissection and retroperitoneal bleeding. The femoral artery is more commonly affected by atherosclerotic disease than the axillary artery, and a careful check of distal pulses is mandatory after decannulation. Occasionally, the arteriotomy will require revision or patch repair to ensure distal flow.

If arterial cannulation alone is carried out peripherally, it is unnecessary to fully heparinize the patient initially. A single dose of 5000 units of heparin will be sufficient to keep the line free of thrombus if the perfusionist flushes the cannula intermittently before institution of CPB. Full heparinization to an activated coagulation time greater than 480 seconds is usually required before venous cannulation, use of pump (cardiotomy) suction, or institution of CPB, although policies may vary from institution to institution.

The main indication for peripheral venous cannulation (which mandates full heparinization) before sternotomy is the surgeon's decision to institute CPB before sternotomy. The axillary vein is sometimes used, but the larger femoral vein, which has a straighter course to the right atrium, provides the most reliable access and venous drainage. These cannulas are more safely inserted with an open technique to directly visualize the vein then with a Seldinger technique.

A major complication of femoral venous and arterial cannulation, which may not manifest until later in the case, is retroperitoneal hemorrhage caused by perforation of the femoral or iliac vessel or retrograde dissection of the aorta. A significant retroperitoneal bleed or dissection on CPB are characterized by low flows, low systemic pressures, poor venous drainage due to loss of circulating volume, and, eventually, abdominal distention from accumulating hematoma and venous stasis. Retrograde aortic dissection from femoral or axillary cannulation may occasionally occur on institution of CPB and is associated with high perfusion line pressures and low systemic perfusion pressure. To avoid these complications, a soft guidewire should be inserted in the vessel under direct vision and without force; the pointed cannula occluder should be withdrawn into the cannula as soon as the cannula is in the vessel; the cannula must not be advanced against significant resistance; and the wire must be kept under tension, checking that it can be moved easily backward and forward at all stages. Inadequate venous drainage caused by malposition, kinking, or placement of a cannula that is too small (particularly in femoral cannulation, where the length of the cannula further contributes to reduced flow) can mimic both of these scenarios with poor venous return, subsequent low flow, and eventual abdominal distention.

Cardiopulmonary Bypass

The patient can be placed on CPB before resternotomy, if indicated (see Table 29.1). Safe institution of CPB should be confirmed by the anesthesiologist, perfusionist, and surgeon. This is even more important if the patient has been placed on bypass emergently because cannula choice and placement may not be optimal. As described earlier, the anesthesiologist should be vigilant and use TEE whenever possible to rule out complications and causes of inadequate perfusion such as retrograde aortic dissection or inadequate venous drainage. Inadequate venous drainage may be signified only by a high central venous pressure and failure to adequately decompress the right side of the heart (which may be apparent only on echocardiography). If adequate flows and venous drainage cannot be established, peripheral arterial or venous cannulas must be supplemented with additional peripheral or central cannulas, with confirmation of satisfactory arterial flow and venous drainage before proceeding to clamp the aorta. Echocardiographic confirmation of correct placement of caval and coronary sinus cannulas before institution of CPB is very helpful, particularly because the surgeon cannot readily palpate these in reoperative cases owing to adhesions.

If proximity of right-sided heart structures to the sternum is a concern (particularly the right ventricle in patients with severe pulmonary hypertension), some surgeons take the precaution of temporarily draining the circulating volume into the venous reservoir of the CPB circuit before sternotomy. This has the theoretical advantage of decompressing the right side of the heart, which may reduce the risk of injury from the sternal saw. After the sternotomy is completed, the remainder of the mediastinal dissection can be carried out with the patient on or off CPB, depending on the challenges presented by adhesions and pathology. Although starting CPB early increases bypass time, it likely reduces the risk of injury to important structures and does not appear to increase morbidity, mortality, or postoperative bleeding.[3] The main reason this is not done routinely is that the patient is fully heparinized while lysis of adhesions is carried out, potentially leading to increased transfusion requirements during the procedure; red cell salvaging may minimize transfusions.

Myocardial Protection

Whereas the approach to myocardial protection for reoperative cardiac surgery follows the same basic principles as for first-time surgery (i.e., decompression of the heart, usually in cold diastolic arrest to minimize myocardial oxygen demand), there are several additional factors that commonly impact the myocardial protection strategy. Patients undergoing reoperative cardiac surgery typically have worse myocardial function and more advanced coronary and valvular heart disease than patients having first-time surgery. In most reoperations, technical challenges increase the cross-clamp time significantly. If one or more patent IMA grafts are present, they will perfuse the coronary circulation with systemic blood flow after the aorta is cross-clamped. The subsequent washing out of cardioplegic solution from the myocardium with systemic blood, which is usually warmer and normokalemic, will cause the heart to resume electrical activity. If this is not addressed, the areas of myocardium not perfused by the IMA may become ischemic. To prevent this phenomenon, there are several approaches. The traditional approach has been to clamp the IMA, but this has been

associated with increased risk of injury to the graft and adverse outcomes.[11] Increasingly, surgeons elect to avoid manipulating patent grafts altogether, cooling the patient to 25 to 27°C so that the heart is supplied continuously with cool, oxygenated blood and remains in diastolic arrest. Alternatively, cardioplegic arrest can be avoided completely, using either off-pump techniques (for coronary artery surgery) or on-CPB techniques with the heart beating and intermittent fibrillatory arrest. If there is any more than mild aortic insufficiency, fibrillatory arrest will result in ventricular distention unless the left ventricle is vented, and retrograde blood flow from the aorta can make mitral valve surgery very challenging in this scenario.

Retrograde cardioplegia is a useful adjunct, but correct placement of a coronary sinus catheter is more challenging in reoperative patients because manual palpation is usually prevented by diaphragmatic adhesions. Consequently, the surgeon is more reliant on TEE to assess coronary sinus placement, and it is crucial to continuously monitor the coronary sinus pressure during cardioplegia to confirm an appropriate pressure response (see Chapters 13 through 15). Additionally, if the aorta is open, the surgeon should see cardioplegia effluent from the left and right main coronary ostia. If necessary, the right atrium can be opened and the retrograde cardioplegia catheter can be placed directly in the coronary sinus; this requires bicaval cannulation and either vacuum-assisted venous drainage or snaring of both cavae to prevent a venous airlock.

Surgical Strategy

Reoperative surgery presents specific challenges after safe institution of CPB. Exposure of the coronary arteries for bypass grafting is usually hampered by adhesions, which must be completely divided to access the circumflex coronary distribution. Exposure of the cardiac valves can be made challenging by the presence of bypass grafts or prosthetic valves in other positions, and the size of prosthesis that can be placed may be limited by the presence of a prior prosthesis in the same or a different position. Excision of prosthetic valves may result in more extensive damage to adjacent structures, requiring more complex reconstruction; this is particularly the case if prosthetic valve endocarditis is present because extensive débridement of all infected material is required before implantation of a new prosthesis. Performing mitral valve surgery without cross-clamping may result in suboptimal exposure because the full aortic root obscures the anterolateral commissural area, and in the presence of aortic insufficiency (which may be exacerbated by the atrial retractor), the posterior mitral valve may be obscured by blood from the left ventricle. Additionally, careful attention must be paid to maintaining fibrillatory arrest and a fully pressurized aortic root as soon as the mitral valve is competent to minimize the risk of ejecting air into the ascending aorta.

Weaning From Bypass

The main difference in weaning from CPB in reoperative cases compared with first-time surgeries is the need for more extended de-airing. The pulmonary vasculature and left ventricle are fixed open by adhesions and, as a result, entrain more air than in non-reoperative cases. Even if no intracardiac air is visualized, protamine should not be given for several minutes after discontinuation of CPB because air tends to return to the heart from the pulmonary veins for several minutes, requiring continued active venting until it is all ejected. This also facilitates urgent reinstitution of CPB if needed for hemodynamic instability due to intracoronary air emboli, myocardial stunning, or right ventricular failure.

Coagulation Management

Because of the large surface area of dissection (particularly in a fully heparinized patient) and prolonged CPB time, coagulopathy is common in reoperative patients. Point-of-care testing, including platelet function assays and thrombelastography, and transfusion algorithms are useful to guide therapy toward restoration of hemostasis and minimizing transfusion requirements (see Chapters 19, 34, and 35).[12]

Intraoperative Emergency Scenarios

Intraoperative adverse events occur in 3% to 10% of reoperative cardiac procedures, with a quarter occurring before or during sternotomy and most of the remainder occurring during mediastinal dissection before institution of CPB.[3,12,13] Potentially life-threatening injuries related to sternotomy include trauma to patent bypass grafts (which are the most frequently injured structures) and injury to the aorta. Additionally, injuries to the right atrium, right ventricle, and innominate vein are common and challenging to address, especially in patients with right-sided heart failure. Rapid volume replacement via large peripheral or central venous catheters or via the arterial cannula may be required. Major injury to arterial structures is immediately life-threatening, either from hemorrhage or from myocardial ischemia, and usually mandates immediate heparinization, cannulation, and institution of CPB. In a recent series from the Cleveland Clinic, the incidence of injury to a patent IMA graft was 5.3% in 655 patients treated between 1986 and 1996, compared with 3% in a later patient cohort from the same institution. This improvement was attributed to better preoperative imaging and planning.[11] The authors concluded that lapses in preventive strategies, including inadequate preoperative imaging, were responsible for 55% of the intraoperative adverse events in their series.

In the event of major hemodynamic instability that is likely to necessitate CPB (including major bleeding), the anesthesiologist should administer a dose of heparin sufficient to institute CPB (300–400 units/kg or an in vitro titration dose calculated to exceed 2.5–3.0 units/mL of blood). Assuming no access to central cannulation sites, extrathoracic sites should be cannulated emergently and CPB initiated. When the patient is fully heparinized and an arterial cannula is in place, "suction bypass" may be initiated to allow for partial temporary CPB. In this scenario, all venous return to the CPB circuit comes from cardiotomy suction ("coronary suckers") placed into the mediastinum and/or lacerated cardiac structures until venous cannulation can be established. The patient should still be ventilated because the left side of the heart is likely to be ejecting blood returning from the pulmonary veins. The period of cardiotomy suction bypass should be as short as possible; extensive hemolysis results from the turbulent flow and mixture with air in the cardiotomy tubing.

If there is a major injury to the aorta, institution of CPB alone will not be sufficient to control the problem. The primary goal is to obtain some degree of control of the bleeding by direct compression or occlusion sufficient to allow effective CPB for several minutes. Restoration of aortic continuity often requires institution of systemic hypothermia so that the aorta may be assessed and repaired during a period of moderate hypothermic circulatory arrest.

If a patent CABG is inadvertently lacerated or transected, it is possible to reduce the risk of resultant myocardial ischemia and ventricular fibrillation by inserting an intracoronary shunt to restore flow across the injured portion. It is frequently necessary to rapidly institute CPB, however. This is clearly the case if significant ST-segment elevation, bradycardia, or ventricular fibrillation is associated with arterial bleeding in this setting. The primary aim initially is decompression of the left ventricle and restoration of adequate systemic circulation. The eventual goal is restoration of coronary perfusion by repair of the injury or replacement of the graft.

Major intraoperative adverse events can have a significant impact on the plan for surgery. Once the patient is stabilized, it is worth reviewing the need for a revised strategy with the team. For example, the surgeon may elect not to address lesions with borderline indications, so as to reduce subsequent CPB and myocardial ischemic times. Very occasionally, the procedure may be halted and the patient taken to the ICU with a plan to return to the operating room in 24 to 48 hours after a period of stabilization. If there is significant mediastinal compression from pulmonary edema and abdominal distention or if

there is severe right ventricular dysfunction, it may not be possible to close the patient's chest without significant hemodynamic compromise. If chest closure is deferred, the sternum is usually splinted open. Patients with open chests should be paralyzed and fully sedated to avoid laceration of the right ventricle by the sternal edges. Although the skin edges are usually approximated to a sterile membrane and mediastinal drains placed under an air-tight adhesive seal (often with mediastinal packing), continued bleeding from mediastinal structures and sternal edges may be substantial, and these patients may need to be returned to the operating room before planned formal chest closure for mediastinal washout.

Results of Reoperative Surgery

In an analysis from the Cleveland Clinic of adverse intraoperative events during reoperative cardiac surgery in 127 patients between 2002 and 2004, the authors found that patients with prior CABG were twice as likely to experience an adverse intraoperative event (8.2% vs 4.4%, $P = .003$), most of which resulted from injury to bypass grafts.[10] Similarly, in a retrospective analysis from the Mayo Clinic of 231 patients undergoing reoperative cardiac surgery between 1996 and 2007, damage to prior bypass grafts represented one third of all intraoperative injuries observed in the series, with an incidence of 11%.[11] This was most likely to occur before institution of CPB and was associated with higher mortality than most other cardiac injuries.

In a retrospective analysis from Mount Sinai Medical Center of 363 patients who underwent reoperative valve surgery between 2000 and 2011, the incidence of injury to bypass grafts was lower (3%), and the presence of patent bypass grafts was not found to be a significant predictor of intraoperative adverse events.[3] This may be attributed to the introduction of an individualized risk-stratified approach to reoperative surgical strategy. The approach included routine preoperative CT scans, liberal use of peripheral cannulation and CPB before sternotomy, and direct supervision of sternal reentry and mediastinal dissection by attending surgeons. Operative mortality decreased from 5% to 2% over the course of the study period. Injury to a major structure occurred in 3% ($n = 11$) of cases, including lacerations of the right ventricle ($n = 3$), aorta ($n = 1$), pulmonary artery ($n = 1$), and patent bypass grafts ($n = 2$), but the only predictor of early morbidity or mortality was severe pulmonary hypertension (odds ratio [OR] 2.7; 95% confidence interval [CI] 1.17–6.2) with higher operative risk scores. Pulmonary hypertension is an indicator of advanced valvular cardiomyopathy and is associated with pulmonary dysfunction. Strategies to address pulmonary hypertension include aggressive management with preoperative nesiritide infusion; perioperative inhaled and intravenous pulmonary inodilators; decompression of the right ventricle with CPB before sternotomy, if indicated; meticulous cardioprotection; a liberal approach to tricuspid annuloplasty to treat tricuspid annular dilatation or moderate tricuspid regurgitation; and intraaortic balloon counterpulsation in the setting of postoperative right ventricular dysfunction.

Emergency Reexploration

Indications

Emergency reexploration is needed in approximately 1% to 3% of patients in the first few hours to days after cardiac surgery. Emergency resternotomy is indicated for definitive management of cardiac tamponade and acute massive mediastinal hemorrhage. Emergency resternotomy permits internal cardiac massage (which has been shown to increase the cardiac index to 1.3 L/min per m^2 from 0.6 L/min per m^2 in the closed chest), placement of epicardial pacing wires, relief of tension pneumothorax, internal defibrillation, and management of excess mediastinal bleeding.[14] Consequently, the other main indication for emergency reexploration is cardiac arrest that does not respond satisfactorily to a few minutes of cardiopulmonary resuscitation and is likely to have a cause that can be addressed by emergency resternotomy. After cardiac surgery, 20% to 50% of cardiac arrests result in emergency sternotomy.[14]

With the exception of catastrophic surgical bleeding or acute cardiac tamponade, the timing of intervention for excess mediastinal bleeding is almost always subject to some debate. When the surgical team has specific concerns about surgical bleeding sites, the threshold for surgical reexploration may be low. It may be much higher in the setting of significant coagulopathy, particularly if an extended effort was made to secure hemostasis in the operating room. In general, indications that the patient may require reexploration for bleeding include (1) greater than 400 mL bleeding in 1 hour; (2) greater than 200 mL/hour for more than 2 hours; (3) greater than 2 L of blood loss in 24 hours; (4) increasing rate of bleeding, particularly in the absence of coagulopathy; and (5) bleeding associated with hypotension, low cardiac output, or tamponade.

General Considerations

Anesthetic and surgical considerations in patients undergoing emergency reexploration differ from those in patients undergoing reoperative cardiac surgery, including surgical revision of bypass grafts or other cardiac procedures in the early postoperative setting. In the setting of emergency reexploration, patients are characteristically hemodynamically unstable and often undergoing cardiopulmonary resuscitation with external cardiac massage. The trigger for emergency resternotomy may have been preceded by several hours of a low cardiac output state, with profound metabolic disturbances. In the case of persistent hemorrhage, the patient may be coagulopathic and may have already received massive transfusions. Emergency reexploration often takes place in the ICU if the patient is too unstable to be transferred to the operating room. Advanced preparation in the form of practice drills and team protocol development is important to help overcome the disadvantages of reduced access to operating room personnel, equipment, and space that can be major obstacles to the safe and effective resuscitation of these patients. Additionally, the longer the time between the index cardiac surgery procedure and cardiac arrest, the less likely it is that the cause of cardiac arrest can be effectively addressed by emergency resternotomy. The following recommendations are based on the excellent guidelines for resuscitation in patients with cardiac arrest after cardiac surgery produced by the European Association of Cardio-Thoracic Surgery Clinical Guidelines Committee.[14]

The identification of cardiac arrest and rapid initiation of advanced life support are essential and include external cardiac massage, defibrillation, and airway management in cardiac surgery patients. Swift and accurate confirmation of airway patency and bilateral lung auscultation are essential. Hypoxia is a cause of cardiac arrest that will not be satisfactorily addressed (i.e., effective management may be delayed) by emergency resternotomy. High airway pressures or reduced compliance on manual ventilation are most commonly caused by bronchospasm, endotracheal tube obstruction, selective bronchial intubation, or tension pneumothorax. Cardiac arrest not caused by ventricular fibrillation or ventricular tachycardia after cardiac surgery may be caused by hypoxia, tamponade, profound hypovolemia, tension pneumothorax, and complete conduction block with failure of epicardial pacing. Ventricular fibrillation and tachycardia cause approximately one third of cardiac arrests after cardiac surgery and may result from myocardial ischemia, metabolic and electrolyte disturbances (particularly acidosis and hypokalemia), or asynchronous pacing resulting in an R-on-T phenomenon whereby a pacing spike occurs on the T wave, which may cause ventricular arrhythmias (i.e., premature QRS complex interrupting the preceding T wave). In an analysis of 79 emergency resternotomies in the setting of cardiac arrest, the major determinant of survival was chest reopening within 10 minutes.[14]

Location of Resternotomy

The decision to preform reexploration in the ICU or to transfer the patient to the operating room is dictated primarily by the stability

of the patient. If the patient is hemodynamically stable enough for safe transfer to the operating room, this is almost always preferable to resternotomy in the ICU, for several reasons. First, equipment for surgical intervention in the ICU is usually limited, which is a key consideration for any patient who is likely to require reinstitution of CPB. Second, once in sterile gloves and gown, the surgeon is completely reliant on other personnel to locate instruments and equipment. The operating personnel are often unfamiliar with the location of equipment within the ICU, and ICU staff are almost invariably unfamiliar with the specific supplies required and preoccupied with the other critical aspects of patient care. Third, impediments to sterility, light, and access on the wide and relatively immobile intensive care bed hamper effective surgical interventions. Regular practice of emergency sternotomy drills and team protocols allows the whole team to overcome some of these limitations, but units where this is done regularly are the exception rather than the rule.[14]

Performing Emergency Resternotomy

The primary role of the anesthesiologist is to ensure that the patient is adequately ventilated during resternotomy, which may require emergency reintubation and should always include confirmation of airway patency and bilateral air entry as outlined earlier. The second priority is to maintain circulation by securing venous access with large-bore volume infusion, management of potentially massive transfusion requirements, and vasoactive infusions. The third priority is to administer 300 units/kg of heparin to the patient as soon as the decision is made to use CPB. The cessation of sedatives and anesthetic agents for a few minutes in the setting of cardiac arrest is unlikely to cause awareness. These medications can be reinstituted once hemodynamic stability and cerebral perfusion are achieved. Clear and focused communication with the surgical and nursing teams is vital. A dedicated nurse should be identified to remain at the bedside to assist with infusion pumps, drugs, and airway management.

If the patient is receiving chest compressions, these are continued until the surgeon is gowned and gloved. Use of an all-in-one sterile drape (with a clear adhesive window that covers the incision) is faster than preparation of the skin with antiseptic and assembly of multiple drapes. Chest compressions are then resumed by the gowned and gloved surgical team. The minimum equipment required to reopen the chest is a sterile Yankauer suction tip and tubing attached to wall suction, a blade, a wire cutter, and a heavy needle driver. The wound is incised down to the wires, which are cut and pulled out so that the sternal edges can be retracted. The process from chest compressions to open chest should take no more than 3 to 5 minutes, with minimal compromise of sterile technique. Opening of the sternum often relieves tamponade, with a large spike in the patient's blood pressure if there was a cardiac output before resternotomy. If there is no cardiac output, the surgeon's priority is to perform internal cardiac massage without disrupting any bypass grafts, followed by internal defibrillation if indicated, epicardial pacing, or control of bleeding. It is generally safest to perform internal cardiac massage with two hands, with the right hand placed so that knuckles are against the diaphragm and fingertips at the apex of the heart and the left palm placed over the right ventricle, squeezing palm to palm to generate a systolic pressure of 50 to 60 mm Hg. Emergency institution of extracorporeal membrane oxygenation or CPB may be required if cardiac output cannot be restored. The patient must be fully heparinized. If hemodynamic stability and bleeding can be achieved only temporarily, the patient may be transferred to the operating room with an open chest for definitive control. A sternotomy is indicated for reexploration in the setting of cardiac arrest after nonsternotomy cardiac surgery, such as minimally invasive direct coronary artery bypass (MIDCAB) or minithoracotomy valve surgery, in order to permit internal cardiac massage and institution of CPB; a sternal saw should be kept in the ICU for this purpose.

Approximately 40% to 50% of patients survive emergency reexploration for cardiac arrest after cardiac surgery, of whom half survive to leave the hospital. Sternal wound infections have been described in 5% of survivors. Empiric antibiotics are usually given during emergency reexploration, and antibiotic washout with a prolonged course of antibiotics postoperatively is a reasonable adjunct.

In the case of awake patients who are stable enough to transfer to the operating room, it is often appropriate to place any needed catheters and to prepare and drape the patient before induction of anesthesia because induction may precipitate acute hemodynamic decompensation. The most common scenario in which this happens is delayed tamponade. Although these patients may appear to be quite well compensated and the surgical plan may be limited to drainage via a small subxiphoid incision, these patients should be regarded as potentially requiring emergency resternotomy and should have large-bore venous access, arterial and central venous pressure monitoring, and TEE in place.

Conclusion

This chapter has discussed the risks of reoperative cardiac surgery. An evolution in management strategies at major cardiac centers appears to have decreased morbidity and mortality over time. The anesthesiologist plays a vital role in managing large-bore venous access, using TEE to monitor the adequacy of cannulation and cardiac function, managing hemostasis, among other functions. The collaboration of a cohesive team of surgeons, anesthetists, perfusionists, and nurses is key to further improvement in outcomes in this high-risk patient cohort.

Patient Safety in the Cardiac Operating Room

JOYCE A. WAHR, MD | T. ANDREW BOWDLE, MD, PhD | NANCY A. NUSSMEIER, MD, FAHA

KEY POINTS

1. Cardiac surgical patients are at significant risk from preventable adverse events. These events occur through human error, by either faulty decision making (diagnosis, decision for treatment) or faulty actions (failure to implement the plan correctly).
2. Human error is ubiquitous and cannot be prevented or eliminated by trying harder or by eliminating the one who errs. Reduction in human error requires system changes that prevent errors from occurring (forcing functions) or prevent errors from reaching the patient.
3. Sleep deprivation and fatigue can render a person more likely to make an error. Although residents' hours are limited, those of other physicians in the United States are not, unlike in other countries.
4. Nontechnical skills such as leadership, communication, cooperation, and situational awareness are critical to patient safety, but they are rarely taught. Distractions, disruptions, noise, and alarms contribute to technical errors and increase mortality rates in cardiac surgery.
5. Communication is the leading root cause of sentinel events, whether through missing information or through misunderstanding. Use of structured communication protocols reduces errors. Handoffs performed without a protocol involve significant numbers of omitted items.
6. Team training reduces surgical mortality rates, but it must be done with careful preparation and with regular retraining.
7. Surgical briefings that use a checklist significantly reduce surgical mortality rates (World Health Organization Safe Surgery Saves Lives). Debriefings allow teams to identify hazards and formulate improvements.
8. Simulation is an effective means to teach both technical and nontechnical skills and to allow teams to train for rare but dangerous events.
9. Cognitive aids should be available in every operating room to provide direction during rare crisis events (eg, malignant hyperthermia, pulseless electrical activity).
10. Medication errors occur approximately in 1 in every 150 to 200 anesthetic cases. The Anesthesia Patient Safety Foundation published a set of recommendations to reduce medication errors, including standardization, use of technology such as bar codes and smart infusion pumps, having pharmacy involvement in every step of the medication process, and building a culture of safety.
11. Awareness during anesthesia occurs approximately 1 to 2 times per 1000 anesthetic cases, and it occurs more often in cardiac surgical procedures. Use of a processed electroencephalogram or achieving an end-tidal concentration of 0.7 minimum alveolar concentration is effective in reducing the incidence of awareness.
12. The culture of an organization or a unit contributes significantly to patient safety or danger. Strict hierarchical cultures typically harbor a culture of blame and shame, which inhibits identification and correction of hazards. A "Just Culture" acknowledges that human error occurs and seeks to redesign the system to prevent future errors, but also holds individual persons accountable for willful violations.

The early days of cardiac surgery saw amazing successes and crushing defeats for the pioneers such as Blalock, Gibbons, and Lillihei.[1] The knowledge that their patients were certain to die without surgical treatment drove these physicians to find ways to provide safe and effective extracorporeal circulation and oxygenation. Today, nearly half a million patients undergo coronary artery bypass graft (CABG) procedures each year, with mortality and morbidity rates that would astound those early pioneers.[2] Indeed, over the decade between 2000 and 2009, the mortality rate associated with isolated CABG decreased from 2.4% to 1.9%, representing a relative risk reduction of 24.4% (Fig. 30.1).[2]

Despite impressive advances, reports show that cardiac surgical patients each year become ill and die because of preventable adverse events.[3] In the study by Gawande and colleagues,[3] cardiac surgical patients were more likely to have adverse events than other surgical patients (12.2% vs. 3%), and 54% of these were considered to be preventable. These numbers may underestimate the true rate of adverse events. A systematic review by He and associates[4] found that 6.7% of cardiac surgical patients had hospital-acquired ventilator-associated pneumonia, a complication generally believed to be preventable.[5]

The difficulty of assessing the incidence of preventable adverse events is demonstrated by studies reporting that 99,000,[6,7] 280,000,[8] and possibly as many as 400,000[9] hospitalized patients die each year in the United States as a result of preventable adverse events. Starfield[8] postulated that preventable adverse events are the third leading cause of death in the United States. Despite significant attention and discussion, eradication of these preventable medical events has proved

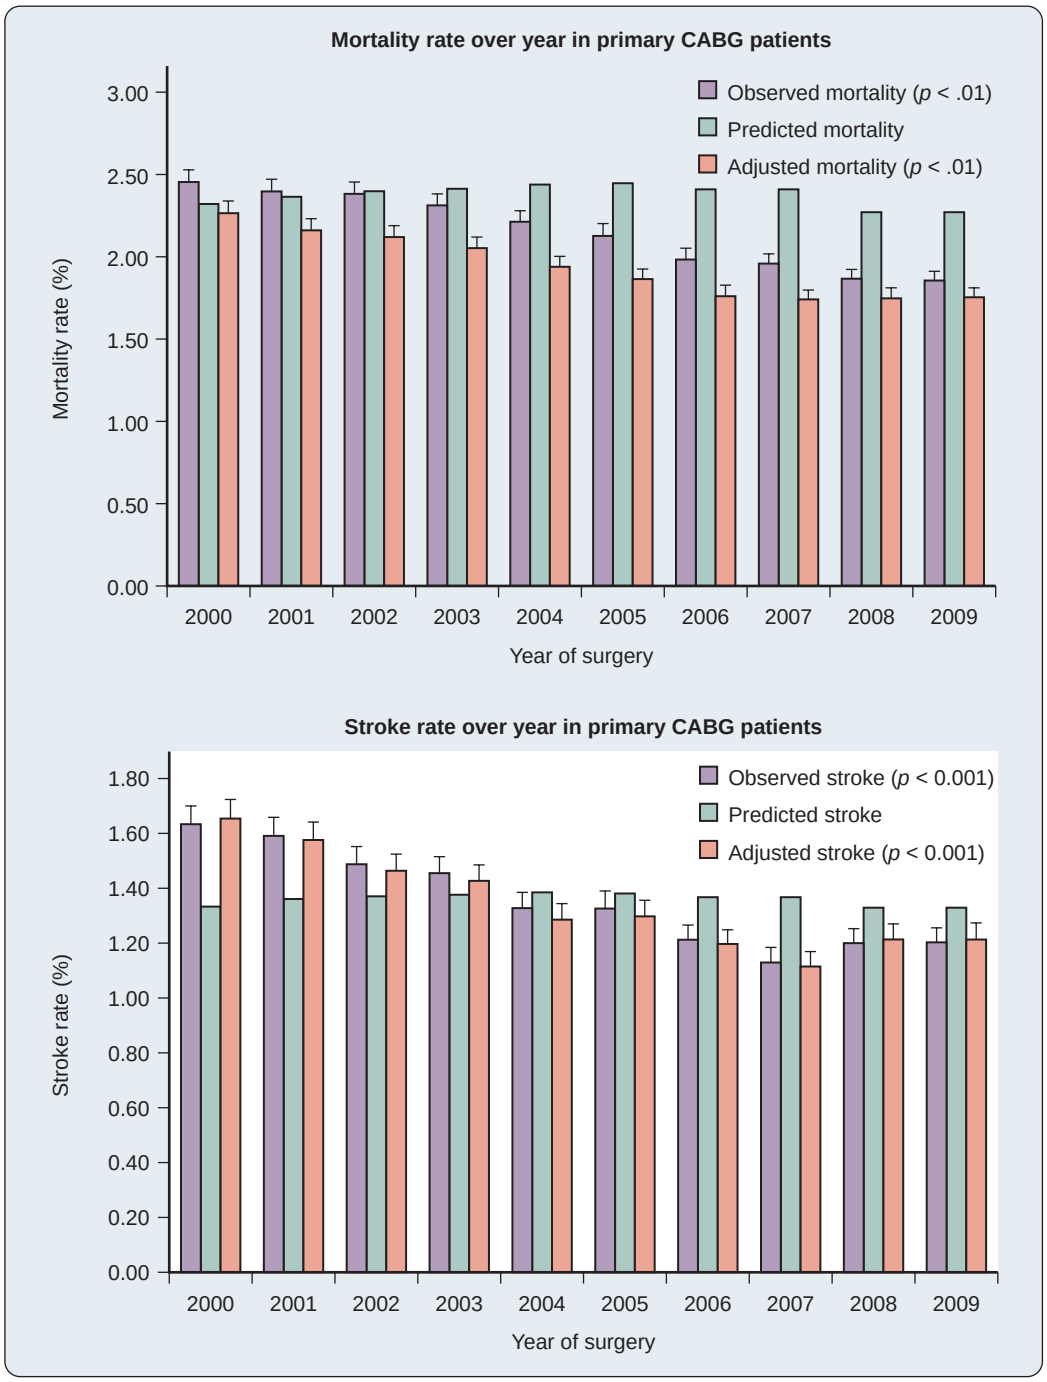

Fig. 30.1 Change in mortality and morbidity in patients with primary coronary artery bypass grafting (CABG) between 2000 and 2009. *(From ElBardissi AW, Aranki SF, Sheng S, et al. Trends in isolated coronary artery bypass grafting: an analysis of The Society of Thoracic Surgeons adult cardiac surgery database.* J Thorac Cardiovasc Surg. *2012;143:273–281.)*

difficult,[10] largely because medical education remains focused on technical rather than nontechnical aspects of medicine. Far more time is spent teaching anesthesia residents how to intubate the trachea and how to cannulate the internal jugular vein than in how to communicate clearly and without error or how to understand the complexities of human error.[11]

Patient safety involves both doing the right thing (ie, applying best practice to every situation) and doing the right thing the right way (ie, avoiding human error). Whereas most of this textbook is devoted to discussion of the right thing to do in a given circumstance, this chapter discusses both requirements for safe practice: (1) formulation of the correct plan for patient care (implementing evidence-based best practices) and (2) flawlessly carrying out the plan (preventing or correcting human error.)

The Science of Safety

In the past, efforts to reduce preventable harm focused on the individual health care professional, on trying harder, being more alert and vigilant, and "doing better." Fortunately, extensive scientific evidence

exists to inform clinicians on how teams and institutional and system culture influence safety.[12,13] Like aviation, the nuclear industry, and the military, medicine is a complex, high-stakes field in which errors can result in great harm. Although patients are not airplanes, and performing a surgical operation is not precisely analogous to flying a plane, much can be learned from other high-reliability industries. Rigorous patient safety science has improved the understanding of how errors occur and how to design safe practices, test them for efficacy, implement changes effectively, and measure the effectiveness of interventions, thus ensuring improvements.

The need for science in our efforts is exemplified by the approach to the wrong-site surgical procedure, which was recognized as a major issue in 2000. In 2004, The Joint Commission published the Universal Protocol to prevent wrong-site surgical procedures. Nonetheless, in 2013, wrong-site and wrong-patient errors occurred some 50 times a week in the United States.[14] The approach to reducing the frequency of wrong-site surgical procedures failed at many levels.[15] First, the Universal Protocol put forward by The Joint Commission did not address the complexity of wrong-site occurrences (eg, wrong-side errors on radiographs or in the medical record were not addressed). Second, the protocol was implemented from the top down rather than by involving frontline staff in designing a solution; the result was cavalier performance by many staff members.[16] Third, the proposed intervention (time out to identify the patient and the surgical site) was not tested for effectiveness before a national mandate was issued.[14]

If patient safety is to be improved, it will be through scientific study and application.[17] However, much of the descriptive, observational, or qualitative science that relates to patient safety is foreign to physicians, who are primarily familiar with rigorous quantitative experimentation.[18] In addition, traditional scientific medical journals have been reluctant to publish qualitative studies, even studies conducted with statistical and scientific rigor. Thus, most patient safety studies are found in journals of safety and quality, journals often not available in a medical library. These qualitative studies, however, hold promise for improving patient safety and will need to become part of the medical lexicon.[19]

One such comprehensive observational study of the hazards in the cardiac operating room (OR) was undertaken in the Locating Errors Through Networked Surveillance (LENS) group as part of the FOCUS project (Flawless Operative Cardiac Unified Systems).[20,21] This collaborative study involved the Society of Cardiovascular Anesthesiologists and the Johns Hopkins Armstrong Institute, and it consisted of observations of 20 cardiac operations by a team of trained observers, including human factors engineers, anesthesiologists, and organizational psychologists.[21] The analysis identified a myriad of hazards in the cardiac OR and detailed the complex interaction of organizational structure (lack of policies), teamwork behaviors (poor communication), system shortcomings (inadequate support requiring multiple workarounds), equipment and technologies (poorly designed and integrated), and individual failings (situational awareness).[21–25] The complexity of interactions among systems, providers, and processes highlights the truth that a simple solution to patient safety is not feasible. Experts from a variety of disciplines will be required to examine every aspect of perioperative cardiac surgical care and integrate proposed solutions.[19,26,27]

Evidence-Based Best Practice

Knowing is not enough; we must apply. Willing is not enough; we must do.

Johann Wolfgang von Goethe (1749–1832)

Patients are less safe when they are exposed to practices that are outmoded and substandard relative to the current best practice. For anesthesiology, some of the first "guidelines" for practice were put forward in 1986, with the adoption of formal standards of monitoring.[28] The proliferation of guidelines since that time has been significant. The National Guideline Clearinghouse houses 2300 medical guidelines and nearly 1000 surgical guidelines. Despite this proliferation, guideline development is not simple or easy. In one study, nearly half of the reviewed guidelines were based on expert opinion rather than grade A evidence; many guidelines did not grade the evidence, and many authors had conflicts of interest.[29,30]

In 2011, the Institute of Medicine published a set of eight standards to be met when developing guidelines.[31] The standards address the following:

1. Transparency
2. Management of conflicts of interest
3. Group composition
4. Systematic review
5. Establishing the evidence foundations for and rating strength of recommendations
6. Articulation of recommendations
7. External review process
8. The need and process for regular updating of guidelines

The eighth standard recognizes the Bill Kelley adage that "The great questions in medicine never change; the answers do with regularity."[32] The continual need to update and revise guidelines, and the finding that many are based on opinion, albeit expert, are often used to provide an excuse for not implementing guidelines. However, rather than waiting for the evidence to become perfect and without uncertainty, physicians should use the best evidence available to achieve consensus.[33]

Many articles have detailed improvement in outcomes after published guidelines are implemented.[34–36] However, it is clear that guidelines or best practices are not always implemented. Perhaps the most widely known historical example of resistance to adoption of best practices is the failure of Dr. Semmelweis to persuade his fellow Viennese physicians to wash their hands between patients. Despite the excellent evidence that hand washing could virtually eliminate puerperal fever, his colleagues not only rebuffed his attempts, but they also ensured that he would not be reappointed.[37] Of course, physicians now readily accept that sterile technique is mandatory in surgery and do not view it as an individual physician's choice.

In 2003, Leape and colleagues[38] reviewed CABG and angioplasty procedures and found that 24% of angioplasties and 9% of CABG procedures were inappropriate according to guidelines published by the American College of Cardiology and the American Heart Association (ACC/AHA) and by the RAND Corporation. Another example of inadequate implementation of guidelines is transfusion practice. Guidelines for transfusion in cardiac surgery have existed since the mid-1980s, but a review of institutional practice in 1998 found poor adherence to these guidelines.[39] In 2007, The Society of Thoracic Surgeons and the Society of Cardiovascular Anesthesiologists published more formal and society-specific joint guidelines for transfusion in cardiac surgery[40]; 3 years later, 80% of surgeons, anesthesiologists, and perfusionists reported that they had read the guidelines, but only 20% had implemented any of them.[41]

Resistance to implementing guidelines either can be passive (lack of attention to guidelines, no attempt to learn the latest guidelines or best practices) or active, with a conscious decision not to implement published guidelines. Active resistance can be based on a perceived loss of a physician's clinical autonomy, a belief that implementing guidelines reduces the physician's "unregulatable art—an art that depends on our ability to build relationships with patients and families; to integrate answers to patients' questions into the content of their lives; and to heal, even when our science cannot cure."[33]

Perhaps more difficult for many physicians is that new evidence often shows previous guidelines to be incomplete at best and wrong at worst. When perioperative hyperglycemia was shown to be associated with adverse outcomes, increasingly stringent glycemic protocols and guidelines were developed, moving from a target of less than 180 mg/dL to less than 140 mg/dL to a target of 80 to 110 mg/dL.[42] A subsequent randomized, controlled trial demonstrated that tight glucose control (80–100 mg/dL) was related to hypoglycemic episodes and increased morbidity and mortality rates.[43] Similarly, guidelines

concerning the preoperative use of β-antagonists in cardiac patients changed following demonstration of benefit (atenolol)[44] and then deleterious effects (metoprolol).[45] These guidelines may change again with increasing evidence that agents with a high beta1:beta2 affinity (sotolol) are beneficial, whereas those with lower beta1:beta 2 affinities, such as metoprolol, agents are deleterious.[46] This continual change in what is "best practice" causes many clinicians to disregard excellent guidelines for fear that the recommendations subsequently may be proved to be wrong. Even though new evidence will always arise, clinicians must apply the currently available best evidence but always remain alert to the new.

Whatever the rationale, implementation of even well-supported guidelines takes significant effort. Widespread and effective implementation of the ACC/AHA guidelines regarding β-blockade following acute myocardial infarction required extensive effort on a national level.[47–49] With the increasing number of evidence-based guidelines and best practices, it is necessary to reduce the effort and resources needed to ensure implementation. Each institution or cardiac surgical unit should develop processes that address both rapid adoption of proved innovations and elimination of less effective therapies.[33] Failure to do so will cause the government or third-party payers to institute audits and penalties for care that does not meet an external quality level.

Human Error

Errare humanum est, perseverare autem diabolicum.
Lucius Annaeus Seneca, 4 BC to AD 45

Theory of Human Error

The universality of human error is well known and is accepted in virtually every walk of life, except perhaps medicine. Here it is expected that physicians and providers will be perfect, that the natural cognitive slips and trips and biases inherent in daily life will be overcome by the importance of the work being done and the fact that lives hang in the balance. Although most anesthesiologists acknowledge that they have made a medication error in the past, most also believe that they are less likely to make an error than their colleagues.[50]

The elegant exploration of the physiology and psychology of human error by Dr. James Reason[51] and research into system accidents[52] have made it clear that patient safety in the cardiac OR will not come about by identifying and eliminating error-prone individual clinicians.[51,53] In general, if the system is designed such that one person can make a given error, it is virtually guaranteed that another human will as well. For example, despite a Joint Commission Sentinel Alert in 2006 to caution care providers of the dangerous errors made possible by the use of universal connectors (Luer), hundreds of patients have died since then because intravenous fluids, pressure lines, or enteral feedings were erroneously connected to epidural catheters or arterial lines and vice versa.[54] The appropriate system change is now being implemented, with unique connectors for intravenous, arterial, enteral feeding, and pressure tubing and neuraxial catheters established by the International Standards Organization.[55]

Even in the least complex systems (eg, leaving the house to go to an interview), a trivial misstep (car door not properly latched, overhead light on, dead battery) can lead to far-reaching consequences (failure to be hired) because of concurrent defects (neighbors not available, bus strike, taxis unavailable as a result of bus strike).[52] Highly complex systems such as health care or the nuclear power industry are far more vulnerable, even though many of the worst events similarly begin with a trivial misstep (O-ring not tested in low temperatures in the space shuttle rocket). Even when the initiating event is a human error, correcting or preventing adverse outcomes nearly always requires a system change.[51,56] Reason's Swiss cheese model is now well accepted to demonstrate how system defenses must be in place to prevent or at least detect human errors before harm is done to patients (Fig. 30.2).[56]

At the individual patient level, inciting events that can culminate in a patient's harm or death typically begin with an erroneous process

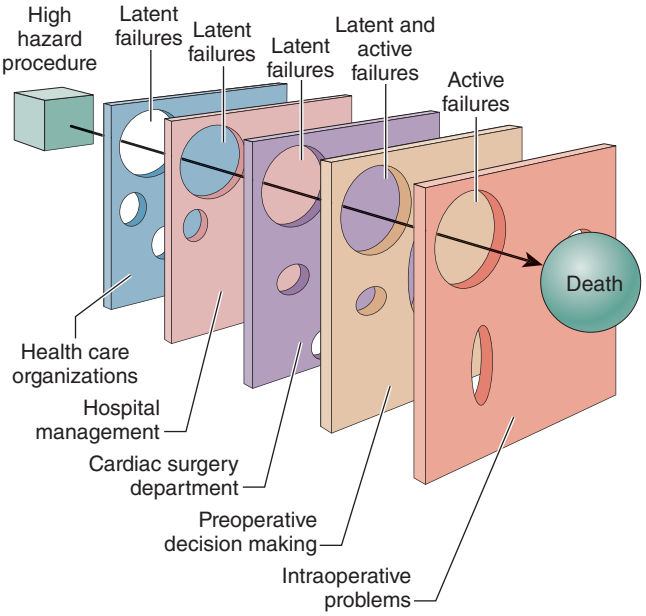

Fig. 30.2 Accident model. Active and latent failures in health care organizations, hospital management, and individual human error can all contribute to adverse events during high-risk procedures. *(From Carthey J, de Leval MR, Reason JT. The human factor in cardiac surgery: errors and near misses in a high technology medical domain.* Ann Thorac Surg. *2001;72:300–305.)*

that is part of the inherent cognitive processes (Fig. 30.3). As presented by Reason, much of what is done every day is the running of a subconscious, automatic schema.[51] Errors in the completion of automatic schema are *action errors,* such as a syringe swap, or neglecting to turn on the ventilator when terminating bypass (failure to complete a planned sequence). *Decision errors* occur when the plan or diagnosis is in error, and these errors can result from either inappropriate pattern recognition or faulty reasoning (administering atropine for bradycardia that is caused by electrocautery interference with a pacemaker). *Reasoning errors* occur when the subconscious has no preset schema or rule that applies, and decisions regarding what is happening or what to do occur through a relatively slow and methodical conscious process (hypoxemia resulting from undiagnosed large pulmonary arteriovenous malformations).[51] With time, diagnoses that were made initially through a reasoning process can become more rote and subconscious, based on learned pattern recognition (Fig. 30.4).[57,58] However, whether decisions are based on pattern recognition or conscious reasoning, a host of influences can contribute to cognitive errors (Fig. 30.5).[57,59,60]

Reasoning or cognitive errors are less common than are action errors (eg, taking a wrong turn, missing an exit), but their consequences are more serious and more difficult to uncover, and recovery is more difficult. The near nuclear meltdown at the Three Mile Island nuclear plant in Pennsylvania in 1979 was based on the incorrect assumption (cognitive error) that a lit bulb on the control panel indicated an open coolant valve when it only meant that the switch had been flipped (in reality, the valve was stuck shut). In many high-risk industries such as aviation and nuclear power, conscious decision making is rarely required because almost all processes and procedures are well defined and tested. In addition, rare scenarios that could require diagnosis or conscious thought have been planned for and rehearsed (water landing in the event of total engine failure). In medicine, however, clinicians often encounter an unexpected event (large cyst on the epiglottis) that requires conscious reasoning, frequently under time pressure. The cognitive process used to deal with unexpected events is estimated to result in erroneous diagnoses anywhere from 2% to 50% of the time.[59]

Although cognitive psychologists largely have defined the process by which humans make decisions, as well as the inherent biases that

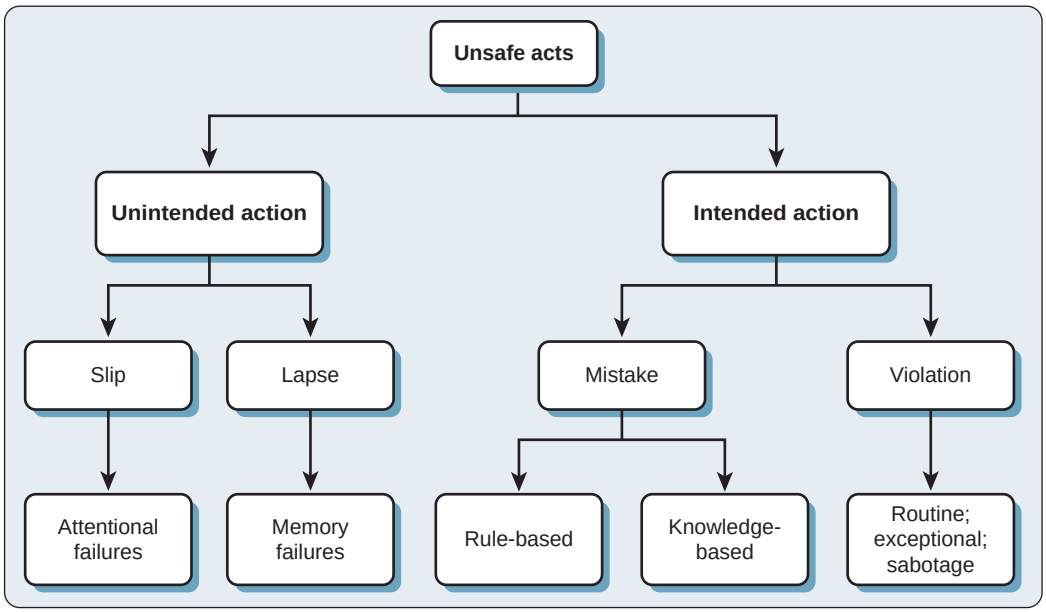

Fig. 30.3 Human error types. *(Adapted from Reason J. Human Error. New York: Cambridge University Press; 1990.)*

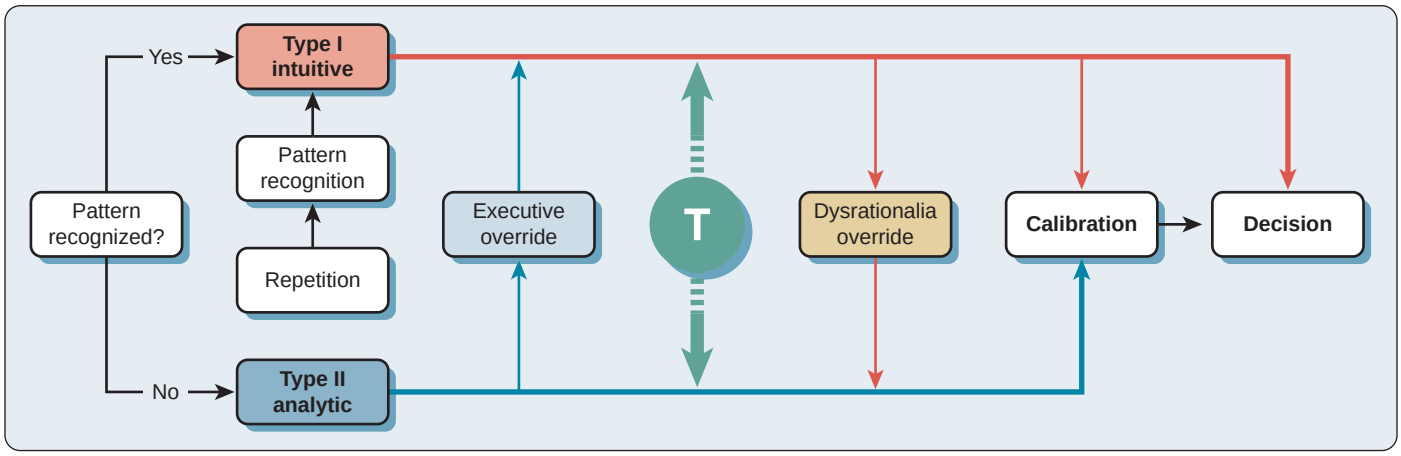

Fig. 30.4 Dual process model of reasoning: how intuitive processes (type I) and analytic processes (type II) interact to influence diagnostic thinking. Some type I processes go directly to end decisions without any overrides, toggling, or calibration and represent largely unexamined decision making. Explicit effort allows for toggling *(T)* between type I and type II processes. Repetition of analytic processes until they become automatic is the basis of skill acquisition. This model does not account for proportion of time spent in, or the superiority of, one process over another. Error may be made in either system at any point, including the starting point (ie, patterns may be "recognized" incorrectly). *(From Stiegler MP, Tung A. Cognitive processes in anesthesiology decision making.* Anesthesiology. *2014;120:204–217, as adapted with permission from Croskerry P, Singhal G, Mamede S. Cognitive debiasing 1: origins of bias and theory of debiasing.* BMJ Qual Saf. *2013;22(suppl 2):ii58–ii64.)*

can lead to cognitive errors,[57,58] little of this science is known to the average physician or is taught in medical school. Although some of the biases are better known and discussed (anchoring, availability heuristic, confirmation), others are not yet well recognized or managed (loss aversion, preference for certainty, blind-spot bias) but can significantly influence cognitive error (Table 30.1).[57] In addition, the need to make a rapid decision in a life-threatening situation results in further dependence on availability and approximation heuristics, a strategy that clearly speeds decision making, but one that is susceptible to cognitive error.[61] Although medicine is beginning to follow aviation and develop cognitive aids to assist in handling unexpected events, the use of these aids is not yet widespread.[61–64]

As noted earlier, a single adverse clinical event actually involves multiple latent risks: situations that permit an error to occur or allow an error to reach the patient (see Fig. 30.2.)[51] In a case report, Spiess and associates[65] detailed a near-catastrophic failure of oxygenation during cardiopulmonary bypass (CPB) at the point of suturing a prosthetic aortic valve in place. The inciting event occurred when a perfusionist inserted an oxygen sensor into the fresh gas line, a sensor not designed for use in the presence of anesthetic gas; the sensor cracked, allowing the fresh gas flow to escape, so that no oxygen reached the oxygenator. Although an individual clinician performed the inciting unsafe act, latent risks existed at the system level (refusal to purchase appropriate sensors), at the unit level (no process for vetting and approving such

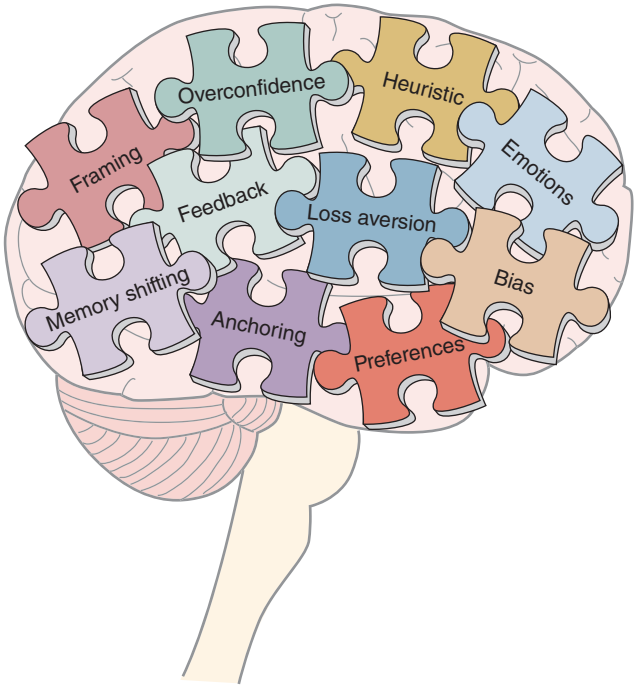

Fig. 30.5 Influences on decision making and diagnostic error. Various nonrational factors influence decisions; these factors themselves are neither good nor bad. Decisions may also use rational processes. *(From Stiegler MP, Tung A. Cognitive processes in anesthesiology decision making.* Anesthesiology. *2014;120:204–217.)*

workarounds), and at the individual level (staff members afraid to speak up because of an irascible surgeon).

Taxonomy of Errors

Analyzing adverse events and developing solutions require in-depth review of all system and organizational characteristics that may contribute to errors.[53,56,66] One such approach is the Human Factors Analysis and Classification System (HFACS) developed by Wiegmann and Shappell and their colleagues[67–69] to analyze adverse events in aviation, and it has been adapted for use in many different high-risk industries (Fig. 30.6). The HFACS taxonomy was developed from the original four categories of unsafe acts as proposed by Reason (see Fig. 30.3), and it provides a detailed framework for analysis of error and latent risk. It has been adapted for use in both cardiac surgery and health care in general, and it has been found to provide a robust analysis (Box 30.1).[26,70] Using structured interviews of cardiac surgical teams, ElBardissi and colleagues detailed the relationships and significant influences among the categories and identified significant correlations (Fig. 30.7).[26] It is obvious that personal readiness failures, such as fatigue or stress, can degrade skill and decision-making ability and result in errors. Less clear is that problems with teamwork represent equal or even greater latent risks than do individual factors.

Personal Readiness (Fatigue, Stress)

The Institute of Medicine Committee on Optimizing Graduate Medical Trainee Hours and Work Schedules to Improve Patient Safety conducted a comprehensive review of the medical and scientific literature and concluded that working for more than 16 consecutive hours is unsafe for both trainees (marked increased risk of an accident while

TABLE 30.1 Nonrational Cognitive Factors That Influence Decision Making

Cognitive Factor	*Explanation*
Representativeness heuristic	Diagnosing or identifying by the degree of resemblance to preexisting or "classic" mental models
Availability heuristic	Diagnosing or identifying by resemblance to previous, highly memorable, events; "memorableness" may be induced by an emotionally charged past experience (usually negative), a peer review "morbidity and mortality" conference, or another novelty
Anchoring, fixation, "tunnel vision"	1. Insufficient adjustment from an initial assessment of a value or a state. "Anchoring" on the starting point can bias subsequent estimates. 2. Focus on a single feature of a case or event exclusively, at the expense of considering other aspects of the case. This may include task fixation, such as troubleshooting of an alarm at the expense of maintaining situation awareness
Retrospective biases	Tendency to view events that have already occurred differently once the outcome is known 1. Hindsight bias: tendency to view events as having been more predictable, and thus actions more correct or incorrect, than was apparent as the situation was unfolding 2. Outcome bias: favorable (if the outcome is good) or unfavorable (if the outcome is bad) assessments of judgments, regardless of actual decision quality (eg, drunk driver who arrives home safely rationalizes that he made a "good choice")
Confirmation bias	A tendency toward seeking (or "seeing") only information that supports a diagnosis or hypothesis, rather than information that refutes it
Visceral (transference) bias	The tendency to allow feelings about a patient to affect care decisions, as with a "VIP patient," a victim of trauma, or a "high-maintenance" patient
Omission bias	Tendency toward inaction rather than action, out of fear of causing harm (to patient, if action failed; to self, by damaging professional reputation if wrong); may be especially likely when a significant authority gradient is perceived or real
Bias blind spot	A flawed sense of invulnerability to bias; may be more prominent among cognitively sophisticated and highly intelligent persons
Overconfidence	Inaccurately high self-assessment with regard to positive traits; can refer to medical knowledge, certainty regarding diagnosis, technical abilities, and situational assessment
Memory shifting or reconstruction	Failure to recall information accurately; occurs when meaning and verbatim information are coded differently and results in "filling in" details (sometimes misinformation) when memories are recalled; also called "memory reconstruction error"
Preference for certainty	Human preference for certainty over risk, even at the expense of sacrificing a greater expected value (ie, calculated by expected utility theory)
Framing	A schema of interpretation that changes perception without altering facts; equivalence framing refers to the interpretation of the same set of data as either a gain or loss; emphasis framing focuses on a subset of selected data to match an event or explanation
Loss aversion	Tendency for humans to view a loss as significantly more psychologically powerful than a gain of the same amount
Affect (emotion); anger; regret	Emotional influences on decision behavior; anger describes the tendency for angry or disruptive behavior to influence the decisions of oneself or others; regret describes the tendency to allow regret for previous decisions to affect future ones; anticipated regret is the desire to avoid regret from future consequences or outcomes of decision choices
Feedback bias	Significant time elapses between actions and consequences; lack of outcome data reporting
Commission bias	Tendency toward action rather than inaction, even when those actions are not indicated or founded on desperation; the "better safe than sorry" mentality of adding additional invasive monitors, central access, or liberal blood transfusion; backfires when those actions have unintended effects

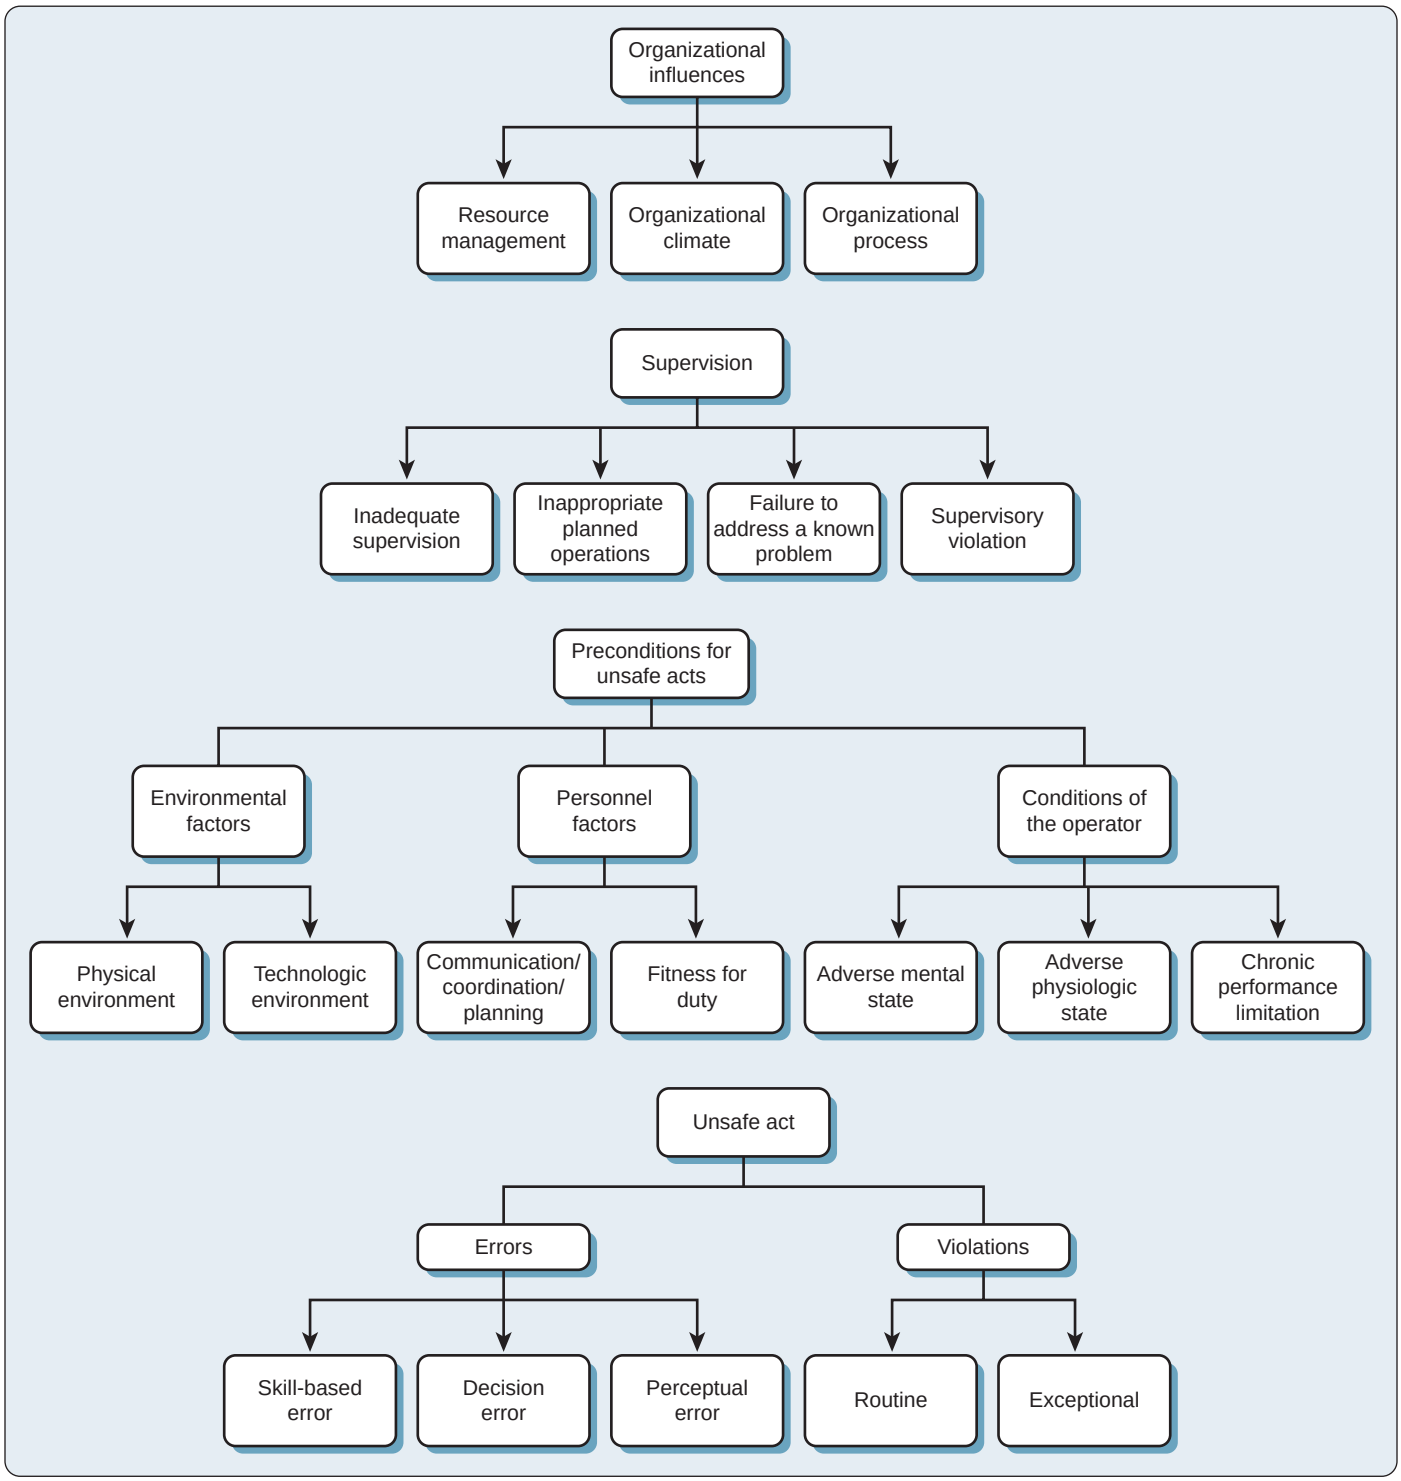

Fig. 30.6 The Human Factors Analysis and Classification System. *(Modified from Shappell S, Detwiler C, Holcomb K, et al. Human error and commercial aviation accidents: an analysis using the human factors analysis and classification system.* Hum Factors. *2007;49:227–242.)*

driving home) and for their patients (attention failure, serious errors, and diagnostic mistakes.)[71] After 24 hours of being awake, impairment of reaction time is comparable to that produced by a blood alcohol concentration of 0.10 g/dL.[72,73] Sleep-deprived persons have a poor capacity to recognize their fatigue, thus reducing their capacity to work safely.[74] A survey of resident physicians suggested that fatigue-related errors resulting in death or injury of a patient are not uncommon.[75]

Landrigan and associates[76] reported that trainees working recurrent 24-hour shifts had 36% more serious medical errors compared with trainees with 16-hour shifts, five times as many serious diagnostic errors, 61% more needlestick and sharps injuries, double the risk of a motor vehicle crash when driving home, a 1.5- to 2-standard deviation deterioration in performance, and 300% more fatigue-related medical errors leading to a patient's death.

Individual persons vary in susceptibility to the effects of sleep deprivation. Young people are more susceptible to a single night of sleep deprivation, whereas older people are more vulnerable to a sequence of night shifts.[77] Differences also exist among otherwise

BOX 30.1 DESCRIPTION OF HUMAN FACTOR LEVELS

Organizational Influences

1. Climate: vision within the organization including policy, command structure, and culture
2. Process: means by which the vision of an organization is carried out, including operations, procedures, and oversight
3. Resource management: how human, monetary, and resources necessary to carry out the organizational vision are managed

Unsafe Supervision

4. Inadequate supervision: oversight, management of personnel, and resources, including training, guidance, and leadership
5. Problem correction: instances when deficiencies among individual persons, equipment, training, or other safety areas are "known" to the supervisor yet allowed to continue
6. Inappropriate operations: management of work, including aspects of risk management, crew pairing, and operational tempo

Preconditions to Unsafe Acts

7. Environmental factors
   a. Technologic environment: design of equipment and controls, display-interface characteristics, checklist layouts, task factors, and automation
   b. Physical environment: operational setting and environment (heat, lighting)
8. Adverse mental states: psychological and/or mental conditions, such as fatigue, pernicious attitudes, and misplaced motivation that negatively affect performance
9. Adverse physiologic states: medical and/or physiologic conditions such as illness, intoxication, and abnormalities known to affect performance
10. Physical or mental limitations: physical or mental disabilities, such as poor vision; lack of skill, aptitude, or knowledge; and other mental illnesses that affect performance
11. Teamwork: communication, coordination, and other teamwork issues that affect performance
12. Personal readiness: off-duty activities, such as adhering to rest requirements, alcohol restrictions, and other mandates required to perform optimally on the job

Unsafe Acts

13. Decision errors: "thinking" errors representing intended behavior that proceeds as designed, yet the plan proves inadequate for the situation. Errors manifest as poorly executed procedures, improper choices, or simply the misinterpretation of relevant information.
14. Skill-based errors: highly practiced behavior that occurs with little thought. These errors frequently appear as breakdown in visual patterns, forgotten intentions, and omitted items during procedures. The technique with which one performs a task is included.
15. Perceptual errors: errors arising when sensory input is degraded. Faced with acting on imperfect or incomplete information, operating room staff members run the risk of misjudging procedures as well as responding incorrectly to a variety of visual-vestibular illusions.
16. Routine violations: "bending the rules," a type of violation that is habitual and often enabled by management that tolerates departures from the rules
17. Exceptional violations: departures from authority, neither typical of the individual nor condoned by management

From ElBardissi AW, Wiegmann DA, Dearani JA, et al. Application of the human factors analysis and classification system methodology to the cardiovascular surgery operating room. *Ann Thorac Surg.* 2007;83:1412–1418; discussion 8–9.

healthy young people, and these differences have been linked to particular genetic polymorphisms.[78,79] Czeisler[80] speculated that in the future it may be possible to differentiate, from a cheek swab, the genetic subset of persons who tolerate sleep deprivation relatively well from those persons who are very sensitive.

Recognition that sleep deprivation may adversely affect performance has led to policies that limit work hours, beginning with pilots in the 1950s. In the United States the Accreditation Council for Graduate Medical Education (ACGME) limits the hours of trainees in approved programs, but no work limitation exists for nontrainee physicians, including attending physicians. New Zealand attempts to limit consecutive work hours for trainees to 16 hours.[81] In the European Union, all occupations are limited to 13 consecutive work hours and 48-hour work weeks. Whether limiting trainees' work hours lessens the effectiveness of training programs has been the subject of much debate, and it has been reviewed.[82] Noncompliance with work hour limits in ACGME-accredited training programs has been widespread.[83]

An effect of sleep deprivation on overall patient morbidity and mortality rates has not been demonstrated convincingly. A retrospective cohort study of procedures performed by physicians with and without preceding overnight procedures found no difference in complication rates.[84] Complications were more likely (odds ratio, 1.72; 95% confidence interval [CI], 1.02–2.89) if sleep opportunity was less than 6 hours. In three studies that evaluated the role of fatigue in cardiac surgery, no relationship was found between sleep deprivation and major morbidity or mortality rates.[85–87] However, given the available evidence connecting sleep deprivation with impairment in performance, it seems likely that work hour limitations will become more stringent rather than less so. The unintended consequence of limiting the number of consecutive hours worked is increased risk with more frequent handovers and introduction of a new team. A retrospective review by Hudson and colleagues[88] of 14,421 cardiac surgical procedures found that 966 involved handover to a new anesthesia team. After propensity matching, handover was found to increase mortality rates (match-adjusted odds ratio, 1.425; 95% CI, 1.013–2.006; $P = .0422$) and major morbidity rates (match-adjusted odds ratio, 1.274; 95% CI, 1.037–1.564; $P = .0212$) (Fig. 30.8).[88]

Fatigue has been implicated as a contributor to impaired performance, critical incidents, and errors in anesthesia.[89,90] The work hours and schedules of anesthesiologists expose them to circadian disruption, with both acute and chronic sleep deprivation causing fatigue. Anesthesiologists may be more susceptible to even mild sleep deprivation compared with other medical specialties because of the vigilance required to provide safe anesthesia care.

In a well-designed, realistic, simulation-based trial, in both a sleep-deprived state and a rested state, 12 residents anesthetized a simulated patient for 4 hours.[91] The sleep-deprived group had a trend to poorer vigilance with slower response times. The sleep-deprived group took numerically longer (not significant) to detect and correct abnormal clinical events, and during the simulated anesthetic regimen, nearly one-third of the sleep-deprived group fell asleep at some stage. Similarly, a survey of perfusionists found that 15% reported performing CPB after 36 hours, and 50% reported experiencing microsleep during bypass.[92] Two-thirds reported fatigue-related errors, and 6.7% reported serious perfusion accidents related to fatigue.[92]

In an analysis of the first 5700 critical incidents reported to the Australian Incident Monitoring System database, 2.7% of incidents listed fatigue as a contributing factor.[90] Drug errors were more frequent, and anesthesiologists reported that haste, distraction, inattention, failure to check equipment, fault of technique, and pressure to proceed with surgical procedures were all more common with fatigue. Experience and training did not render an anesthesiologist any less likely to make a fatigue-related error. A healthy patient and a relief anesthesiologist were factors identified that minimized the critical incident. Eighty-six percent of surveyed anesthesiologists reported that they had made a fatigue-related error. Fifty percent of trainees and 27%

of anesthesiologists believed that their average work week exceeded what they could do and maintain patient safety.[93] The anesthesiologists who exceeded their self-defined hourly or weekly limits were more likely to report a fatigue-related error.[93]

In a study by Gander and associates,[94] attending anesthesiologists showed a progressive decline in postduty psychomotor vigilance task performance, even with relatively small amounts of sleep loss (<1 hour/day). An analysis of incident reports in one of the hospitals found that in 23% of the reports, the anesthesiologist involved had more than 2 hours of sleep loss. Anesthesiologists who cited fatigue as a contributing factor were 7.4 times more likely to report sleep loss of more than 2 hours.[94]

Sleep quality and quantity become impaired at approximately age 50 and older.[95,96] No formal studies have assessed how these changes may affect the performance of older anesthesiologists. However, tolerance for late-night and shift work is reduced with aging.[96] Thus many of the fatigue-related performance impairments identified in residents potentially are worse in older anesthesiologists.

Despite studies showing no effect on mortality rates, the overall weight of evidence suggests that fatigue and sleep deprivation have harmful effects. Pressure exists to reduce total and consecutive work hours. The European Working Time Directive (EWTD) (also enacted into UK legislation) prescribes a maximum of 48 to 56 hours per week and only 13 consecutive work hours. The EWTD limits doctors-in-training to a maximum 48-hour week, averaged over a 6-month period, which is substantially less than allowed in the United States by the ACGME. Clearly, the implications of reduced work hours are significant at an individual level (eg, training experience with fewer work hours, importance of handover of care at shift changes) and at a departmental level (rostering changes, medicolegal and compliance issues). Given the trend to reduced work hours, more staff members may be required to fill rosters, with financial implications for hospital anesthesia departments and health services.

In addition, the nature of anesthetic work makes it difficult to avoid at least some work at night. Work patterns need to be designed to minimize the possibility of shift work– or fatigue-related error and must consider both total individual work hours and the effect of shift work on sleep and circadian rhythm. Useful overviews are available for individual practitioners on the impact of fatigue on learning and on good sleep hygiene to mitigate the impact of fatigue and for departments on the impacts of different rostering systems.[97–101]

Vigilance While Performing Transesophageal Echocardiograms

The introduction and subsequent widespread use of transesophageal echocardiography (TEE) brought about a major advance in cardiac surgery and anesthesia for both diagnosis and intraoperative monitoring. Anecdotally, we have noticed times when all attention in the OR is focused on the TEE machine rather than on the patient, especially with trainees. This seems to be more noticeable during the phase of learning TEE than with clinicians who are more experienced. Only one study has addressed this issue. During a study on task distribution, workload, and vigilance during cardiac anesthesia, Weinger and colleagues[102] found a significant increase in response time to vigilance probes (a light on the monitor screen) during the TEE examination. These investigators concluded, "use of the TEE may decrease vigilance to changes in other clinical data." Several factors limit the applicability of this study: the residents had limited anesthesia and TEE experience, the location of the TEE machine and monitors was poor, and the study involved only 20 patients. The findings of the study were questioned in a subsequent letter to the editor.[103]

In a report of four retained central venous catheter guidewires from a single institution, two of the cases involved performance of TEE by the attending anesthesiologist while the central venous catheter was being placed by a trainee.[104] This finding suggested the possibility that TEE distracted the attending anesthesiologist from noticing that the guidewire had not been removed from the patient.[104]

This area needs further investigation, but consideration should be given to where the TEE machine is placed in relation to the patient and the other monitors. The anesthesiologist working alone may be more vulnerable, given that attention can be focused on only one place at a time. Although all cardiac anesthesiologists recognize the poor ergonomics of machines and monitors,[24,105] no studies define best practices.

Violations

A significant section of the HFACS and of the original Reason taxonomy addresses "violations," when someone deliberately and consciously disobeys the existing rules or safe practices.[26,51,56,67] For a violation to occur, the following must exist: (1) a set of rules or regulations, or at least social norms; (2) an action that is contrary to those rules or guidelines; and (3) an intentional action to violate. Alper and Karsh[106] provided a categorization of violations based on Reason's original taxonomy of error (Fig. 30.9).

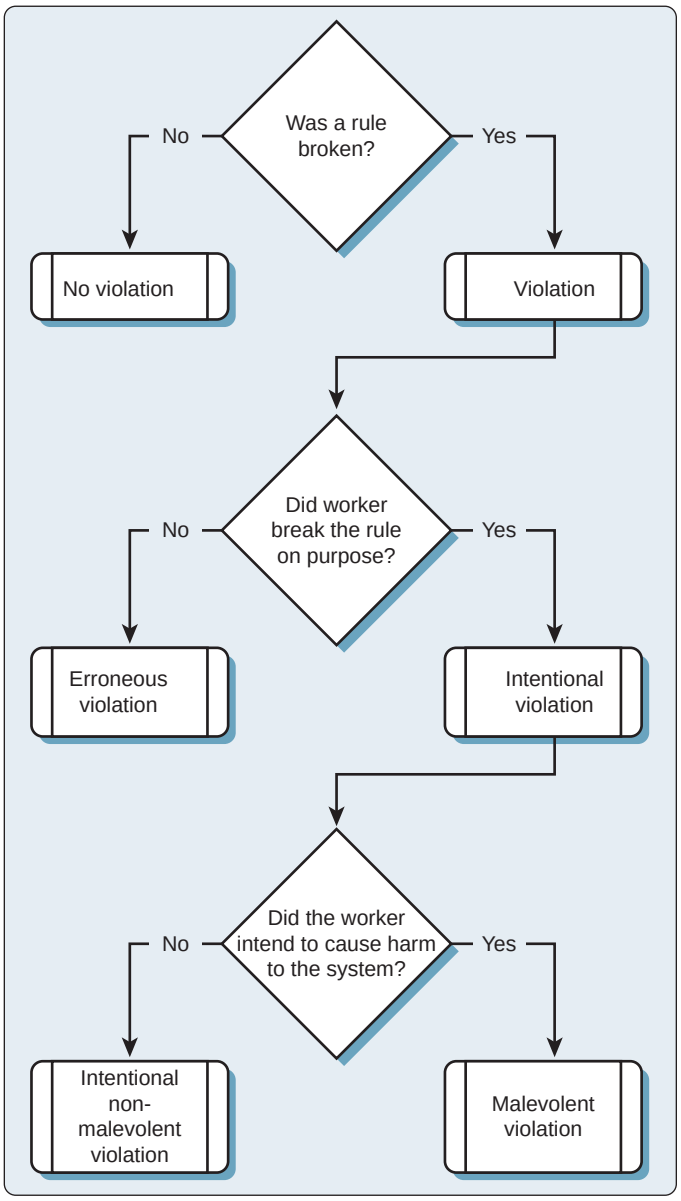

Fig. 30.9 Categorization of violations. *(From Alper SJ, Karsh BT. A systematic review of safety violations in industry.* Accid Anal Prev. *2009;41:739–754.)*

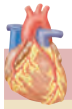

BOX 30.2 FACTORS CONTRIBUTING TO SAFETY VIOLATIONS IN HEALTH CARE

Individual Traits
- Experience (knows a better way to get it done, which may be correct)
- Attitude toward compliance (worker's beliefs about likely outcomes)
- Previous accident (no previous incident leads to belief that violation is safe)
- Previous injury
- Laziness (reported only as a contributing factor in others)

Information, Education, Training
- Level of knowledge (knowledge of rules, policies, and regulations)
- Conflict or confusion among staff members
- Level of training (lack of familiarity with regulations)
- Level of training (may increase or decrease likelihood of violation)
- Unfamiliarity with design

Design Flaws
- Poor design requiring violation (design of tool or environment makes compliance impossible)
- Changes to approved design (rules apply to previous design and do not fit the newer design)
- Required equipment not available
- Complicated design

Safety Climate
- Poor management (lack of supervision, senior workers giving advice to violate)
- Management tolerating or approving violations (management ignores or encourages violation to meet other goals)
- Subjective norm to comply (normalization of deviance)
- Perceived expectations by doctors (nurse perceives expectation is to violate)

Competing Goals
- Time pressure (quicker way of working or save time)
- Work pressure (unable to complete task unless rule is violated)
- Perceived risk (if low or no risk, more likely to violate)
- Conflicting demands (cannot achieve one goal without violating another goal)
- Physical fatigue or exhaustion

Problems with Rules
- Impossible rule to work within
- Complex rule (no one understands the rule)
- Outdated rule (violation may result in greater safety)
- Difficult rule to comply with (technically difficult to comply)

Modified from Alper SJ, Karsh BT. A systematic review of safety violations in industry. *Accid Anal Prev.* 2009;41:739–754.

As noted by Alper and Karsh[106] and Reason,[51,56] violations can be routine and at times even necessary to get the work done (workarounds), but they clearly put the patient at risk. As summarized by Alper and Karsh,[106] workers provide many reasons that they or others violate rules and regulations (Box 30.2). Although certainly some individual traits contribute to violations, many of the cited factors are system-level issues, including rules that cannot be understood or followed, outdated rules, poor management, and superiors who expect violations to enhance productivity. For example, a violation is often the result of "normalization of deviance," in which poor hand hygiene or failing to use a full-barrier drape during central line placement occurs among junior staff members because they follow the example of senior staff. The complexity of reasons that workers violate safe practices, rules, and regulations led Alper and Karsh[106] to conclude that "the conversation about violations needs to continue to evolve from one of automatically assigning blame to one that views violations as symptoms of system design problems."

Teamwork and Communication

As noted earlier, preventable adverse events or human errors in the cardiac OR often are related not to technical skill or knowledge base but to cognitive, teamwork, or system failures.[107–111] With the publication of an examination of errors and near misses in pediatric cardiac surgery by de Leval and colleagues,[112,113] the role of human factors (ie, nontechnical skills) has become apparent. Skills such as communication, cooperation, and leadership are recognized to be critical components of teamwork, and deficiencies in these skills have been associated with adverse outcomes.[114] Stress levels can be determined accurately among surgical staff across the surgical case and also are related to team performance.[115] In a systematic review of the literature, Hull and colleagues[116] found that these nontechnical aspects of team performance also can affect a surgeon's technical performance. As Frankel and associates stated,[117] "we can assure our patients that their care is always provided by a team of experts, but we cannot assure our patients that their care is always provided by expert teams."

Communication failures, human factors, and leadership deficiencies have been found to be the top three causes underlying sentinel events in every review from The Joint Commission since 2004.[118] In a review of litigated surgical outcomes, a communication failure among caregivers was responsible for the adverse outcome in 87% of cases.[119] Clearly, teamwork behaviors and communication are critical to patient safety. A scientific approach requires validated measurement tools and rigorous studies of how these nontechnical skills can be strengthened in a way that improves patient outcomes.[120]

Measurement

The technical skills of a surgeon or anesthesiologist can be assessed in an objective fashion. For example, the rate of completion of critical steps in a laparoscopic cholecystectomy and the time required to complete a simulated fiberoptic intubation can be quantified.[121] The qualitative and observational assessment of nontechnical skills, although still rigorous and scientific, can seem arbitrary and subjective to physicians inculcated in quantitative science.[18,122] However, observational, qualitative research is able to capture the number and nature of adverse events in cardiac surgery.[107,123,124] Furthermore, observational research has identified team behaviors that are associated with teamwork failures and with surgical excellence.[114,123,125,126] Observational research does have limitations. Observers must be trained to be effective,[18,127] and not all observers can become proficient.[128] Moreover, the location and focus of observers in the OR determine what events are captured.[129] These limitations, however, have not precluded significant advances in the measurement of teamwork skills.

The need for objective assessment of nontechnical skill is underscored by the finding that the ability of physicians to assess their own skill level is poor. Although assessment of technical skill is similar between self and observer in simulation studies, self-assessment of nontechnical skills by both junior and senior physicians is consistently higher (more skilled) than the ratings of expert observers.[130,131] Observers also are able to assess disruptions, communication failures, environmental issues, and the impact of those factors on outcome

more accurately than the involved clinicians.[115,130] OR personnel rate disruptions as affecting others more than themselves, whereas trained observers find the disruptions affect all team members equally.[132] Finally, nontechnical skills must be explicitly taught and monitored because senior physicians do not demonstrate higher nontechnical skill levels than juniors unless the senior physicians are specifically trained in these skills.[130,133,134] Unfortunately, although most physicians agree that nontechnical skills are important, not all physicians agree that they can be taught.[135]

The nontechnical skill measurement tools in current use have been developed primarily from established and validated aviation tools (Box 30.3). Five instruments have been designed for surgical teams and subteams: the Observational Teamwork Assessment for Surgery (OTAS),[127,128,136–140] the Oxford Non-technical Skills (NOTECHS),[116,126,141–144] the Non-technical Skills for Surgeons (NOTSS),[128,130,145,146] the Anesthetists' Nontechnical Skills (ANTS),[147–149] and the Scrub Practitioners List of Non-Technical Skills (SPLINTS).[150–152] Specific tools also have been developed to measure individual skills, such as leadership by the Surgeons' Leadership Inventory.[153,154] Most measurement tools assess skill in multiple domains, including communication, cooperation and teamwork, leadership (shared, coordination), situational awareness (shared monitoring), and problem solving and decision making. These tools have been proved to be valid (ie, they measure what they purport to measure), reliable (ie, they have high interobserver correlation), feasible, and sensitive.[128] NOTECHS, which is specifically designed to evaluate skills across the team, has been used to evaluate the effect of teamwork training, and it shows a significant inverse relationship between nontechnical score and number of technical errors.[126,143]

Scientific development of patient safety interventions also requires measuring effectiveness, with the gold standard being changes in morbidity and mortality rates after implementation. Although such interventions have been successfully implemented,[155–165] demonstration of a further reduction in the already low rate of death among surgical patients (2–3%) requires a large sample size. For this reason, many studies of interventions in patient safety use surrogate outcomes, such as a change in the effect of disruptions (the Disruptions in Surgery Index,[132,166] the Surgical Flow Disruption Tool[167]), or changes in the safety climate.[168] Many safety climate surveys exist and are considered reliable. However, most studies using these surveys have described the existing culture,[168–172] as well as changes in climate after teamwork training.[173,174] Only rarely have studies attempted to demonstrate a relationship between the measured safety climate and patient outcome.[175,176]

Disruptions, Distractions, Major and Minor Events

The cardiac OR is a highly complex setting where professionals from multiple disciplines interact with complicated and often poorly designed equipment to complete hazardous interventions—typically under significant time constraints—in patients with challenging cardiac disease and other comorbidities.. Despite the apparent need for quiet concentration, distractions and disruptions rule the day.[111,132,166] In cardiac surgical cases, door openings average 19.2/hour, 22.8/hour if prosthetic devices are involved.[177] OR traffic, door openings, conversations, alarms, and even music can result in an excessive noise level.[178] It is no wonder that failures of teamwork resulting in surgical flow disruptions occurred at a rate of 11.7/hour in one study,[124] and at 11/case in another.[111]

Team members perceive disruptions and distractions, as well as team behaviors, in discipline-specific ways. Surgeons tend to downplay disruptions and report them as having a lesser effect on performance than do nurses or trained observers.[166] All too often, significant disruptions and distractions simply are treated as annoyances and part of the daily work. Data show, however, that technical errors and adverse patient outcomes increase as disruptions accumulate.[179,180] Moorthy and colleagues[181] found that OR noise reaching 80 dB is associated with a significant increase in surgical technical errors.

A landmark study of pediatric cardiac found that even minor events (ie, those not expected to affect outcome) reduced the team's ability to compensate for or recover from a major event (Fig. 30.10).[113,122] In observing 250 arterial switch operations, de Leval and associates[112,113] and Solis-Trapala and colleagues[122] reported that, for every 3 minor problems above the mean of 10 per case, intraoperative performance diminished and operative duration increased. As noted, "little things matter."[123,182]

Equipment and Alarms

As noted earlier, distractions and disruptions are rife in the cardiac OR. In addition, the quantity and complexity of the equipment required for cardiac operations are significant. Equipment-related problems are responsible for 10% to 12% of flow disruptions.[111,183,184] Even though ergonomic design is known to be an important factor in patient safety, it has been suboptimal, both for OR room design and layout and for equipment design.[24,185,186] ORs built years or decades ago are now necessarily cluttered with equipment, each device requiring electrical cords and communication tethers. Cesarano and Piergeorge[187] describe the "spaghetti syndrome": how cluttered equipment and tangled lines limit access to the patient, thereby putting both patients and staff at risk. Slips, trips, and falls cause workplace injuries and are related to cords and cables, low-profile equipment, and protective and absorptive mats.[188]

In a study of disruptions observed in 10 cardiac operations, 33% of flow disruptions were related to OR design and physical layout.[105] The investigators developed a taxonomy that can be used to categorize flow disruptions and design flaws that can guide further research and improvements. Using observations drawn from 20 cardiac operations, Pennathur and colleagues[24] identified many unique technology-related hazards and demonstrated how these hazards negatively affected the

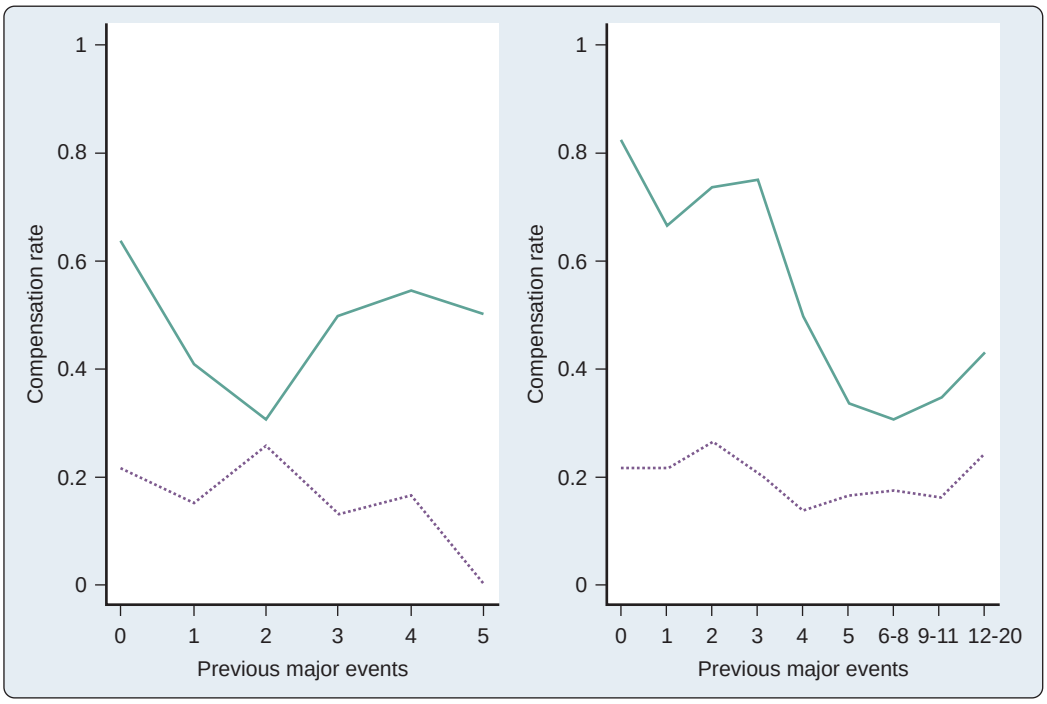

Fig. 30.10 Effect of major *(solid line)* and minor *(dotted line)* events on a team's ability to compensate for subsequent events. *(Solis-Trapala IL, Carthey J, Farewell VT, de Leval MR. Dynamic modelling in a study of surgical error management.* Stat Med. *2007;26:5189–5202.)*

cognitive processes of the team. As the investigators stated, "the interaction of poorly designed spaces, organizational constraints, and functional capability has the potential to multiply latent risks inherent in [cardiovascular] OR technologies."[24]

In a literature review regarding hazards associated with cardiac surgery, Martinez and colleagues[185] identified four ways in which equipment harms the patient: (1) poor design and ergonomics, (2) poor training or negligence with use, (3) poor maintenance and upkeep, and (4) risk inherent in use of the device (eg, the risk that a TEE probe will cause esophageal injury). Medical devices and equipment typically are designed by engineers who spend little time in the environment in which the devices will be used. Even rarer is the participation of human factors engineers in the pre-purchase evaluation of equipment for device-specific form and function, as well as for integration of the equipment into the existing physical layout out of a typical OR. As a result, the interaction between people and technologies in the OR is suboptimal.[186,189,190] Wiegmann and colleagues[191] studied the design and function of CPB machines and found significant deficiencies. Information displays were poorly placed and difficult to read, components were poorly integrated and not well positioned, and alarms were either too quiet or had inappropriate tonality.

Indeed, one of the most problematic factors in cardiac surgery is the sheer volume of noise in the OR. Beepers, ringing telephones, ancillary conversations, and alarms often raise OR noise levels to those considered hazardous by the US Occupational Safety and Health Administration.[178,192–195] Noise, including music, can adversely affect auditory processing in the cardiac OR, and the impact of noise is particularly great when the listener is intent on a task.[196] Furthermore, unexpected sentences (low predictability) were significantly less well processed than those that were expected and predictable.[196] This finding has serious implications for conversations that carry critical information that is not expected ("I'm having difficulty oxygenating").[196] Some experts have advocated for the "sterile cockpit" concept that is common in aviation, in which no conversation occurs except for the task at hand during takeoff and landing. In a surgical operation, however, it is difficult to identify which periods are critical versus noncritical. Wadhera and associates[197] pointed out that the critical time

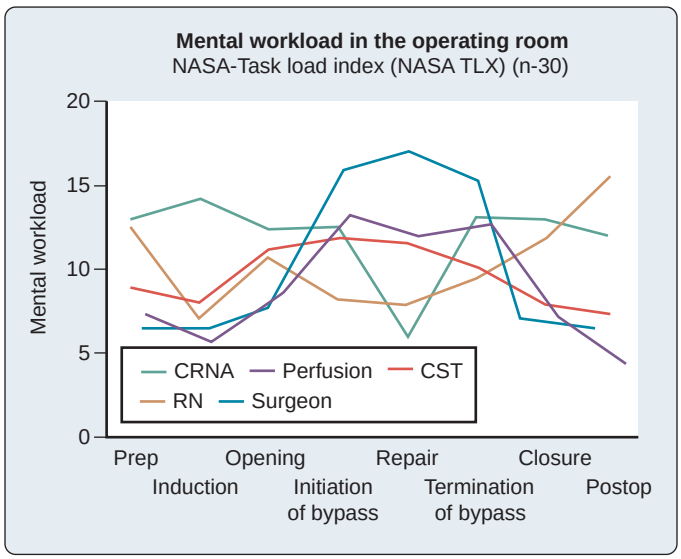

Fig. 30.11 Varying level of mental workload in the cardiovascular operating room by role. *CRNA,* certified registered nurse anesthetist; *CST,* certified surgical technologist; *NASA,* National Aeronautics and Space Administration; *Prep,* preparation; *RN,* registered nurse; *TLX,* Task Load Index. *(From Wadhera RK, Parker SH, Burkhart HM, et al. Is the "sterile cockpit" concept applicable to cardiovascular surgery critical intervals or critical events? The impact of protocol-driven communication during cardiopulmonary bypass.* J Thorac Cardiovasc Surg. *2010;139:312–319.)*

for the surgeon may be noncritical for an anesthesiologist. Thus level of concentration and workload vary by discipline across the surgical procedure such that every moment is critical to one discipline or another (Fig. 30.11).[197]

Perhaps the most distressing single contribution to OR noise is the frequency of alarms. Alarms clearly are designed to alert to parameters

outside the norm, but a typical cardiac OR has some 18 alarms, each with manufacturer-chosen visual and audio alerts.[198] Unfortunately, the volume or tonality of the alarm has no rhyme or reason. A "not ventilating" alarm can be quiet and nearly undetectable, whereas a circuit humidifier alarm can be hair-raising. Schmid and colleagues[199] reported that 359 alarms occurred per cardiac operation, for a rate of 1.2/*minute*. In one study, 90% of alarms were found to be false-positive events, often resulting in alarms being turned off or ignored.[200] In a study of 731 alarm warnings, only 7% were found to be useful, and 13% were triggered by a planned intervention.[198] As concerning as the noise and disruption are, even more concerning is the tendency to tune out the alarms or even turn off the alarms when they become too annoying, potentially resulting in a serious preventable adverse event. The Joint Commission made alarm management a goal in 2012, but true correction will require a comprehensive national (or international) approach to standardize the volume and tonality of alarms by system (eg, ventilation, cardiac) and by urgency and then to require all manufacturers to meet these standards.

Teamwork

In the highly complex world of cardiac surgery, teamwork and communication are critical to outcome. As already noted, communication and teamwork failures are common in significant preventable adverse events.[201] As described earlier, these issues are not trivial. Poor nontechnical skills and teamwork directly affect patient outcomes. System failures,[119] communication failures,[175,202] poor teamwork behaviors,[114] unfamiliarity among team members,[180,203] and the number of minor events[122] are all associated with increased technical errors, morbidity, and mortality.

In other studies, the quality of teamwork behaviors has been linked to surgical duration,[179] number of technical errors,[116,126,142,180] and number of major events.[204] Mishra and colleagues[126] found zero to six technical errors per operation (mean, 2.62 errors) and observed an inverse correlation between errors and the surgeon's situational awareness score. Poor teamwork has been found to directly increase stress levels among surgeons,[166,205] and stressful situations degrade teamwork behaviors.[206] At a systems level, Meterko and colleagues[207] found a significant and positive correlation between institutional teamwork culture and patient satisfaction scores and a significant and negative correlation between bureaucratic culture and satisfaction scores. In this analysis of data from 125 Veterans Affairs (VA) hospitals, a full standard deviation in patient satisfaction scores was noted between hospitals that ranked in the top third and those ranked in the bottom third for teamwork culture.

Conversely, teams with high levels of teamwork suffer less interference from observed distractions and interruptions.[124,208] ElBardissi and colleagues[209] examined the relative influence of attending surgeons' experience (years since fellowship) versus the number of previous collaborations with a given cardiac fellow on CPB duration and cross-clamp time. A multivariate model for cross-clamp time showed that the cumulative experience of the attending surgeon with a fellow mattered much more than the years of experience of the attending surgeon (Fig. 30.12). In another analysis, teams that were familiar with the operating surgeon had significantly fewer event failures (8.6 versus 22) and teamwork failures (5.6 vs 15.4) than teams in which most members were not familiar with the surgeon.[180] Operations conducted with the "day" team had shorter length of stay, duration of ventilation, and duration of surgical procedure, whereas operations that had a change in teams were associated with an increase in incidence of septicemia.[203] As noted earlier, transfer of a case to a new anesthesia team (handover) increased morbidity and mortality rates.[88,210] Teams engaged in more complex operations tend to demonstrate better teamwork performance, but even in these cases, the presence of nonroutine events is associated with more complications postoperatively.[211]

As noted earlier, team members (especially physicians) are poor at assessing their own teamwork and communication skill level. In multiple studies, surgeons' and anesthesiologists' teamwork and

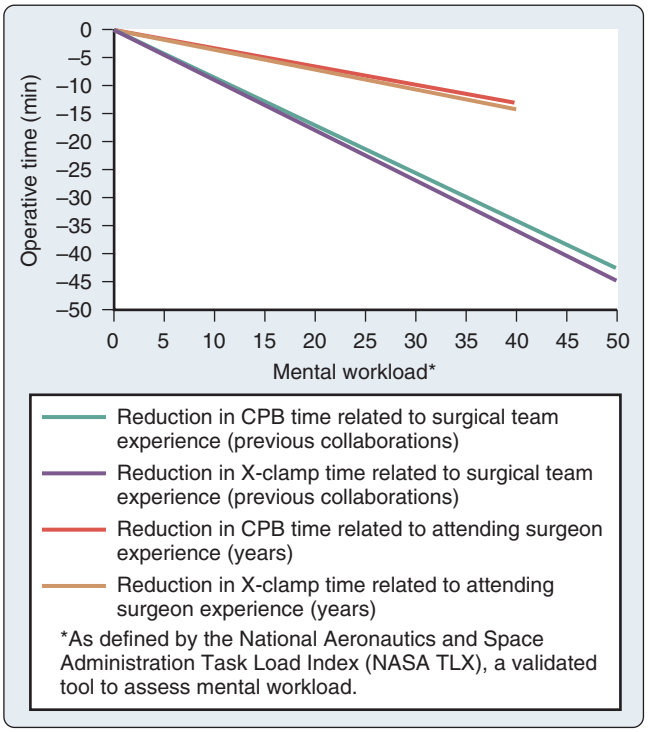

Fig. 30.12 Relative influence of attending surgeons' experience and cumulative experience on cardiopulmonary bypass *(CPB)* and cross-clamp *(X-clamp)* times. *(From ElBardissi AW, Duclos A, Rawn JD, et al. Cumulative team experience matters more than individual surgeon experience in cardiac surgery.* J Thorac Cardiovasc Surg. *2013;145: 328–333.)*

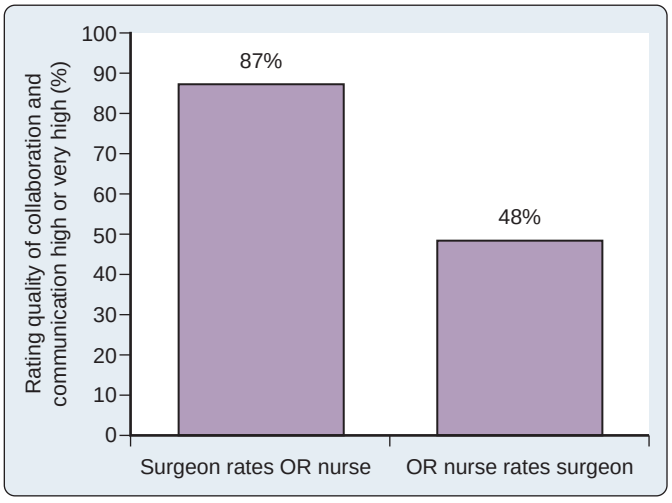

Fig. 30.13 Differences in perceptions of teamwork between surgeons and operating room *(OR)* nurses. *(From Makary MA, Sexton JB, Freischlag JA, et al. Operating room teamwork among physicians and nurses: teamwork in the eye of the beholder.* J Am Coll Surg. *2006;202: 746–752.)*

communication skills were rated much more highly by themselves than by nurses and perfusion staff members.[212,213] In one study, surgeons rated the quality of other surgeons' teamwork as high or very high 85% of the time, whereas nurses rated the collaboration with surgeons as high or very high only 48% of the time (Fig. 30.13).[214]

In a study of attitudes about teamwork among OR teams, surgeons and anesthesiologists reported that they understood the staff members' roles, whereas staff members did not appear to believe that their roles were understood.[215] In that study, the physicians perceived the team

TABLE 30.2 Definitions of Types of Communication Failure With Illustrative Examples and Notes

Failure	*Definition*	*Illustrative Example*
Occasion failures	Problem in the situation or context of the communication event	The staff surgeon asks the anesthesiologist whether the antibiotics have been administered. At the point of this question, the procedure has been under way for more than an hour. Because antibiotics are optimally given within 30 minutes of incision, the timing of this inquiry is ineffective both as a prompt and as a safety redundancy measure
Content failures	Insufficiency or inaccuracy apparent in the information being transferred	As the case is set up, the anesthesia fellow asks the staff surgeon whether the patient has an ICU bed. The staff surgeon replies that the "bed is probably not needed, and there isn't likely one available anyway, so we'll just go ahead." Relevant information is missing, and questions are left unresolved: has an ICU bed been requested, and what will the plan be if the patient does need critical care and an ICU bed is not available?
Audience failures	Gaps in the composition of the group engaged in the communication	The nurses and anesthesiologist discuss how the patient should be positioned for operation without the participation of a surgical representative. Surgeons have particular positioning needs, so they should be participants in this discussion. Decisions made in their absence occasionally lead to renewed discussions and repositioning of the patient on their arrival
Purpose failures	Communication events in which the purpose is unclear, not achieved, or inappropriate	During a living donor liver resection, the nurses discuss whether ice is needed in the basin they are preparing for the liver. Neither knows. No further discussion ensues. The purpose of this communication—to find out whether ice is required—is not achieved

ICU, Intensive care unit.

structure to be that of separate subteams, whereas nurses viewed the team as unitary.[215] In a survey of adequacy of communication, teamwork, and situational awareness, surgeons rated both communication and establishing a shared understanding as "adequate," whereas anesthesiologists and nurses rated both as inadequate ($P < .01$ for both). Coordination of team activities and performance of briefings were similarly rated as inadequate by all team members but the surgeons.[213] In a survey of 90 physicians and 230 nurses working in intensive care units (ICUs), only 33% of nurses rated the quality of collaboration and communication between nurses and physicians as high or very high, compared with 73% of physicians.[216] Surgeons also perceive the organizational culture of safety and teamwork to be stronger than do anesthesiologists and nurses.[212] Finally, perceptions of teamwork climates are not just different among types of caregivers, but they also are distinctly different among institutions.[217]

In a survey of attitudes toward error, stress, and teamwork, Sexton and colleagues[218] compared the responses of 1033 doctors, nurses, fellows, and residents working in ORs and ICUs with the responses of more than 30,000 airline cockpit crew members (captains, first officers, and second officers). Only one-fourth of pilots denied that fatigue affected their performance, whereas 70% of surgeons and 47% of anesthesiologists did. Similarly, most pilots (97%) rejected hierarchies in which senior members resisted input from junior members, but only 55% of surgeons rejected such hierarchies. Nearly two-thirds of medical staff reported that errors were handled inappropriately by their hospital; one-third of ICU staff did not acknowledge that they make errors, and more than one-half of ICU staff stated that it is difficult for them to report or discuss errors.[218] Similarly, Flin and associates[219] found that all team members had a positive attitude toward behaviors associated with safety and teamwork, but that both nurses and surgeons expressed a belief in their invulnerability to stress or fatigue. Surgeons viewed surgical team leadership and communication more positively than did nurses on the same team.[219]

In a study using a survey of pediatric cardiac surgical teams, most team members believed that open communication channels were maintained during surgical procedures; nonetheless, 29% reported having trouble speaking up if they perceived a problem with patient care.[169] Fewer than half (45%) reported that morale was high, and 60% reported having trouble discussing mistakes, even though 83% reported they had made errors with the potential to harm patients. Only 30% stated that debriefings occurred after mistakes are made.[169]

Communication

One specific aspect of teamwork is communication, defined as the exchange of information between a sender and a receiver.[220] Systematic literature reviews indicate that effective communication is a hallmark of successful teams and is critical to providing high-quality patient care.[220,221] In cardiac surgery, an enormous amount of information is continuously exchanged among multiple providers. Studies have shown that communication failures are common,[139,184,222,223] and such failures represent the most frequent root cause of adverse events.[180,224,225] Breakdowns in communication contribute significantly to failures in patient safety.* In an observational study of 48 cardiac surgical procedures, a total of 421 communication events occurred during 90 hours of observed procedures; 129 of these events were classified as failures (ie, one-third of all communications failed, at a rate of 1.43/hour).[223] In 45.7% of events, the timing was poor; 35.7% involved missing or inaccurate content; 24% occurred when issues raised were not resolved; and 20.9% involved "audience," in which key persons were missing (Table 30.2). More than one-third of these failures had a visibly deleterious effect on system processes.[223] As seen in other teamwork skills, providers tend to rate their own profession as being less responsible for the effects of poor communication.[231]

One very specific aspect of communication is that required during a transition of care from one provider to another (relief during surgical procedures) or between teams (OR to ICU), termed "the handoff" (also known as the handover). A handoff is essentially a contemporaneous process of passing patient-specific information from one caregiver to another to ensure continuity and safety of patient care. Standardized handoff communication was a safety goal of The Joint Commission for 2006 (Goal 2E).[232] Handoffs occur multiple times during surgical procedures as staff members are relieved, and multiple handoffs occur among teams: from cardiology to cardiac surgery, from the preoperative team to the intraoperative team, even from anesthesia to perfusion at the initiation of bypass, from the OR to the ICU, from the ICU to the ward, and, finally, from the hospital back to the primary care provider or cardiologist. Greenberg and associates[201] and Rogers and colleagues[233] reviewed 258 surgical malpractice cases in which error led to injury of a patient; 60 cases involved communication failures. Forty-three percent of the failures occurred during a handoff, and 19% occurred across departments. Most of the communication failures (92%) were verbal, involved a single transmitter and receiver, and were equally the result of omission of critical information (49%) and misinterpretation (44%).[201,233]

These errors are understandable, given the complexity of cardiac surgical procedures, the nuances of patients' physiology (often understood as much at a subconscious level as at a conscious one), and the frequent distractions that arise during patient care.[88,228,229,234–236] Handoffs rarely occur in a quiet setting, and distractions are common. Occasionally, no handoff occurs at all.[235,237] A review of the literature portrays handoffs as being highly variable, unstructured, and

*References 113, 118, 119, 175, 180, 223, 224, 226 to 230.

performed under pressure from competing tasks.[238] In one study of pediatric cardiac surgical handoffs, important content items were reported only 53% of the time, and distractions occurred at a rate of 2.3/minute of reporting.[239] Handoffs from OR to postanesthesia care unit (PACU) personnel are nonstandardized and depend on the staff involved; typically, no specific point occurs at which responsibility is transferred.[240]

In a process that first rigorously defined critical information items in the handoff from the OR to the recovery room, Nagpal and colleagues[134,236] found a median of 9 omissions out of 29 elements; they noted that one-third of critical tasks were not performed and that critical team members often were not present. Furthermore, information degraded as the patient progressed through sequential handoffs.[229] Only 56% of essential information was transmitted from OR to recovery and only 44% from recovery to the ward. At least one critical event associated with these omissions occurred in 75% of patients.[229]

Interventions to Improve Patient Safety

It is clear from the preceding discussion that nontechnical aspects of cardiac surgical procedures play a vital role in patient outcomes. Efforts to improve these aspects of cardiac operations are required to decrease the number of patients who suffer preventable harm. Key areas of focus include the following: standardizing care as much as possible, including implementing evidence-based best practices; undertaking formal training and practice in teamwork behaviors and skills; implementing pre-surgery briefings, and the use of cognitive aids such as checklists; using regular debriefings to identify areas in which improvement is needed; strengthening structured communication protocols both during surgical procedures and during transitions of care; and using simulation to provide directed practice both for nontechnical skills and for the technical aspects of crisis management.

Although these interventions have been shown to increase patient and staff satisfaction and to reduce mortality rates,[162,176,241–244] interventions are often met with ambivalence at best and hostility at worst.[141,245] As noted, this response can have several causes: overestimation of skill level; discounting of the effects of stress, fatigue, and disruptions; and a view that imposition of external guidelines limits individualized patient care or is insulting to staff members' intelligence and dedication.[†] In short, "patient safety is hard."[247]

In addition, even in the best of circumstances, fully implemented protocols and teamwork skills do not totally eliminate errors or accidents; they only lengthen the period between accidents.[52] Continual external changes to a system (ie, new equipment, change of personnel or roles) introduce new complexities, each with new opportunities for error. Although Duncan and colleagues[248] described how development of a training program for elimination of retained guidewires during central line insertion reduced the incidence of this error, Vannucci and colleagues[104] reported a different result. After two guidewires were retained, a comprehensive training program was instituted; in a short time, another two events occurred. The two persons associated with the last two events had completed the training. Whether they truly embraced the education and implemented the policy is unclear.[104] It is clear that patient safety requires a multifaceted, multidisciplinary, and continual process involving a broad range of tools and techniques.[249]

Teamwork Training

The evidence presented earlier (ie, that poor teamwork skill is directly linked to technical errors and adverse patient outcomes) indicates that specific teamwork training should improve outcomes. Many investigators and experts have pointed to the aviation industry's use of Crew Resource Management (CRM) to achieve excellent teamwork and reduce errors and accidents and have suggested that medical teams adopt CRM.[141–143,173,250–259] Key components of effective teamwork are similar between aviation and medicine: leadership and management, situational awareness, shared decision making, cooperation, and coordination.[141–144] However, the effect of teaching CRM to surgical teams has been mixed. When pilots were brought in to teach surgical staff how to perform effective briefings, no change in safety attitudes occurred among faculty physicians, and only a modest change occurred among junior physicians.[173] France and colleagues[253,260] instituted an 8-hour, aviation-style CRM training and found that, after training, compliance with the CRM practices was only 60%.

An experienced patient safety research team in Oxford, United Kingdom developed a 9-hour educational program based on aviation-style CRM, followed by 3 months of twice weekly coaching from CRM experts. In the 55 procedures studied after this training, nonprocedural errors were reduced (8.5 to 5.16 per procedure), operational technical errors were reduced (1.73 to 0.98) and the Safety Attitudes Questionnaire teamwork climate increased from 64 to 69. These improvements were, however, modest, and the investigators noted, "Non-technical skills training improved technical performance in theatre, but the effects varied between teams. Considerable cultural resistance to adoption was encountered, particularly among medical staff. Debriefing and challenging authority seemed more difficult to introduce than other parts of the training."[142] However, more recent reviews demonstrated that CRM-based team training consistently increases team effectiveness,[261] and it improves teamwork practices and complication rates.[262]

Teamwork training appears to improve patient safety, but positive effects are not achieved by simply implementing aviation-style CRM. Team training must be developed that specifically addresses surgical team issues and acknowledges the significant differences between aviation and medicine. The largest study of the effect of team training of surgical teams was performed in Veteran's Health Administration hospitals, led by a former astronaut and physician, Jim Bagian. The Medical Team Training program consisted of 2 months of preparation, a full-day interactive session facilitated by health care clinical peers, and (perhaps most significant) quarterly coaching activities with discussions of lessons learned.[163,252] In a comparison of surgical mortality rates for the year before and the year after training, the 74 participating facilities had a 18% reduction in annual mortality rate (rate ratio [RR], 0.82; 95% CI 0.76–0.91) compared with a 7% decrease in the 34 facilities that were not participating.[163] Propensity matching showed that the decrease in risk-adjusted surgical mortality rate was 50% greater in the training facilities. In addition, a "dose effect" occurred: for every quarter of training, a reduction of 0.5 deaths/1000 procedures performed was reported (95% CI, 0.2–1.0; $P = .001$).[163]

The Agency for Healthcare Research and Quality (AHRQ) has developed a similar team training program, called TeamSTEPPS. Although it is used more widely than the VA Medical Team Training, no large-scale study of the effect on mortality rates has been conducted. However, multiple studies have shown improved teamwork climate measures and improved compliance with quality measures (eg, time of antibiotic administration),[125,263,264] clinical care,[263] and teamwork skills.[125] One of the most detailed studies undertook a 2-month training program for all members of the OR teams.[125] Significant improvements were reported in overall OR teamwork score and communication score, as well as improvements in first case starts, quality measures, and patient satisfaction. More importantly, surgical mortality rates decreased from 2.7% to 1.0%, and morbidity rates decreased from 20.2% to 11.0%. However, 1 year later surgical mortality rates had increased slightly from 1% to 1.5%, and morbidity rates had increased from 11% to 13%, thus indicating a deterioration in gains, although rates were still better than before the intervention.[125] The investigators concluded that team training can improve OR team performance and improve patient outcomes, but continued efforts are required to sustain these gains.[125]

Although all currently tested team training methods are built on aviation-style or well-recognized team training methods, few data are available to support which elements are required. Training sessions range from a few hours with little coaching or follow-up[171,265] to several days with regular coaching sessions over at least a 12-month

[†]References 115, 130, 142, 169, 205, 206, 213, 216, 246, 247.

period.[163,212,252] The content is variable, and sustaining improvement is challenging.[125,265] From the current data, it appears that teams must be trained as a team and not by roles,[266] simulation is particularly effective in defining hazards and creating team coordination,[266–268] both executive leadership[269,270] and frontline managers are key for effective implementation,[271] and the impact wanes after a few months without continual coaching and training.[125,260,265]

Checklists and Briefings

Checklists and briefings can improve team communication and reduce errors of omission. A checklist is a simple listing of specific tasks or information that is verified as completed or as being correct, and it serves to ensure that no steps are omitted. A briefing is an open-ended discussion and review of the salient points of the plan at hand, and it typically uses a checklist to ensure that all pertinent details are addressed. A checklist is the *tool* that defines the pertinent details, whereas a *briefing* is the process a team goes through to review these details.[272] Checklists do not vary in content between uses because each item represents critical steps not to be missed; in contrast, each briefing is defined by the unique aspects of the case. Briefings open a dialogue among team members and encourage each member to agree to the details of the plan, exchange information, raise critical points or questions, and identify concerns.[245]

Checklists are simple cognitive aids that can improve performance of simple tasks (shopping) or complex endeavors (landing a fighter plane on an aircraft carrier deck), and they serve as reminders of routine tasks that may otherwise be missed.[273,274] Checklists successfully have been used to ensure completion of critical steps in a variety of surgical procedures,[258,275,276] as well as in preparation for anesthesia.[277]

Two of the best-known patient safety efforts, the World Health Organization (WHO) Safe Surgery Saves Lives[162,176] and the Surgical Patient Safety System (SURPASS),[160,278] are termed checklists but are actually guided briefings that use a checklist (Fig. 30.14). They are discussed later in this section.

Checklists have been developed to provide direction in rare, crisis situations such as malignant hyperthermia or pulseless electrical activity. Ziewacz and colleagues[64] identified 12 of the most frequently occurring OR crises and developed evidence-based essential care steps for each (Fig. 30.15). In simulations of crisis situations, access to and use of the checklist resulted in a sixfold reduction in missed critical steps. Arriaga and colleagues[63] then tested the checklist in hundreds of simulations with 17 different surgical teams and demonstrated a significant reduction in steps missed (6% of critical steps missed with checklist vs 23% without). Harrison and Gaba and their team at Stanford University in California[279] similarly designed cognitive aids that use checklists for a variety of anesthesia-related emergencies.

Checklists can help drive implementation of best practices, often by reducing voluminous guidelines to a simple set of the most critical evidence-based best practices.[274,280] The Keystone Project implemented a list of five key evidence-based elements to prevent central line–associated bloodstream infections (CLABSI).[280] In the 108 ICUs participating, the median rate of CLABSI fell from 2.7 per 1000 catheter-days to 0 at 3 months, and the mean rate decreased from

7.7 per 1000 catheter-days to 1.4 at 18 months.[280] The reduction in CLABSI is sustainable,[281] and it can be replicated in other settings.[282] Similar evidence-based checklists have reduced ventilator-associated pneumonia and mortality rates.[5,283] Effective development and implementation of checklists are not, however, as simple as the checklist itself.[284,285] Efforts have been made to identify how effective checklists should be designed and implemented.[284,286–288]

Although the value of the checklist itself has been widely touted,[273] experts argue that it is the adaptive work of the team that results in improved patient safety rather than the technical use of a checklist.[289] When a checklist is imposed by management without the willingness of the team to embrace a change in attitudes and behaviors, the checklist can be seen as undermining clinicians' autonomy and authority, as infantilizing, and it actually may delay improvement.[247,286,288,290] In 2008, the Dutch Health Authority mandated implementation of the WHO checklist; compliance with all three phases of the checklist occurred in only 39% of the 11,151 cases.[165] Although overall mortality rates decreased from 3.13% to 2.85%, the reduction was strongly associated with the degree of compliance (Fig. 30.16). The effectiveness of the Michigan Keystone project was ascribed by the leaders to the creation of a "densely networked community" with a shared mission, as well as a willingness to use data to create discipline, rather than the mere existence of a checklist.[291]

Briefings are reviews of the salient points of the plan, and they allow teams to develop a closely shared mental model of the operation to be performed. In aviation, even training runs that have been performed countless times before by the same team begin with an extensive brief. During a brief, all members of the team assume equal hierarchy in

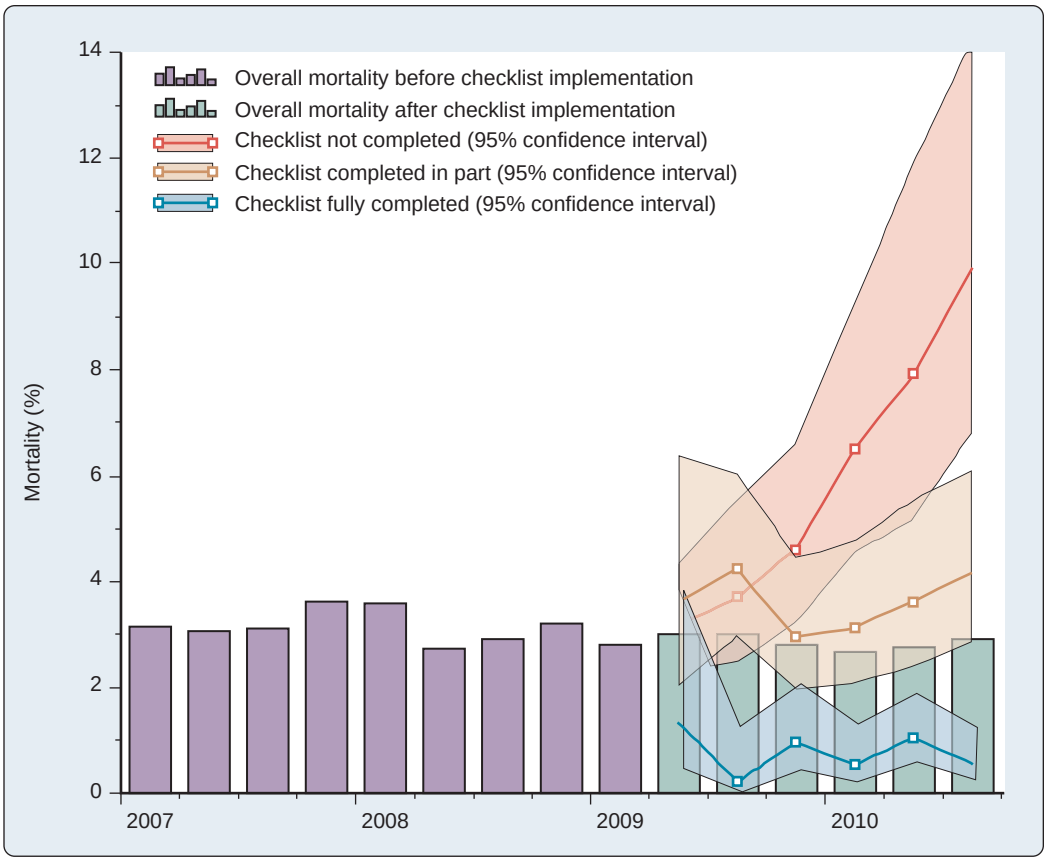

Fig. 30.16 In-hospital 30-day mortality during the study period. *Bars* show the overall mortality rate per trimester; *lines* show mortality rates with 95% confidence interval per trimester for the three compliance groups (completed, completed in part, and noncompleted checklists) after checklist implementation at April 1, 2009. *(From van Klei WA, Hoff RG, van Aarnhem EE, et al. terms of raising concerns and identifying vulnerabilities. In surgery, as was common in aviation before implementation of CRM, strict hierarchies inhibit trainees and low-status staff from raising concerns or questioning the plan. Many OR personnel report that they would have trouble speaking up, even if they believed that patient safety was compromised.[169] Without formal intervention or team training, few if any briefings are performed, and poor agreement exists about what constitutes a briefing.[246,292,293] Although 39% of surgeons in a UK survey stated that they performed a brief for every surgical procedure, 96% of the nurses disagreed.[246] The WHO Safe Surgery study found that few briefings occurred among the 3733 procedures performed before implementation of the checklist or briefing.[162]

As mentioned earlier, the WHO Surgical Safety Checklist (see Fig. 30.14) contains the elements of a brief in the section termed "Anticipated Critical Items," by inviting the surgeon, the anesthesiologist, and the nursing staff to review the critical or nonroutine steps and voice any concerns.[162] Implementation of this tool in eight hospitals in eight cities, representing a wide range of economic circumstances and a diverse population, reduced the mortality rate from 1.5% to 0.8% and the complication rate from 11% to 7%.[162] A second global study found that use of this checklist in urgent surgical cases had the same effect, by reducing the mortality rate from 3.7% to 1.4%.[244] In a follow-up national study of 25,513 patients, a reduction of the in-hospital 30-day mortality rate from 3.15% to 2.85% was demonstrated (odds ratio, 0.85; 95% CI, 0.98.)[165] This effect was, however, dependent on compliance: the odds ratio in cases with full implementation was 0.44 (95% CI, 0.28–0.70) versus 1.09 (95% CI, 0.78–1.52) for partial compliance and 1.16 (95% CI, 0.86–1.56) for noncompliance,[165] respectively (see Fig. 30.16).

The SURPASS is a checklist that covers the entire continuum of cardiac surgery and includes a presurgical briefing as well as a postsurgical debriefing.[278] Implementation of the SURPASS tool reduced the complication rate from 27.3% to 16.7% and decreased the mortality rate from 1.5% to 0.8% (Fig. 30.17) in one series.[160] A closed claim review of adverse events that occurred before implementation found that some 40% of the events would have been prevented with use of the SURPASS tool.[294]

Briefings enhance team performance and require little time. In an analysis of 37,133 briefings, Berenholtz and colleagues[295] found that briefings averaged 2.9 minutes and debriefings averaged 2.5 minutes. Implementing briefings reduced the number of nonroutine events in cardiac surgical procedures by 25%,[293] and it increased the perception that wrong-site operations would be prevented.[296] After briefings were instituted at 16 cardiac surgical centers, surgical flow disruptions decreased from 5.4 per case to 2.8 ($P = .004$), disruptions resulting from inadequate procedural knowledge decreased from 4.1 to 2.2, and miscommunication events fell from 2.5 per case to 1.2.[297] Nurses made fewer trips to the core and spent less time there. Briefings improved communication; they reduced the number of communication failures per case from 3.95 to 1.31 and identified new problems or knowledge gaps.[298]

Briefings improve the teamwork climate and teamwork behaviors and are associated with greater satisfaction within the team.[‡] In one study of perceptions after briefings were instituted, respondents commented, "Your opinions seem to matter. You feel more valued," and "People are willing to say when they are not happy. They are not worried about backlash."[300] In an Israeli study, team members reported feeling more valued for their work, teamwork, and safety climate.[293] In a UK study, teams reported that the team culture was better and that potential problems had been identified after briefings were instituted.[241] Preoperative briefings reduced unexpected delays in surgical procedures by 31% in one study.[301] Implementation of briefings improved compliance with best practices, including antibiotic dosing, venous thromboembolism prophylaxis, and maintenance of normothermia and normoglycemia.[302–304]

Despite the evidence demonstrating the value of briefings, certain institutional, interpersonal, and psychological factors "constrain safety."[290] Resistance to or acceptance of briefings varies by team roles, and the attitude of and participation by key team members influences compliance, with significant latent failures (ie, those not grasped by the participants) reducing the effect of briefings and training.[141] In the VA team training effort, effective institution of briefings and debriefings was entirely dependent on executive leadership.[305] In an analysis of 756 briefings, Whyte and colleagues[245] found that the response to briefings depended on the institutional and social milieu in which the briefings

[‡]References 141, 173, 241, 292, 293, 295, 299, 300.

occurred and on individual perceptions of the purpose of the briefing. Surgeons randomly assigned to an intervention group demonstrated better team behaviors than did the control surgeons, but they reported lower levels of comfort, communication, and team efficiency, thus indicating that adoption of briefings or checklists may be uncomfortable at first.[286] Even with effective executive leadership and local champions, a wide range of attitudes and physiologic responses can hinder implementation. Identifying and understanding potential obstacles and resistances are necessary for effective implementation.[213,245,246,292]

Debriefings and Learning From Defects

As noted earlier, critical parts of any safety program include identifying latent hazards and formulating system changes to decrease the chance that patients will be harmed. Identifying these hazards can involve an institutional quality improvement process, as discussed later or, at the team level, by continually asking "Did anything happen today that we don't want to see happen again?"

Regular team debriefings at the end of surgical procedures can serve as a means to identify hazards and formulate improvements. Although debriefings are often discussed in conjunction with briefings and occur in the same context as briefings, they differ in timing, content, purpose, and practice. Debriefings should occur at the end of each surgical procedure and provide an opportunity for the team to reflect on the procedure and verbalize lessons learned or deficiencies identified.[306] It can be as simple as asking "Did everything go as well as we wanted it to (or as we expected) today?" Debriefings allow the team to come together to rectify problems and to find ways to improve performance in the next case.[241,295,302,305] They give the teams a chance to identify latent hazards and vulnerabilities, develop and implement system improvements, address areas of teamwork weakness, and formulate future plans.[306–308] Like briefings, debriefings are associated with enhanced team behaviors, climate, and performance. Unfortunately, like briefings, they are difficult to implement and are viewed with resistance by some staff.[241]

Learning from defects (LFD) is one of many ways for teams continually to identify and mitigate hazards. The LFD tool, developed by Pronovost and colleagues[309] at Johns Hopkins University in Baltimore, is a simplified and streamlined root cause analysis that provides a structured approach to identifying the elements that contribute to the hazard or defect and developing safety improvements. When used as a part of a comprehensive unit safety program (CUSP) developed by the Johns Hopkins researchers, it promotes team cohesion and enhances perceptions of the local safety climate.[310]

Structured Communication Protocols (Closed Loop, Handoff Protocols)

As noted in multiple studies, communication failures underlie the majority of serious adverse events that harm patients.[§] In the cardiac OR, messages are continually sent and received. Failure occurs when messages are not encoded clearly or decoded correctly, when the appropriate audience is not reached, and when critical information is omitted.[223,313] Closed-loop communication can address many of these failures, by requiring the sender to identify the intended recipient, who then repeats the message as heard, after which the sender verifies the accuracy.[110] This type of communication is especially important in stressful situations and when the potential audience is large.[314] Structured communication ensures that the team has a shared mental model, with shared goals, expectations, and plan execution.[315] Unfortunately, only perfusionists routinely practice closed-loop communication in the cardiac OR.[110]

Structured communication techniques include both standardized word use (eg, words for letters such as in the North Atlantic Treaty Organization [NATO] phonetic alphabet) and protocols for stating numbers (1-1 instead of 11, which can sound like 7). Using such techniques can reduce ambiguity, enhance clarity, and eliminate many potential errors.[316] The armed forces and aviation teams have used techniques such as read-backs, Situation-Background-Assessment-Recommendation (SBAR), advocacy and inquiry, and critical assertions to improve information transfer, reduce omission of information, and facilitate communication across ranks. Despite many recommendations to adopt these techniques,[317] few surgical teams have done so; consequently, few data exist to demonstrate efficacy in reducing harm in the OR.

Structured communication protocols have been studied extensively in information transfer during handoffs of a patient from one caregiver or team to another. As noted earlier, handoff failures represent a significant source of medical errors and harm to patients, both between and within teams.[134,229,233,235,236] The complexity of the information to be transmitted and the chaotic settings in which handoffs occur, with frequent interruptions and disruptions, virtually guarantee loss of critical information.[228,236,238] Nagpal and colleagues[134] undertook a systematic modified Delphi process to identify the critical elements of a handover from OR to PACU and then structured a protocol to ensure that all elements were included. Use of this tool reduced critical omissions from 9 to 3 per handover and task errors from 2.8 to 0.8 (Fig. 30.18).[318] In a study of handovers in pediatric cardiac surgical procedures, use of a teamwork-driven process and use of a protocol reduced critical information omissions from 6.33 to 2.38.[319] In another study, implementing a process based on a Formula-1 pit stop that specified preparation before handoff (phase 1), tasks to be completed before information transfer (phase 2), and specific information to be transmitted (phase 3) reduced the number of information omissions and shortened the handover process (Fig. 30.19).[320]

Zavalkoff and colleagues[321] found that implementing a simple fill-in-the-blank tool improved total handover scores as well as information subscores, and it did not prolong the process. These results were echoed by Craig and associates,[322] who reported that implementing a handover tool improved attentiveness, organization, and information flow and reduced interruptions. Petrovic and colleagues[323] used a standardized handoff protocol from the cardiac OR to the cardiac ICU and found that information omissions decreased from 26% to 19%, the presence of all critical personnel increased from 0% to 68% of handovers, and satisfaction scores increased. The finding that information omissions still occurred 19% of the time may indicate a need for a better protocol, a lack of participation by personnel, or simply the complexity of the problem.

The use of electronic technology in handover protocols has been proposed, but it has not been tested widely. One such system developed and implemented at Columbia University, (Multimedia Abstract Generation of Intensive Care, MAGIC) generates an automated briefing from the patient's electronic record; these briefings have been found to be accurate and better than a physician-generated handover because the information is available earlier to the receiving team.[324–326] The use of a dedicated Internet connection between catheterization centers and a cardiac surgical center shortened the time between cardiac catheterization and surgical decision from 36 hours to 1 hour and the time interval between diagnosis and operation from 56 to 18 hours.[327] The widespread use of electronic patient records and information-sharing systems, such as that provided by the Epic Care Everywhere (Epic, Verona, WI) system, certainly will increase the accuracy of patient information that is immediately available and will hopefully reduce errors.[328]

Simulation

Simulation in medicine is growing rapidly and has been used to train individual clinicians in specific skills, assess the technical and nontechnical skills of individual clinicians and teams, understand how and why errors occur, and devise means of preventing them. Simulation is, first and foremost, changing the face of medicine from "see one, do one, teach one to an approach in which students and residents practice on

[§]References 201, 213, 222, 223, 228, 262, 311, 312.

Improving postoperative handover: a prospective observational study.* Am J Surg. *2013;206:494–501.)*

simulators, not actual patients. Using simulation, procedures such as intubation, laparoscopic operations, and bronchoscopy are learned and, hopefully, perfected before attempted in patients.[329–335] The technical skill of trainees can be assessed before they perform procedures on patients.[133,336–339]

Simulation is an effective tool both to teach[263,340–343] and to assess nontechnical skills and teamwork.[130,131,144,181,344,345] In one study, simulation using crisis situations resulted in better teamwork attitudes than did specific teamwork training.[267] In addition, simulation is especially valuable in teaching the management of rare crisis situations,[63,330,346–350] as well as investigating successful ways to manage crises.[63,64,279,351] Simulation is an effective way to test the effects of stress, caffeine, fatigue, and other factors on performance[140,352–354] and to test the ability of certain interventions to reduce errors.[355–357] Simulation is such an effective tool that it is now used in some institutions as the primary method for teaching perfusionists management of CPB (E. Darling, SUNY Upstate, Syracuse, NY; personal communication as presented at the CREF 35th Annual Meeting, Long Beach CA, 2015). Finally, adequate performance in simulated events is a part of medical and nursing licensure.[358,359]

Medication Safety

Drug Errors

Substantial evidence indicates that drug administration errors are common in anesthetic practice. In 1993, the Australian Incident Monitoring Study (AIMS) identified 144 instances of a wrong drug being given or nearly given to a patient out of the first 2000 incidents reported.[360] In 1995, Merry and Peck[50] reported a survey of 75 anesthesiologists in New Zealand, 89% of whom indicated that they had made at least one error of drug administration, with 12.5% indicating that they had harmed a patient by a drug-related error. In a voluntary survey of 10,806 anesthetic cases in 2 hospitals in New Zealand,[361] the overall rate of drug error was 1 in 133 anesthetic cases (0.75%). Drug errors resulted in 1 case of intraoperative awareness, 2 cases of

Summary of the new handover protocol

Phase 0: Prehandover	The Patient Transfer Form is completed by the anesthetist and is collected from the operating room at least 30 min before the patient is transferred to the ICU. The receiving nurse ensures the bed space is set up according to the monitoring, ventilation, and other requirements specified on the Patient Transfer Form. The receiving doctor ensures that all appropriate paperwork is ready.
Phase 1: Equipment and technology handover	On arrival the team transfers the patient ventilation, monitoring, and support from portable systems used during the transfer to the ICU systems.  Safety check: the anesthetist checks the equipment and that the patient is appropriately ventilated and monitored and is stable. The receiving nurse and doctor are identified and confirm their readiness.
Phase 2: Information handover	The anesthetist, then the surgeon, speak alone and uninterrupted, providing the relevant information about the case, using the Information Transfer Aid Memoir. Safety check: the receiving nurse and doctor should use the Information Transfer Aid Memoir to check that all necessary information has been obtained and ask appropriate questions.
Phase 3: Discussion and plan	The surgeon, anesthetist, and receiving team discuss the case as a group. The receiving physician manages the discussions and identifies anticipated problems, and anticipated recovery is discussed. The ICU team now has responsibility for patient care and confirms the plans for the patient.

Fig. 30.19 Phases of a handover protocol as developed from Formula-1 pit stop concepts. *ICU,* Intensive care unit; *ODA,* operating department assistant. *(Modified from Catchpole KR, de Leval MR, McEwan A, et al. Patient handover from surgery to intensive care: using Formula 1 pit-stop and aviation models to improve safety and quality.* Paediatr Anaesth. *2007;17:470–478.)*

prolonged neuromuscular blockade, and 47 cases of transient physiologic effects. A similar survey in Canada found that 85% of anesthesiologists reported that they had made at least 1 drug error or "near miss," with 4 deaths in the 1038 reported errors.[362] A report based on annual surveys conducted by the Japanese Society of Anesthesiologists between 1999 and 2002, reflecting 4,201,925 anesthetic cases,[363] found an incidence of "critical events" caused by drug administration error of 0.02%. The incidence of death resulting from drug error was 0.00044%. Additional reports from Australia,[364] Japan,[365,366] and South Africa[367] suggest that anesthetic drug error continues to be a significant problem around the world. The incidence of drug administration errors in an academic practice in the United States appears to be similar to that reported from elsewhere in the world. In a self-reporting study performed in a single center in the United States, Cooper and associates[368] found a rate of error of 0.40% (35 in 8777, or 1 in 203 anesthetic cases) and a rate of pre-error of 0.19% (17 in 8777).

The majority of reported drug errors can be classified as Webster and colleagues[361] proposed (Table 30.3). In the study by Abeysekera

and associates,[364] nearly 50% of the errors were syringe and drug preparation errors, with 18.9% being swaps of correctly labeled syringes and 20.8% caused by selection of the wrong ampoule or vial, thus resulting in an incorrectly labeled syringe. Equipment misuse or failure accounted for 26%, incorrect route for 14%, and communication error for 4%. Administration of a drug in the OR is a complex procedure, with up to 41 steps involved in the first-time administration of a drug.[364,369] Human factors experts classify 36 of these steps as automatic behavior with muscle memory (susceptible to skill based or action errors), whereas 5 steps require conscious attention, decision, and judgment (decision errors, susceptible to cognitive errors).[369] Traditionally, the anesthesiologist performs all the steps alone, eliminating the opportunity for a double-check that is common elsewhere in medicine, in which a pharmacist checks the physician's prescription and a nurse checks both.

In addition, cardiac surgical procedures requiring CPB present the relatively unusual situation in which the anesthesiologist and the perfusionists may be administering drugs intravenously. Perfusionists frequently administer anesthetic drugs during CPB, and they may administer a variety of other drugs as well. Rarely, the perfusionist also may be an anesthesiologist (particularly in Australia), but whether the anesthesiologist even supervises the perfusionist in the administration of drugs varies depending on the particular practice setting. In some practice settings the anesthesiologist may leave the OR during CPB.

In a voluntary survey of incidents during perfusion, 29% of perfusionists in Australia and New Zealand reported related incidents during bypass.[370] In a similar survey of US perfusionists, 524 respondents reported a total of 5023 incidents, of which only 78 were medication errors.[371] The respondents also reported 11 cases of incorrect units of blood given, with 2 deaths. An updated survey by the same researchers found a total of 4882 events that occurred over 2 years; 63 events were related to medication errors, and 10 were related to incorrect units of blood.[372]

Surveys and voluntarily reported incidents may underestimate the true incidence of medication error in the operating room. In one of the only prospective, observational studies of medication errors in the operating room, Nanji and colleagues[372a] reported that 193 of 3671 (5.3%) medication administrations during 277 operations involved a medication error and/or an adverse drug error; 79.3% were preventable. The voluntarily reported errors typically have a low harm rate, but analysis of the American Society of Anesthesiologists (ASA) Closed Claims Project database provides a different view of the same problem because this database contains only errors that resulted in substantial harm and thus malpractice litigation.[373] As of 2003, 205 drug errors were recorded in the database, representing 4% of 5803 cases of litigated malpractice claims in anesthesiology. In these cases of serious harm, succinylcholine was the primary drug in 17% of the cases and epinephrine in 8%. In 12 of 35 cases succinylcholine was given inappropriately. Drug administration errors involving epinephrine were particularly dangerous, with death or major morbidity resulting in 11 of the 17 epinephrine-related cases. Six of the 17 cases involving epinephrine were caused by ampoule swaps. An informative case report describing the nearly fatal results of inadvertent epinephrine administration resulting from an ampoule swap has been published.[374]

Among the Closed Claims were 19 cases of intraoperative awareness (9%), 14 of which involved inadvertent administration of muscle relaxant to awake patients; the remaining cases were caused by inadequate or omission of anesthetic agents. ASA Closed Claims Project reviewers judged the care to be "less than appropriate" in 84% of the drug error claims, compared with 35% in non–drug error claims. Payments were made to plaintiffs in 72% of the drug error claims compared with 52% of the non–drug error claims. An analysis of litigation against the National Health Service in England related to anesthetic drug errors found a spectrum of errors that were similar to those found by the ASA Closed Claims Project.[375]

Wrong-route errors are particularly problematic and are caused in large part by the universality of the Luer connector.[376] In a notable case, bupivacaine solution intended for epidural use was administered free flowing into an intravenous infusion; although the baby was saved, the young parturient died.[377] Case reports abound: aminophylline[378] and tranexamic acid[379] given by the subarachnoid route; vecuronium,[380] ondansetron,[381] potassium chloride,[382] and rocuronium[383] given through epidural catheters; and vecuronium nearly given into an intraventricular (intracerebral) port. Human ingenuity has found a way to place a catheter into virtually every location in the body; human error has found a way to make every possible misconnection between infusion type and access line, often with disastrous outcomes (Table 30.4).[384] Erroneous injection of drugs into the intrathecal space has devastating outcomes. Accidental injection of vincristine into the subarachnoid space was first reported in 1968; since then at least 58 deaths have occurred worldwide, despite extensive publicity of the danger.[385] Enteral feedings (death, meningitis), formaldehyde (death), and chlorhexidine (parturient death) have all been given into the subarachnoid space.[384]

TABLE 30.3 Types of Drug Errors

Error Type	*Definition*
Incorrect dose	Wrong dose of an intended drug
Substitution	Incorrect drug instead of the desired drug; a syringe or vial swap
Omission	Intended drug not given (eg, missed antibiotic redosing)
Repetition	Extra dose of an intended drug
Incorrect route	Intended drug erroneously given by an unintended route
Other	Patient allergic to drug; rapid infusion of drug intended to be given slowly; wrong selection of antibiotic

TABLE 30.4 Types of Misconnections (JC Sentinel Event Alert 36)

Misconnection Type			*Notes*
Enteral feeding solution	to	IV line, central line, hemodialysis line	116 reports, 21 deaths known, underreported
Epidural infusion	to	IV line	Bupivacaine deaths
Blood pressure cuff	to	IV line	Air embolism, multiple deaths
IV solution	to	Nasogastric tube	—
IV solution	to	Epidural route	Dopamine, epinephrine
Syringe bolus	to	Epidural route	Antibiotics, NMBs, narcotics, sedatives
IV solution	to	Arterial line	Relatively easy to detect
Syringe	to	Arterial line	Wide variety of drugs
IV solutions	to	Foley catheter, dialysis lines, ventriculostomy port, tracheal cuff	—
Capnography sampling	to	IV line	—
Oxygen tubing	to	Needleless IV port	Potential air embolus
Pneumatic stockings insufflation line	to	Piggy-back port of IV line	Air embolus

IV, Intravenous; *NMBs,* neuromuscular blocking agents.

Infusion pumps have become increasingly prevalent in the cardiac OR, and they offer significant advantages, including the ability to deliver very small volumes of fluids or drugs at precisely programmed rates. They are not, however, a panacea for medication errors. From 2005 through 2009, the US Food and Drug Administration (FDA) received approximately 56,000 reports of adverse events associated with the use of infusion pumps, including numerous injuries and deaths.[386] Adverse events were related to hardware issues (battery failures, sparking, and fires), as well as software issues (error messages, double recording a single key strike such that 10 becomes 100). However, as any anesthesiologist can attest, many were related to poor user interface design or human factors issues.[386] In addition to issues with the pumps, user error is common. Compliance with the drug library is critical for prevention of error, but a systematic review found numerous studies showing high rates of user override of soft alerts, as well as a variable compliance rate with drug library use.[387]

Prevention of Drug Administration Errors

Although drug administration errors clearly are very important, few studies have tested the effectiveness of interventions to reduce error in randomized controlled trials. A review evaluated the evidence for various measures for reducing drug administration errors in anesthetic practice and made recommendations. [388] However, most of the evidence available for review was anecdotal, and it was based on the opinions of clinician experts without input from human factors engineers.[388] Recommendations included carefully reading the label on any ampoule or syringe, optimizing legibility and contents of labels, labeling syringes, formally organizing drug drawers and workspaces, and double-checking drugs with another person or a device.

In 2010, the Anesthesia Patient Safety Foundation convened a consensus conference of more than 100 participants to develop strategies to improve medication safety in the OR.[369] The consensus statements focused on four key areas: standardization, technology, pharmacy involvement, and culture (Box 30.4). Standardization focused primarily on having a single concentration of a drug available in the OR, but it also involved using standardized drug trays across all anesthetizing locations and having a single concentration of infusions that are administered by infusion devices with drug libraries. Pharmacy involvement was believed to be critical to reducing errors, from educational duties to managing the entire dispensing process from ordering of drugs to providing them to the anesthesiologists. Cultivating a culture of safety, as addressed later, was believed to be critical to improving safety, but "The fact that anesthesia professionals are 'fiercely independent' and thus reluctant to change their individual practice habits (as related to medication preparation and delivery) to fit a standardized protocol was noted."[369]

Bar code reading devices represent an underused technology, and bar coding drugs at the point of care to verify the correctness of the drug and the dose is widely regarded as a technologic solution that could improve the accuracy of drug administration.[369,389–394] The FDA issued a rule in February 2004 (updated in April 2014) that requires bar codes on most prescription drugs, certain over-the-counter drugs, and blood products.[395] The FDA believes that effective bar code use could

BOX 30.4 CONSENSUS RECOMMENDATIONS FOR IMPROVING MEDICATION SAFETY IN THE OPERATING ROOM

Standardization

1. High-alert drugs (eg, phenylephrine and epinephrine) should be available in standardized concentrations or diluents prepared by the pharmacy in a ready-to-use (bolus or infusion) form that is appropriate for both adult and pediatric patients. Infusions should be delivered by an electronically controlled smart device containing a drug library.
2. Ready-to-use syringes and infusions should have standardized, fully compliant, machine-readable labels.
3. *Additional ideas*
   a. Interdisciplinary and uniform curriculum for medication administration safety to be available to all training programs and facilities
   b. No concentrated versions of any potentially lethal agents in the operating room
   c. Required read-back in an environment for extremely high-alert drugs such as heparin
   d. Standardized placement of drugs within all anesthesia workstations in an institution
   e. Convenient required method to save all used syringes and drug containers until the case is concluded
   f. Standardized infusion libraries and protocols throughout an institution
   g. Standardized route-specific connectors for tubing (intravenous, arterial, epidural, enteral)

Technology

1. Every anesthetizing location should have a mechanism to identify medications before drawing up or administering them (bar code reader) and a mechanism to provide feedback, decision support, and documentation (automated information system).
2. *Additional ideas*
   a. Technology training and device education for all users, possibly requiring formal certification
   b. Improved and standardized user interfaces on infusion pumps
   c. Mandatory safety checklists incorporated into all operating room systems

Pharmacy/Prefilled/Premixed

1. Routine provider-prepared medications should be discontinued whenever possible.
2. Clinical pharmacists should be part of the perioperative and operating room team.
3. Standardized pre-prepared medication kits by case type should be used whenever possible.
4. *Additional ideas*
   a. Interdisciplinary and uniform curriculum for medication administration safety for all anesthesia professionals and pharmacists
   b. Enhanced training of operating room pharmacists specifically as perioperative consultants
   c. Deployment of ubiquitous automated dispensing machines in the operating room suite (with communication to central pharmacy and its information management system)

Culture

1. Establish a "just culture" for reporting errors (including near misses) and discussion of lessons learned.
2. Establish a culture of education, understanding, and accountability through a required curriculum and continuing medical education and through dissemination of dramatic stories in the *APSF Newsletter* and educational videos.
3. Establish a culture of cooperation and recognition of the benefits of the STPC paradigm (standardization, technology, pharmacy/prefilled/premixed, and culture) within and among institutions, professional organizations, and accreditation agencies.

result in a 50% reduction in medication errors, thereby preventing 500,000 adverse events and transfusion errors while saving $93 billion over 20 years.

Several studies of the use of bar code scanning systems in hospital nursing units suggested that errors may be reduced.[396–399,400] The VA Health Care System was an early adopter of bar code technology, but centers experienced some significant difficulties with point-of-care bar coding.[397] Some of the most common problems were simple but critically important, such as nonreadable bar codes on patients' wristbands and drug containers. According to Mills and colleagues,[397] "The VA discovered that introducing new technology to complex medical systems, while beneficial, also presents new challenges."

The federal code mandating bar-coded drugs is imperfect. Only approximately 90% of drugs arrive at a pharmacy with a bar code; the linear bar codes mandated are easily rendered illegible, the locations of bar codes on inhalers render them unreadable when inserted in the administration device, and so on.[401,402] In addition, between 2015 and 2017, manufacturers are mandated to follow the more stringent labeling required by some states and countries, requiring many more details about the drug. These new requirements may increase the price of many drugs but could improve patient safety—but only if hospitals fully implement bar code scanning across the delivery process.

Several commercially available systems allow bar code scanning of drugs in the anesthesia clinical environment, including the SAFERsleep system (SAFERSleep LLC, Nashville, TN), BD Intelliport (BD Medical, Franklin Lakes, NJ), and the Plexus Information System (Plexus Technology Group, Jackson, MI). The SAFERSleep system devised by Merry and associates[403] is the only one that has been tested in a randomized prospective clinical trial. No significant differences in errors occurred when the system was used compared with conventional methods, primarily because of sample size but also due to user error or violation. In a subset analysis, significantly fewer errors occurred when the system was used as intended, including that users scanned the bar code of each drug before administration and kept the voice prompt active (a computer voice speaks the name of the drug after the bar code is scanned).[403] A drug safety system has been described combining the Codonics printer (Codonics, Middleburg Heights, OH), which scans the bar code on drug vials and prints corresponding syringe labels, with a syringe label bar code scanner driven by Smart Anesthesia Manager software; as with SAFERSleep, the Smart Anesthesia Manager system includes a voice prompt that speaks the name of the drug when the syringe is scanned.[404,405] A study to determine whether this system reduces errors is ongoing.

Although no comprehensive assessment of the incidence and nature of errors related to infusion pumps has been made, it is clear from the available evidence that programming errors are significant sources of error.[387] Infusion pumps play a major role in drug administration in cardiac surgical patients, so errors related to infusion pumps are of significant concern to cardiac anesthesiologists.

Some infusion pumps use drug libraries with predefined dosing limits and warn the practitioner if the dosing parameters entered will result in a dose that is outside the predefined dosing limits. Smart infusion pumps, although not perfect, repeatedly have been shown to intercept and prevent errors, primarily wrong rate and dose.[387] A smart pump can potentially intercept errors during multiple steps in the medication delivery process (Fig. 30.20).[387] Most intercepted errors represented a low level of harm, but some studies included examples of many-fold errors of high-alert drugs (100 times the intended dose of norepinephrine) or more than 100-fold underdoses.

However, the evidence for the effectiveness of pumps with drug libraries is mixed, with some studies suggesting benefit and others not.[406] Lack of compliance with "soft alerts" that warn users but do not prevent drug administration may limit effectiveness.[387] Pumps that allow for bar code identification of medications and that interact with the electronic medical record or anesthesia information system may prove more effective.

A prospective, randomized trial of smart infusion pumps in a cardiac surgical ICU found approximately 2 serious medication errors per 100 patient-pump-days.[407] No significant improvement occurred with the use of smart pumps, although the pumps frequently were not used as intended. The drug library intended to prevent programming errors was bypassed 25% of the time. This study demonstrated that technology alone may not solve a problem; close attention to the details of implementing the technology and making it work properly are essential. Nuckols and colleagues[408] found that the smart pumps they tested could prevent only 4% of the adverse drug events in the ICU. Many errors were related to bolus dosing and failure to monitor and respond to drug-related problems adequately. These investigators did not conclude that smart pumps should be abandoned, but they advocated for smarter and more capable pumps.

Although smart pumps can alert to programming errors that may result in an incorrect dose, they do not recognize that a wrong drug has been placed in the pump or that the drug is being administered to the wrong patient. Bar coding may be a solution to this problem. A bar code on a medication bag can be scanned, along with the patient's bar-coded identification, to prompt the pump electronically with the appropriate drug and drug concentration, thus preventing misidentification of the drug or the patient, as well as preventing pump programming errors. Furthermore, if the pump is connected to the electronic medical record, the dosing information from the pump can be automatically documented in the record. Application of bar code scanning to infusion pumps is a relatively new and evolving technology.

Transfusion Safety

Although bar coding of drugs has received greater publicity, bar coding of blood units and the use of bar coding to ensure accurate matching of blood component to recipient comprise a promising technology. A study of transfusion errors in New York State estimated the incidence of ABO mismatched transfusion at 1 per 12,000 to 1 per 33,000.[409] A report from a hospital in Japan specializing in cardiovascular disease described a computer-assisted transfusion management system with bar coding at the bedside.[410] Nearly 60,000 blood components were transfused without error, and 1 human error was prevented. The system also improved the efficiency of blood component management and reduced the outdate rate on red blood cells from 3.9% to 0.32%.[410] Studies of bar code–based blood safety systems in the United States also suggest efficacy.[411,412] Blood components currently are tracked and managed with the FDA-mandated bar codes from the time of donation through release to the ordering team, but bar codes are infrequently used during the transfusion process. Using the existing bar coding on blood components could contribute to both efficiency and accuracy in the OR, especially if the bar code data were electronically linked to the blood bank record (ie, the crossmatch) and to the electronic medical record and anesthesia information system.

Prevention of Intraoperative Awareness

An early report of patients who had experienced awareness during anesthesia was made in 1961 by Meyer,[413] who described the patients as "Expressionless and staring … blank and stunned … having suffered a catastrophic reaction." Since then, intraoperative awareness has become a dreaded complication associated with a significant rate of posttraumatic stress disorder.[414,415] The incidence of intraoperative awareness varied in early published reports; more recently, three large prospective multicenter studies reported similar overall rates of approximately 0.1% to 0.2%.[416–418] A report from China found an larger incidence of approximately 0.4% in that country.[419] Prospective studies of pediatric patients found rates of 0.8% to 1.1%.[420,421] Retrospective studies that rely on self-reporting or quality assurance data tend to find lower rates. Pollard and associates found an incidence of intraoperative awareness of 0.007%[422]; the Fifth National Audit Project (NAP5) from the United Kingdom found an incidence of 0.004%, based on self-reporting.[423] In many studies, the incidence increased if neuromuscular blocking drugs were used.

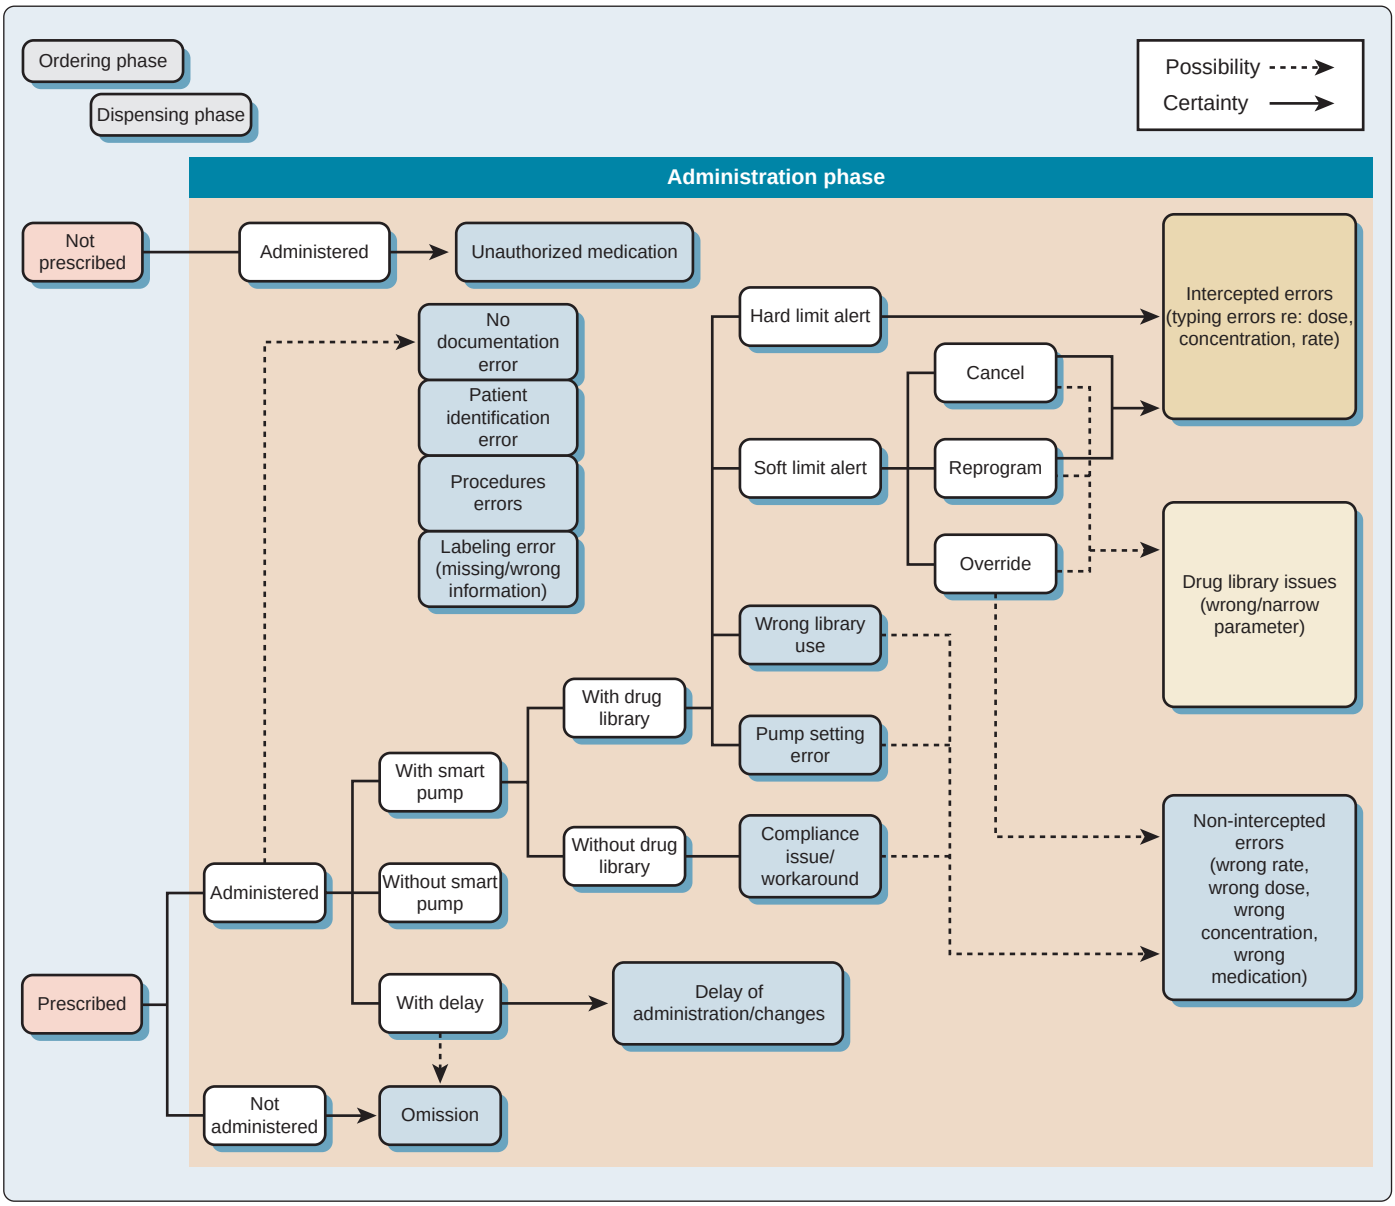

Fig. 30.20 Processes of intravenous medication administration with smart pumps and potential errors or intercepted errors in the prescribing phase to the administration phase. *(From Ohashi K, Dalleur O, Dykes PC, Bates DW. Benefits and risks of using smart pumps to reduce medication error rates: a systematic review.* Drug Saf. *2014;37:1011–1120.)*

Patients experiencing intraoperative awareness report a range of experiences, from isolated auditory perceptions (class 1) to paralysis and pain (class 5), with the additional modifier of D for distress (ie, fear, anxiety, suffocation, impending doom, or imminent death).[424] The sequelae of such an experience are variable, but as many as 70% of patients report sequelae of posttraumatic stress disorder.[414,415,425,426]

The variable rates of occurrence of intraoperative awareness relate in large part to the character of this experience. Patients often are reticent to speak of the experience and frequently do not report it unless specifically queried, and they may not be able to verbalize the experience for days or weeks. Sandin and colleagues[417] interviewed 11,785 patients in the PACU, and then at 6 days, and again at 7 to 14 days following general anesthesia. Only 6 patients reported recall in the PACU, whereas 12 reported it at 6 days and 17 at 7 to 14 days. This delay in the appearance of explicit memory has led many anesthesiologists to be skeptical about an incidence of 0.1% to 1%, because few patients will have had the opportunity to relate the experience to their anesthesiologist.[427,428]

Intraoperative awareness may be caused by specific, identifiable errors in anesthetic drug administration, such as administration of a muscle relaxant instead of a hypnotic agent during induction of anesthesia, unrecognized failure of an infusion pump, or an unrecognized empty vaporizer. However, most cases of awareness cannot be traced to such obvious events,[429] but they are likely related to complex differences among patients in response to anesthetic drugs.[430–434] Current theory, as summarized by Mashour and colleagues,[434] is that intraoperative awareness requires both consciousness, including both arousal and subjective experience, and explicit recall (memory).[434] Arousal, subjective experience, and memory occur at different neural loci and respond to anesthetic agents in different ways. Consciousness appears to be mediated by the coordinated activity of the frontal, higher-order areas, which are disrupted by various anesthetic agents, whereas sensory input and processing appear to be unchanged (Fig. 30.21).[431,432] It is likely that mechanisms of unconsciousness relate to the effect of anesthetics on cortical processing rather than alteration of sensory input.

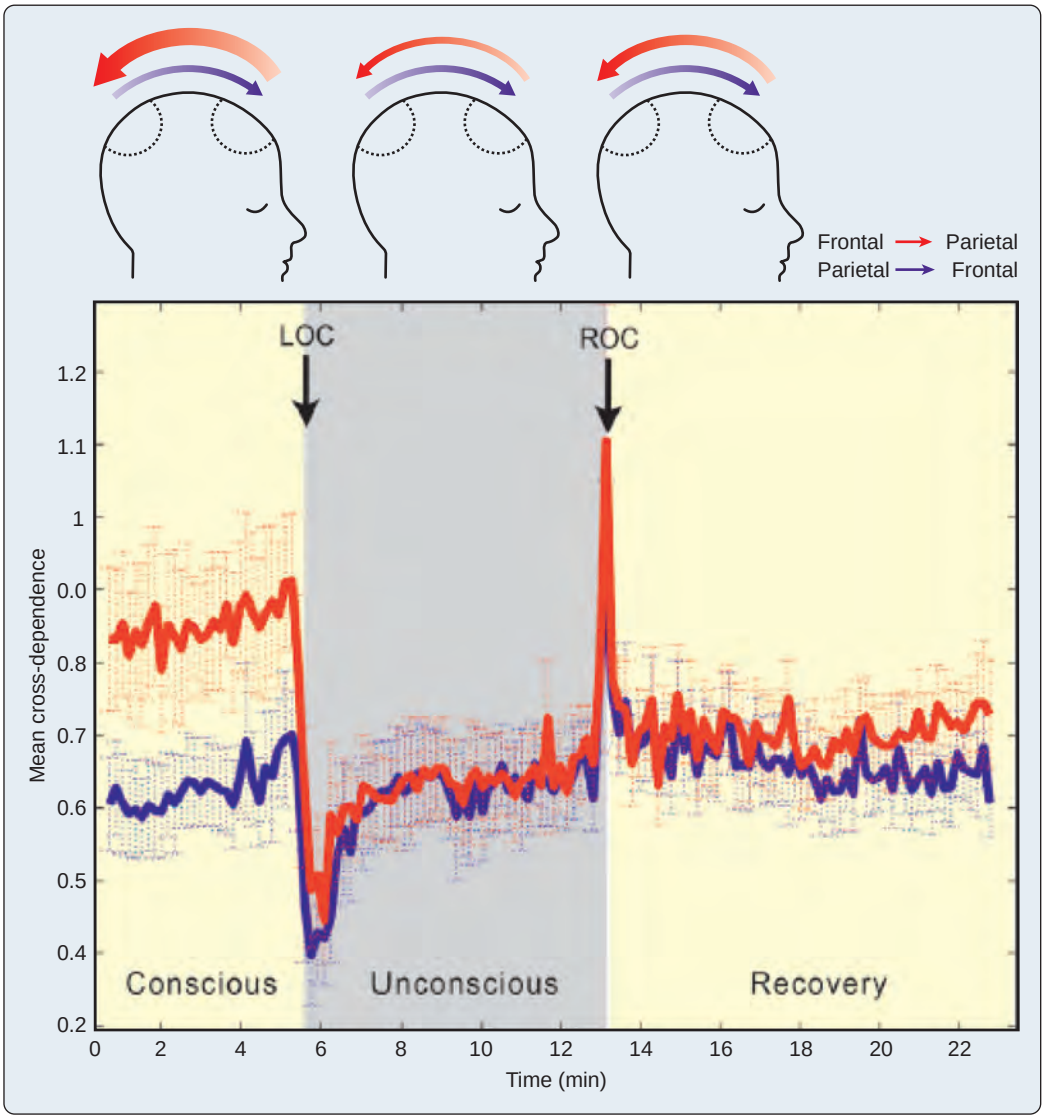

Fig. 30.21 Selective inhibition of frontoparietal feedback activity after induction of general anesthesia with propofol in humans. *LOC,* Loss of consciousness; *ROC,* return of consciousness. *(From Mashour GA, Orser BA, Avidan MS. Intraoperative awareness: from neurobiology to clinical practice.* Anesthesiology. *2011;114:1218–1233; adapted with permission from Lee U, Kim S, Noh GJ, et al. The directionality and functional organization of frontoparietal connectivity during consciousness and anesthesia in humans.* Conscious Cogn. *2009;18:1069–1078.)*

Recall under anesthesia also requires the formation of explicit memory.[434–436] Although it is beyond the purview of this chapter, the neurobiology of memory appears to be closely linked to the γ-aminobutyric acid A ($GABA_A$) receptor, long familiar to anesthesiologists. The specific subtypes of $GABA_A$ receptors modulated by anesthetics are being identified. At least 19 genes code for the various $GABA_A$ subunits, and this finding may indicate a genetic foundation for awareness. Certain subtypes confer resistance to the memory inhibition of isoflurane while not changing the immobilization or hypnotic effects.[437] Indeed, one of the strongest predictors of intraoperative awareness is a previous episode of awareness, thus supporting the view that genetic differences in GABA subunits may be related to awareness.[438] Auditory input is relatively resistant to inhaled anesthetic agents, a possible explanation for the finding that auditory perceptions are some of the events more commonly recalled.[424,435] In addition, large interindividual variations exist in anesthetic drug effect or anesthetic drug clearance.[439]

Genetic and physiologic factors possibly explain why some patients have intraoperative awareness despite apparent appropriate anesthetic management. Specific types of surgical procedures also increase the risk: cardiac surgical procedures increase the risk of intraoperative awareness from the overall level of approximately 0.1% to 0.2%[417,418] to approximately 0.4% to 1%,[418,440–446] a 10-fold increase. Ghoneim and Block and their colleagues[445,446] confirmed that cardiac surgical procedures are associated with an increased risk. The report of NAP5 from the United Kingdom found that cardiothoracic surgical procedures were associated with a threefold increase in the risk, from an overall rate of 0.004% to 0.012%.[417,447] Likely causes for this increased risk include deliberately light anesthesia during periods of hemodynamic instability and gaps in anesthetic delivery during separation from CPB. Administration of neuromuscular blocking drugs, ubiquitous in cardiac surgical patients, also increases the risk for intraoperative awareness.[417,423]

The difficulty of identifying awareness in a paralyzed patient has encouraged the use of processed electroencephalograms (EEGs) to potentially estimate the depth of anesthesia; several commercial products are available for this purpose. The processed EEG monitor known as BIS (bispectral index; Medtronic, Minneapolis, MN) is by far the

most prevalent, and it has been studied the most. In multiple studies, a BIS value lower than 60 has been associated with an extremely low probability of awareness during anesthesia.[448,449] Detailed reviews of BIS monitoring are available (see Chapter 18).[450,451]

Two published studies demonstrated that the use of BIS monitoring can decrease the rate of intraoperative awareness when compared with "usual practice."[444,452] In a multicenter retrospective case comparison study, 5057 consecutive BIS-monitored patients were compared with 7826 non–BIS-monitored patients from the same institution.[452] Two cases of intraoperative awareness occurred in the BIS-monitored series compared with 14 in the non–BIS-monitored series ($P < .039$). In a prospective, randomized multicenter trial (B Aware), 2503 "high-risk" patients were randomized to BIS or non-BIS monitoring.[444] The protocol provided no suggested care for the non-BIS group other than "usual practice." Two cases of intraoperative awareness occurred in the BIS-monitored group compared with 11 in the non–BIS-monitored group (odds ratio, 0.18; 95% adjusted CI, 0.02–0.84; $P = .022$).

Avidan and colleagues[453,454] performed two prospective, randomized trials comparing BIS monitoring with a "targeted end-tidal anesthetic gas analysis (ETAC)" (target range, 0.7 to 1.3 minimum alveolar concentration [MAC], with gas analyzers audibly alarmed for these limits).[453,454] In the B-Unaware trial, 2 of 967 and 2 of 974 patients from the BIS and ETAC groups experienced recall.[454] In the Bag-RECALL trial, 7 of 2861 patients (0.24%) in the BIS group experienced recall, as compared with 2 of 2852 (0.07%) in the ETAC group.[453] This finding suggests that the use of BIS or an inhalation anesthetic protocol with alarmed gas analyzers was similarly effective in reducing awareness.

Mashour and associates[455] performed another prospective trial comparing BIS and ETAC in 21,601 unselected patients. No difference was reported in the incidence of intraoperative awareness in the two groups. However, in post hoc analysis, significantly less awareness was noted in the BIS group (0.08%) compared with the patients assigned to BIS but who received no monitoring and did not use ETAC (0.38%; $P = .001$). This analysis supports the fact that explicit attention to anesthetic level, whether through use of a specific target for end-tidal anesthesia concentration or by BIS monitoring, reduces the incidence of awareness.

A Cochrane Collaboration review of BIS monitoring in 2014 concluded that BIS-guided anesthesia reduced intraoperative awareness in high-risk patients when compared with patients who received only standard monitoring.[456] However, no superiority of BIS was seen in preventing awareness when compared with achieving a targeted anesthetic concentration. A more comprehensive evaluation examined BIS, E-Entropy (GE Healthcare, Chicago, IL), and Narcotrend (MonitorTechnik, Bad Bramstedt, Germany) and found that BIS reduced the risk of intraoperative awareness, at a quality-adjusted life-year cost of $22,339 to $44,198. Data were insufficient to evaluate the effectiveness of Narcotrend or E-Entropy.[457]

Several important caveats for BIS or other processed EEG monitoring should be familiar to clinicians.

- Using processed EEG to evaluate anesthetic depth depends on similarities in the effects of anesthetic drugs on the EEG. Ketamine and nitrous oxide[458] have distinct effects on the EEG that are not taken into account by the BIS algorithm.
- Signals on the EEG are of very low amplitude and are subject to interference by high-frequency devices such as cautery, electromyographic activity, and temporary external pacemakers (all tend to elevate the BIS). Small doses of muscle relaxant usually obliterate high-frequency artifact caused by muscle activity, but not that associated with electrocautery.
- Processing and smoothing of the EEG occurs over 15 or 30 seconds, so the BIS number lags slightly behind clinical events, such as induction, when a patient clearly is asleep before the BIS changes. Similarly, changes from unconscious to conscious state can occur rapidly such that the patient is awake before a change in the BIS.
- BIS numbers reflect the state of the brain on the EEG, but they do not reveal how the brain arrived at that state. For example, BIS declines during sleep,[459] yet clearly, natural sleep is not the same as anesthesia.
- Changes in surgical stimulation can change the BIS rapidly. The propensity of response to a surgical stimulus is more likely with inhaled agents and less likely if opioids are present.[460] The BIS number does not distinguish among the various possible combinations of opioid and hypnotic drugs.[461]
- During thoracic aortic surgical procedures with partial left-sided heart bypass, drugs administered into a vein below the clamp have a lower than expected cerebral concentration, whereas those administered above the clamp may have a higher concentration. These variations in concentration are reflected in the BIS, which may increase if the drugs are administered below the cross-clamp or decrease if the drugs are administered above the cross-clamp.[462,463]
- BIS values should be viewed as providing one more value for use in conducting the anesthetic protocol, but they definitely do not substitute for the conventional judgments that anesthesiologists make in the absence in BIS.

Although BIS monitoring remains controversial, the currently available evidence suggests that cardiac anesthesiologists should seriously consider using BIS or achieve a targeted end-tidal anesthetic concentration, given the high rate of intraoperative awareness demonstrated in patients undergoing cardiac surgical procedures. The ETAC specified in the trials conducted by Aviden and colleagues and Mashour and associates was 0.7 MAC, a level that may not be tolerated in compromised cardiac surgical patients. Mashour and colleagues[434] suggested that the threshold of inhaled anesthetic agent to prevent awareness lies between the point at which 50% of patients do not move with incision (1 MAC) and the concentration at which 50% of patients regain consciousness, typically 0.3 to 0.5 MAC.

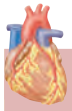
No single foolproof method to avoid all instances of intraoperative awareness exists, but multiple elements that must be considered and managed (Box 30.5). However, given the variations in patients' responses to anesthesia, even the best of attempts is unlikely to reduce the incidence much below 1 to 2 in 1000. Anesthesia providers should also therefore be alert to and elicit any experience of awareness from patients, by using a modified Brice interview.[464] When such patients are identified, evidence demonstrates that early intervention can enhance recovery from posttraumatic stress disorder.[465]

Reducing System Vulnerability

Single Center Interventions

The preceding section focused on individual interventions designed to improve teamwork and communication and to avoid certain common errors in the cardiac OR. However, most quality improvement initiatives in cardiac surgery represent comprehensive, multidisciplinary, and multiunit approaches. Doran and colleagues[466] used the Institute for Healthcare Improvement Breakthrough model of rapid cycle improvements in a community cardiac surgical program and found significant improvements in length of stay, ventilator time, patient satisfaction, and cost. Stanford and associates[467] used a total quality management approach that implemented perioperative checklists, nursing-led progress tracking, morbidity and mortality conferences focused on "fix the problem, not the blame," and multidisciplinary consultations.[467,468]

The Geisinger Health System in Danville, Pennsylvania asked surgeons to develop a care bundle for patients undergoing CABG that would be evidence based and hard-wired into the care processes. A continual improvement approach was used to improve the implementation of the bundle. Significant improvements were seen in ICU readmissions, hospital readmissions, blood product use, and overall costs.[157] Developed in 2006, this program has grown into a true "pay-for-performance" program, in which surgeons receive a base salary with incentives that are based on benchmarks of patient satisfaction and outcomes.



BOX 30.5 RECOMMENDATIONS FOR PREVENTION OF INTRAOPERATIVE AWARENESS

- Check all equipment drugs and doses; ensure that the anesthetic agent is reaching the patient.
- Consider amnestic premedication.
- Use a peripheral nerve stimulator to titrate neuromuscular blockade; minimize it as much as possible.
- If intense paralysis is required, consider using a tourniquet on the forearm to allow movement of that hand if the patient is aware.
- Administer at least 0.5 to 0.7 minimum alveolar concentration of an inhaled agent; set the alarm for an end-tidal concentration lower than this level.
- Monitor the inhaled anesthetic concentration on cardiopulmonary bypass.
- Consider vasoactive agents to manage hypotension rather than lowering the anesthetic concentration.
- If the anesthetic level cannot be maintained because of hemodynamic compromise, consider hypnotic or amnestic agents.
- Supplement hypnotic agents with analgesic agents such as opioids to decrease the experience of pain in the event of awareness.
- Consider use of a processed electroencephalogram such as a bispectral index monitor, particularly if using total intravenous anesthesia; do not seek to lower the anesthetic concentration based solely on a bispectral index number.
- Evaluate known risk factors for awareness; explicitly ask about previous episodes of awareness. In patients with a previous history, consider increasing anesthetic concentrations and using sufficient opioids.
- Redose intravenous anesthetic agents during periods when inhaled anesthesia cannot be used (during long intubation attempt or during rigid bronchoscopy).
- When planning for sedation, explicitly discuss with the patient expectations for recall.

Modified from Mashour GA, Orser BA, Avidan MS. Intraoperative awareness: from neurobiology to clinical practice. *Anesthesiology*. 2011;114:1218–1233.

Culig and colleagues[159] use an operational excellence model based on the Toyota Production System to design and establish a new community cardiac surgical program. The investigators described shifting the culture from a hierarchical "defects are punished" model to a collaborative "Just Culture" model. This change was accomplished with disciplined 10-minute daily meetings, including a formal problem-solving process. Over 2 years, the risk-adjusted complication rate was 60% lower than that observed in their region.[159]

Multicenter Collaboratives

Multicenter collaboratives in cardiac surgery have been developed for the purpose of sharing site-specific and physician-specific data, as well as identifying best practices; these collaboratives have improved quality and safety over the past 2 decades. The first collaborative model began in 1987 with the formation of the Northern New England Cardiovascular Disease Study Group.[469–471] Five hospitals in New England agreed to share patients' demographic, process, and outcome data and developed risk-adjusted methods to create predictive models. Variability in actual versus predicted mortality rates led to round-robin site visits and frequent face-to-face meetings to understand how differences in practices affected outcomes. The teams met to share practices and to develop, test, and implement standardized protocols.[472] This model of shared learning led to reductions in overall mortality rates,[164,471] lower mortality rates in women undergoing cardiac operations,[473] reduced rates of re-exploration for significant bleeding,[474] and more appropriate use of aspirin in patients undergoing CABG.[475]

Other multicenter collaboratives have demonstrated similar success. The Virginia Cardiac Surgery Quality Initiative was initiated in 1996, and it currently includes 17 hospitals and 10 cardiac and thoracic surgical teams.[476] This collaborative has resulted in reductions in the incidence of postoperative atrial fibrillation, decreased blood transfusions,[34] and better glucose management.[477] The Michigan Society of Thoracic and Cardiovascular Surgeons formed a quality initiative that has been funded by a statewide health plan. Their efforts have increased internal mammary artery use and decreased the incidence of prolonged ventilation.[158,478,479] Additional collaborative efforts include the Minnesota Cardiac Surgery Database, the Alabama Coronary Artery Bypass Grafting Project, the California Local/Regional Cardiac Surgery Database, and the Washington Clinical Outcomes Assessment Program.[480]

Culture of Safety

Organizational Culture

Most of the preceding discussion has focused on safety at the individual and team levels. Although there is much that individuals and teams can and must do, individual efforts will fall short unless a well-developed organizational safety culture is present.[290] Deficits in safety culture were cited in the abnormally high death rates in pediatric cardiac hospitals in both Bristol, England (Fig. 30.22)[481–483] and Winnipeg, Canada.[484–486] In both instances, frontline providers had raised concerns about poor outcomes, but they were unheeded. Existing quality assurance programs were woefully ill-equipped to identify and address sentinel events, and both hospitals had an institutional unwillingness to challenge the perceived autonomy of physicians.[487,488] Most concerning was the unwillingness of the hierarchy in Winnipeg to consider or even acknowledge the concerns of nurses and anesthesiologists, who eventually refused to provide anesthesia services for these cases.[487] In both Winnipeg and Bristol, a strong hierarchical culture existed that emphasized deference and power differences, so much so that nurses were judged to be incapable of recognizing substandard surgical care.[487] Few nurses would disagree, even years after those inquiries, that the hierarchical culture that existed in Winnipeg and Bristol is still common in health care settings around the world.

Although the terms *safety culture* and *safety climate* may be used interchangeably, they represent different aspects of the same concept. An organization's safety culture refers to the collective behaviors and values that influence its ability to identify and mitigate hazards and systemic unsafe conditions.[489] Safety climate refers to the commitment that workers bring to carrying out the organization's mission and adhering to the established policy and procedures. Safety culture would include an organization setting policies for briefings and debriefings; safety climate would be the willingness of the surgical team to embrace the value of the process deeply rather than perfunctorily checking a box. Even when institutions appear outwardly similar, quite different cultures and subcultures can exist. Local culture drives behavior: institutions with strong hierarchical cultures have low safety climate levels, whereas those with a group orientation and entrepreneurial efforts have higher safety levels.[170,490] The evidence that a hierarchical culture can affect safety highlights the need for a shift in education and training to a paradigm in health care that is more collaborative and multidisciplinary.[487,491,492]

Although overall organizational culture and climate are critical, those of smaller units, such as the cardiac OR and ICU, are often distinctly different from (albeit influenced by) those of the organization.[493] Numerous studies have investigated the attitudes and beliefs of OR personnel and have raised interesting and potentially actionable issues.[169,171,214,265,494] One large multicenter survey found that the safety climate scores differed widely by hospital, *but not by position*, a finding indicating that nurses nationwide tend to have more concerns about safety climate than do physicians.[493] In a similar study, nurses reported having a more negative view of their work unit's support of and attention to safety than did physicians, who expressed more concern about

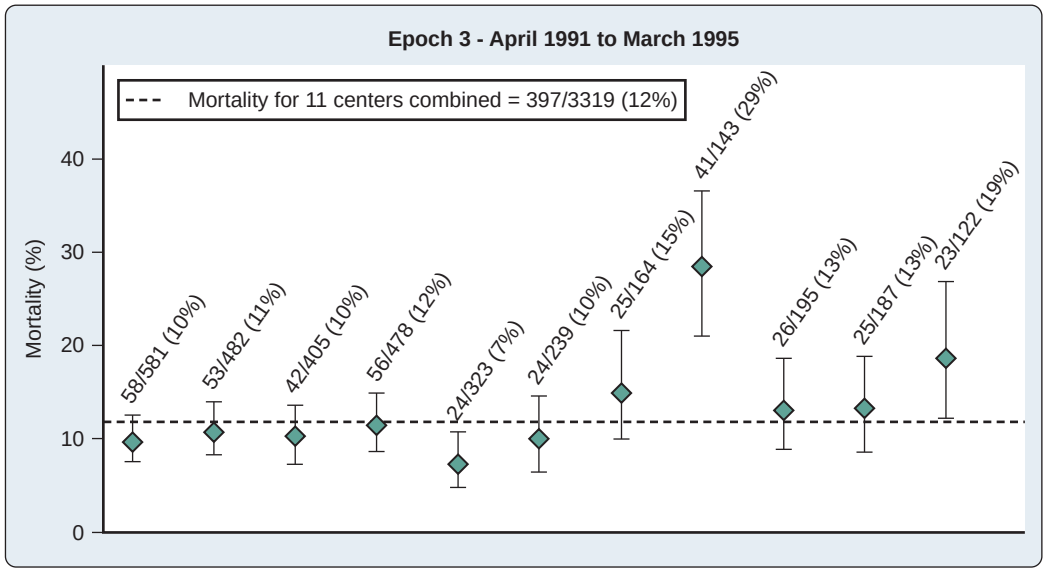


Fig. 30.22 Mortality rates at Bristol (29%) versus other pediatric cardiac hospitals in England. *(From Aylin P, Bottle A, Jarman B, Elliott P. Paediatric cardiac surgical mortality in England after Bristol: descriptive analysis of hospital episode statistics 1991–2002. BMJ. 2004;329:825.)*

being shamed if they commit an error.[494] In another study, a survey of ICU teams found that, "relative to physicians, nurses reported that it is difficult to speak up, disagreements are not appropriately resolved, more input into decision making is needed, and nurse input is not well received."[216]

Fleming and colleagues[495] investigated the leadership, structure, and safety climate of an OR team, as well as their views on stress and fatigue, teamwork, work values, and error and procedural compliance. Respondents reported that procedures and protocols often were not followed, and only 43% stated that they would feel comfortable speaking up if they perceived a threat to patient safety.[495] Although the data are meager, and culture measurement tools have inherent limitations, the detailed findings from Winnipeg and Bristol indicate that these attitudes and climates are deeply embedded in health care and can directly affect patient outcomes.

Effect of Organizational Culture on Outcome

Unfortunately, few studies have formally assessed the effect of organizational culture and characteristics on patient outcomes.[185] One study attempted to link outcomes after CABG with the organization's culture and total quality management scores. The investigators found a fourfold difference between institutions in patient outcomes for CABG (eg, length of stay, length of intubation), but neither the quality management score nor a high supportive organizational culture score was associated with the differences in patient outcome.[496] Several studies investigated the relationship between local climate and culture and threats to patient outcomes or actual outcomes; these studies found that more threats to patient safety occurred in less functional climates.[171]

Data do exist regarding the effect of a strong or rigid hierarchical culture on safety. Organizations with this type of culture place a high premium on stability and are characterized by rigid coordination, uniformity, strict limits on individual authority or innovation, and strong adherence to rules and regulations.[497] These characteristics are not inherently bad. In surgery, as in the military, clear lines of authority and roles as well as adherence to protocols are necessary for excellent performance. However, when a hierarchical culture leads to significant power distance, status asymmetry, or disruptive behavior, team members will be reluctant to speak up or to challenge authority even when threats to patient safety exist.[169,217,493] More distressing is that rigid hierarchical cultures in both Bristol and Winnipeg resulted in a leadership that that discounted and ignored multiple reports of concern.[481,482,486–488] Centralized authority typically causes frontline workers to feel less empowered to speak up or take action when facing safety issues.[490,498] Entities with a rigid hierarchical culture have inferior scores on performance measures and overall safety climate.[207,499,500]

Hierarchical organizations, as noted, are typically rule oriented and bureaucratic. When failures occur, hierarchical organizations focus on identifying someone to blame and holding that person accountable, even if the failure occurred at the system level.[501] These organizations unintentionally establish a culture of blame and shame in which individual persons are often silent about their own mistakes, or about vulnerabilities in the system, in large part because they fear criticism or even retribution. The Joint Commission and the Institute of Healthcare Improvement have emphasized using adverse event reporting to identify and rectify system vulnerabilities. Nonetheless, surveys demonstrate that less than half of staff members report that their hospital has a nonpunitive reporting system.[502]

A hierarchical culture also may foster disruptive behavior, an element of teamwork that may be linked to errors and adverse events. A survey done in 102 hospitals found that, of the respondents (2846 nurses, 944 physicians, 40 executives, and 700 other), 77% had witnessed disruptive behavior in physicians, and 65% reported seeing disruptive behavior in nurses.[503] Disruptive behavior was linked to medical errors by 71% of respondents and to death by 27% of respondents. In a different survey, more than 80% of personnel reported that disruptive behavior had led to reduced focus, reduced communication and collaboration, and poor relationships among the team.[504] Thus, frontline staff members believe that these behaviors affect patient safety and outcomes.[503–506] The Joint Commission implemented leadership standards in 2009 that required creating and maintaining a culture of safety and required having a policy in place to address disruptive behavior.[507] In the 2009 standard, specific types of behavior were enumerated, whereas the newer, revised definitions refer simply to "behaviors that undermine a culture of safety."

As a stressful, intense and complex milieu, the cardiac surgical setting is particularly susceptible to disruptive or bullying behavior.[508] Disruptive behaviors are perpetuated by a hierarchical culture dominated by physicians and a perceived code of silence.[509] The decision not to speak up for fear of retaliation erodes teamwork and a safety culture.[503,509] Vanderbilt University in Nashville, Tennessee studied the effect of a program designed to address professionalism and unprofessional behaviors. The program includes discussions around leadership, a model for intervention, policies, surveillance tools, training,

and accountability.[510] These efforts have led to reduced malpractice claims, better team communications, and behavior changes among physicians.[511]

The best evidence to support the concept that organizational culture and climate affect patient outcome is the work done in the VA Medical Team Training effort. The implementation of Medical Team Training, as reported earlier, reduced operative mortality rates across 108 VA hospitals and significantly improved staff perceptions of the safety climate at their institution.[512,513] Whether the safety climate or culture actually changed at an institution or only the perception of it changed is not clear. Certainly, having executives assigned to a unit or performing executive walkarounds improves safety attitudes.[270,514] It is also possible that the executives carry back to the executive suite knowledge that subtly changes the culture and climate among the leadership.

Improving Organizational Culture

As noted earlier, few studies directly link organizational culture to patient outcomes. Similarly, interventions to change organizational culture, whether at the hospital or unit level, are in their infancy. One such intervention that has been associated with improved patient outcomes is the Comprehensive Unit-Based Safety Program (CUSP), developed during the Keystone project to eliminate central line infections.[280] The CUSP program includes four elements: (1) educating staff on safety science, (2) assigning executives to work with staff to promote safety, (3) identifying and then learning from defects in care, and (4) using teamwork and improvement tools together with quantitative assessments of culture.[515] To date, CUSP primarily has been implemented in ICUs, where it has significantly reduced central line infections, cases of ventilator-associated pneumonia, and surgical site infections.[5,516,517] Implementing the CUSP program improves teamwork climates.[310,518] One of the key elements of CUSP is empowering staff to identify, investigate, and rectify defects in care, within an environment that focuses on vulnerabilities in the system rather than on erring individual members of the system.[310,515,517]

Developing a Just Culture

As noted earlier, health care organizations typically have investigated significant adverse events with great vigor, but all too often they did so to identify someone to blame rather than find out how the system failed. Once identified, that person is shamed at best or prosecuted and jailed at worst.[50,519–521] This culture of blame results in staff members who maintain silence in the presence of performance problems, near misses, and violations because they fear they will be blamed or suffer retaliation.[522]

Although health care organizations typically voice support of a just culture, establishing a climate in which employees feel safe when voicing concerns or identifying vulnerabilities within their own unit requires moving from the ubiquitous control-based management style to a commitment-based style in which employees continually learn from errors and continually eliminate system vulnerabilities.[523] Commitment-based management is believed to be essential to creating a just culture in which individual members are held accountable only when they knowingly and unnecessarily increase risk,[117,501] and in which organizations learn and improve by openly identifying vulnerabilities and correcting them.

31 Cardiopulmonary Bypass Management and Organ Protection

HILARY P. GROCOTT, MD, FRCPC, FASE | MARK STAFFORD-SMITH, MD, CM, FRCPC, FASE | CHRISTINA T. MORA-MANGANO, MD

KEY POINTS

1. Cardiopulmonary bypass (CPB) provides the extracorporeal maintenance of respiration and circulation and permits the surgeon to operate on a quiet, nonbeating heart.
2. CPB is associated with a number of profound physiologic perturbations. The central nervous system, kidneys, gut, and heart are especially vulnerable to ischemic events associated with extracorporeal circulation.
3. Advanced age is the most important risk factor for stroke and neurocognitive dysfunction after CPB.
4. Acute renal injury from CPB can contribute directly to poor outcomes.
5. Drugs such as dopamine and diuretics do not prevent renal failure after CPB.
6. Myocardial stunning represents injury caused by short periods of myocardial ischemia that can occur during CPB.
7. Blood cardioplegia has the potential advantage of delivering oxygen to ischemic myocardium, whereas crystalloid cardioplegia does not carry much oxygen.
8. Gastrointestinal complications after CPB include pancreatitis, gastrointestinal bleeding, bowel infarction, and cholecystitis.
9. Pulmonary complications such as atelectasis and pleural effusions are common after cardiac surgery with CPB.
10. Embolization, hypoperfusion, and inflammatory processes are central common pathophysiologic mechanisms responsible for organ dysfunction after CPB.
11. Controversy regarding the optimal management of blood flow, pressure, and temperature during CPB remains. Perfusion should be adequate to support ongoing oxygen requirements; mean arterial pressures of more than 70 mm Hg may benefit patients with cerebral and/or diffuse arthrosclerosis. Arterial blood temperatures should never exceed 37.5°C.
12. The initiation and termination of CPB are key phases of a cardiac surgery procedure, but the anesthesiologist must remain vigilant throughout the entire bypass period.
13. Total CPB can be tailored to allow deep hypothermic circulatory arrest or partial bypass. These special techniques require sophisticated monitoring and care.
14. Organ dysfunction cannot definitively be prevented during cardiac surgery with off-pump techniques.

An anesthesiologist-in-training once posed the question, "Why is my presence necessary during cardiopulmonary bypass? The perfusionist has direct control of the patient's blood pressure and respiration. The inhalation anesthetic is attached to the bypass circuit. Drugs are administered into the venous reservoir. What is my role?"[1] The resident's answer was incomplete but more robust than that argued by many clinicians, who suggest that the presence of a member of the anesthesia care team (eg, anesthesiologist, nurse anesthetist, credentialed anesthesia assistant) during cardiopulmonary bypass (CPB) is not essential. The American Society of Anesthesiologists (ASA) states that the absence of anesthesia personnel during the conduct of a general anesthetic violates the first of the ASA Standards for Basic Anesthetic Monitoring.[2] The absence of a member of the anesthesia care team during CPB is below the accepted standard of care. At a minimum, the anesthesiologist's role during CPB is to maintain the anesthetic state—a more challenging task than the usual case when the patient's blood pressure, heart rate, and movement provide information regarding the depth of anesthesia. The complexities of CPB and the necessary integration of risk factors with the nuances of cardiac surgery warrant constant thinking and rethinking of how the conduct of CPB and surgery modulates the risks and what protective strategies need implementation. This chapter outlines the tasks, challenges, and responsibilities of the cardiovascular anesthesiologist that extend beyond the maintenance of the anesthetic state, focusing on overall organ protection.

Historical Perspective on Cardiopulmonary Bypass

On May 6, 1953, John Gibbon, Jr., MD, surgically treated a young woman with an atrial septal defect using CPB, and the long-elusive goal of extracorporeal circulation was achieved (Fig. 31.1). The 60th anniversary of the first successful use of CPB was celebrated in 2013. Ten years prior, a number of insightful perspectives on this important medical landmark accompanied the 50th anniversary of this achievement.[3–5] The fundamental importance of this early achievement continues to be recognized today.

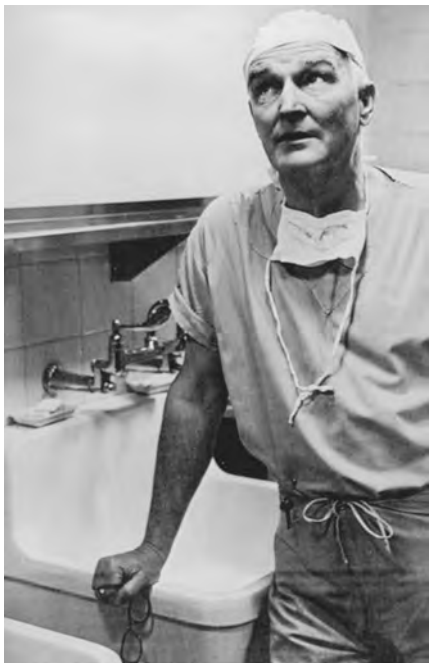

Fig. 31.1 Dr. John Gibbon, Jr., before the first successful application of total extracorporeal circulation for cardiac surgery in humans.

Modern cardiac surgery continues to be challenged by the risk of organ dysfunction and the morbidity and mortality that accompany it. Catastrophic organ system failure was common in the early days of CPB, but advances in perfusion, surgical techniques, and anesthesia have allowed most patients to undergo surgery without major morbidity or mortality. However, organ dysfunction ranging in severity from the most subtle to the most severe still occurs, manifesting most frequently in patients with decreased functional reserves or extensive comorbidities. With more than 1,000,000 patients worldwide undergoing various cardiac operations annually, understanding organ dysfunction and developing perioperative organ protective strategies are paramount.

This chapter briefly describes modern bypass circuits and highlights the many current controversies regarding the management of patients during CPB. It also deals with perfusion accidents that can be life-threatening events. It is critical that all members of the cardiac surgery team anticipate and respond appropriately to mishaps during CPB. More common than the rare catastrophe that can occur are the injurious end-organ effects that can result from the inherent nature of CPB. The multiple pathophysiologic perturbations precipitated by the process of extracorporeal circulation and the putative effects of these phenomena on end-organ function are discussed in detail.

Goals and Mechanics of Cardiopulmonary Bypass

The CPB circuit is designed to perform four major functions: oxygenation and carbon dioxide elimination, circulation of blood, systemic cooling and rewarming, and diversion of blood from the heart to provide a bloodless surgical field.[6] Typically, venous blood is drained by gravity from the right side of the heart into a reservoir that serves as a large mixing chamber for all blood return, additional fluids, and drugs. Because (in most instances) negative pressure is not employed, the amount of venous drainage is determined by the central venous pressure, the column height between the patient and reservoir, and resistance to flow in the venous circuitry. Negative pressure will enhance venous drainage and is used in some bypass approaches, including port-access CPB. Venous return may be decreased deliberately (as is done when restoring the patient's blood volume before coming off bypass) by application of a venous clamp. From the reservoir, blood is pumped to an oxygenator and heat exchanger unit before passing through an arterial filter and returning to the patient. Additional components of the circuit generally include pumps and tubing for cardiotomy suction, venting, and cardioplegia delivery and recirculation, as well as in-line blood gas monitors, bubble detectors, pressure monitors, and blood sampling ports. A schematic representation of a typical bypass circuit is depicted in Fig. 31.2 (see Chapter 32).

The cannulation sites and type of CPB circuit used are dependent on the type of operation planned.[7] Most cardiac procedures use full CPB, in which the blood is drained from the right side of the heart and returned to the systemic circulation through the aorta. The CPB circuit performs the function of the heart and lungs. Aorto-atriocaval cannulation is the preferred method of cannulation for CPB, although femoral arteriovenous cannulation may be the technique of choice for emergency access, "redo" sternotomy, and other clinical settings in which aortic or atrial cannulation is not feasible. Procedures involving the thoracic aorta are often performed using partial bypass in which a portion of oxygenated blood is removed from the left side of the heart and returned to the femoral artery. Perfusion of the head and upper extremity vessels is performed by the beating heart, and distal perfusion is provided below the level of the cross-clamp by retrograde flow by the femoral artery. All blood passes through the pulmonary circulation, eliminating the need for an oxygenator (see Chapter 23).

Physiologic Parameters of Cardiopulmonary Bypass

The primary objective of CPB is maintenance of systemic perfusion and respiration. Controversy arises with the question of whether systemic oxygenation and perfusion should be "optimal or maximal" or "adequate or sufficient." Remarkably, after more than 60 years of CPB, there is continued disagreement regarding many fundamental management issues of extracorporeal circulation. Clinicians and investigators disagree on what the best strategies are for arterial blood pressure goals, pump flow, hematocrit, temperature, blood gas management, or mode of perfusion (pulsatile vs nonpulsatile). Whereas each of these physiologic parameters used to be taken into account individually, the application of each has organ-specific effects. As a result, the ensuing discussions deal with these parameters on an organ-specific basis.

End-Organ Effects of Cardiopulmonary Bypass

Modern cardiac surgery continues to be challenged by the risk of organ dysfunction and the morbidity and mortality that accompany it. A number of injurious common pathways may account for the organ dysfunction typically associated with cardiac surgery. CPB itself initiates a whole-body inflammatory response with the release of various injurious inflammatory mediators. Add to this the various preexisting patient comorbidities and the potential for organ ischemic injury caused by embolization and hypoperfusion, and it becomes clear why organ injury can occur. Most cardiac surgery, because of its very nature, causes some degree of myocardial injury. Other body systems can be affected by the perioperative insults associated with cardiac surgery (particularly CPB), including the kidneys, lungs, gastrointestinal tract, and central nervous system.

Understanding the fundamentals of organ dysfunction, including the incidence, significance, associated risk factors, causes, and pathophysiology, provides a framework for discussing various organ-specific protective strategies. The following section describes the various organ dysfunction syndromes that can occur in patients undergoing cardiac

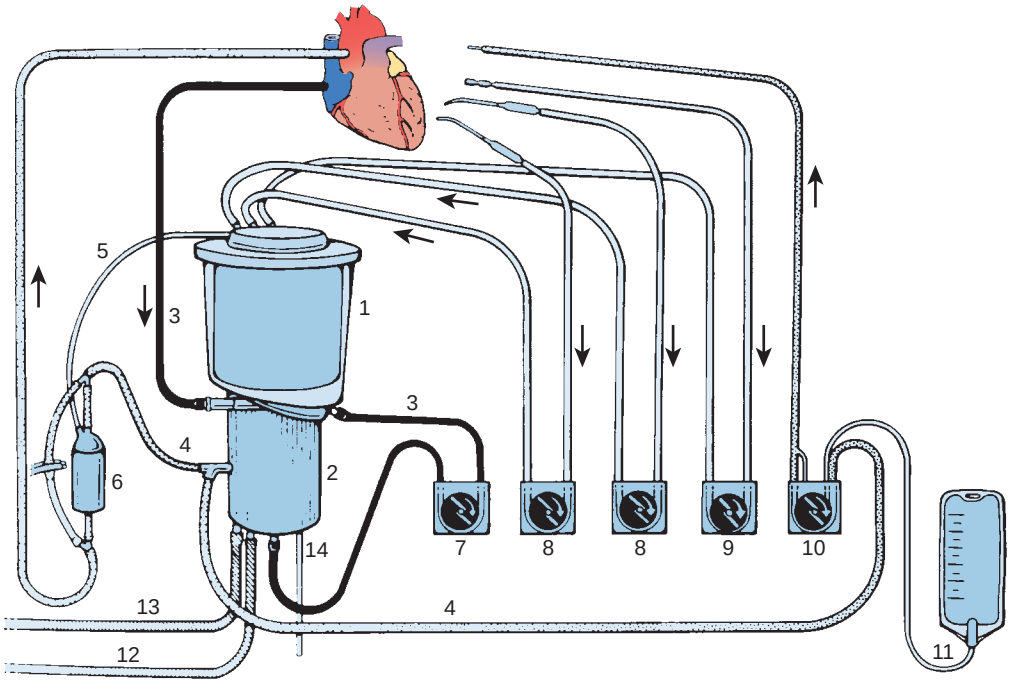

Fig. 31.2 Components of the extracorporeal circuit. *1,* Integral cardiotomy reservoir; *2,* membrane oxygenator bundle; *3,* venous blood line; *4,* arterial blood line; *5,* arterial filter purge line; *6,* arterial line filter; *7,* venous blood pump (also called the arterial pump head; this pump forces venous blood through the membrane oxygenator and arterialized blood to the patient's aortic root); *8,* cardiotomy suction pump; *9,* ventricular vent pump; *10,* cardioplegia pump; *11,* crystalloid cardioplegia; *12,* water inlet line; *13,* water outlet line; and *14,* gas inlet line. *(From Davis RB, Kauffman JN, Cobbs TL, Mick SL.* Cardiopulmonary Bypass. *New York: Springer-Verlag; 1995:239.)*

surgical procedures, with particular emphasis directed at strategies for reducing these injuries.

Central Nervous System Injury

Incidence and Significance of Injury

Central nervous system dysfunction after CPB represents a spectrum of clinical entities ranging from neurocognitive deficits, occurring in approximately 25% to 80% of patients, to overt stroke, occurring in 1% to 5% of patients.[8–11] The significant disparity among studies in the incidence of these adverse cerebral outcomes relates in part to their definition and to numerous methodologic differences in the determination of neurologic and neurocognitive outcomes. Retrospective versus prospective assessments of neurologic deficits account for a significant portion of this inconsistency, as do the experience and expertise of the examiner. The timing of postoperative testing also affects determinations of outcome. For example, the rate of cognitive deficits can be as high as 80% for patients at discharge, between 10% and 35% at approximately 6 weeks after coronary artery bypass grafting (CABG), and 10% to 15% more than a year after surgery. Higher rates of cognitive deficits have been reported 5 years after surgery, when as many as 43% of patients have documented deficits.[9] The issue of whether cardiac surgery causes cognitive loss has been greatly debated. Some have questioned if long-term deficits result as a consequence of surgery,[12] yet, even if only present in the short term, deficits are meaningful to patients and families (see Chapter 40).[13]

Although the incidence of these deficits varies greatly, the significance of these injuries cannot be overemphasized. Cerebral injury is a most disturbing outcome of cardiac surgery. To have a patient's heart successfully treated by the planned operation but discover that the patient no longer functions as well cognitively or is immobilized from a stroke can be devastating. There are enormous personal, family, and financial consequences of extending a patient's life with surgery, only to have the quality of the life significantly diminished.[11,14] Death after CABG, although having reached relatively low levels in the past decade (generally less than 1% overall), is increasingly attributable to cerebral injury.[11]

Risk Factors for Central Nervous System Injury

Successful strategies for perioperative cerebral and other organ protection begin with a thorough understanding of the risk factors, causation, and pathophysiology involved. Risk factors for central nervous system injury can be considered from several different perspectives. Most studies outlining risk factors take into account only stroke. Few describe risk factors for neurocognitive dysfunction. Although it is often assumed that their respective risk factors are similar, few studies have consistently reported the preoperative risks of cognitive loss after cardiac surgery. Factors such as a poor baseline (preoperative) cognitive state, years of education (ie, more advanced education is protective), age, diabetes, and CPB time are frequently described.[15,16]

Stroke is better characterized with respect to risk factors. Although studies differ somewhat as to all the risk factors, certain patient characteristics consistently correlate with an increased risk for cardiac surgery–associated neurologic injury. In a study conducted by the Multicenter Study of Perioperative Ischemia of 2108 patients from 24 centers, incidence of adverse cerebral outcome after CABG surgery was determined and the risk factors were analyzed.[15] Two types of adverse cerebral outcomes were defined. Type I included nonfatal stroke, transient ischemic attack, stupor or coma at time of discharge, and death caused by stroke or hypoxic encephalopathy. Type II included new deterioration in intellectual function, confusion, agitation, disorientation, and memory deficit without evidence of focal injury. A total of 129 (6.1%) of the 2108 patients had an adverse cerebral outcome in the perioperative period. Type I outcomes occurred in 66 (3.1%) of

TABLE 31.1 Risk Factors for Adverse Cerebral Outcomes After Cardiac Surgery

Risk Factor	*Type I Outcomes*	*Type II Outcomes*
Proximal aortic atherosclerosis	4.52 (2.52–8.09)[a]	
History of neurologic disease	3.19 (1.65–6.15)	
Use of IABP	2.60 (1.21–5.58)	
Diabetes mellitus	2.59 (1.46–4.60)	
History of hypertension	2.31 (1.20–4.47)	
History of pulmonary disease	2.09 (1.14–3.85)	2.37 (1.34–4.18)
History of unstable angina	1.83 (1.03–3.27)	
Age (per additional decade)	1.75 (1.27–2.43)	2.20 (1.60–3.02)
Admission systolic BP > 180 mm Hg		3.47 (1.41–8.55)
History of excessive alcohol intake		2.64 (1.27–5.47)
History of CABG		2.18 (1.14–4.17)
Arrhythmia on day of surgery		1.97 (1.12–3.46)
Antihypertensive therapy		1.78 (1.02–3.10)

Differential effects of advanced age on neurologic and cardiac risks of coronary artery operations.* J Thorac Cardiovasc Surg *1992;104:1510–1517.)*

2108 patients, with type II outcomes occurring in 63 (3.0%) of 2108 patients. Stepwise logistic regression analysis identified eight independent predictors of type I outcomes and seven independent predictors of type II outcomes (Table 31.1).

In a subsequent analysis of the same study database, a stroke risk index using preoperative factors was developed (Fig. 31.3). This risk index allowed for the preoperative calculation of the stroke risk based on the weighted combination of the preoperative factors, including age, unstable angina, diabetes mellitus, neurologic disease, previous coronary artery or other cardiac surgery, vascular disease, and pulmonary disease.[14] Of all the factors in the Multicenter Study of Perioperative Ischemia analysis and in multiple other analyses,[11,17–21] age appears to be the most overwhelmingly robust predictor of stroke and of neurocognitive dysfunction after cardiac surgery.[8,9] Tuman and colleagues[21] described that age has a greater impact on neurologic outcome than it does on perioperative myocardial infarction (MI) or low cardiac output states (LCOSs) after cardiac surgery (Fig. 31.4).

The influence of gender on adverse perioperative cerebral outcomes after cardiac surgery has been evaluated. Women appear to be at higher risk for stroke after cardiac surgery than men.[19,22] Hogue and coworkers[23] found that women appear more likely to suffer deficits in the visuospatial cognitive domain after cardiac surgery, although the frequency of cognitive dysfunction after cardiac surgery is similar for women and men.

Another consistent risk factor for stroke after cardiac surgery is the presence of cerebrovascular disease and atheromatous disease of the aorta. With respect to cerebrovascular disease, patients who have had a prior stroke or transient ischemic attack are more likely to suffer a perioperative stroke.[22,24–26] Even in the absence of symptomatic cerebrovascular disease, such as the presence of a carotid bruit, the risk of stroke increases with the severity of the carotid disease. Breslau and associates[27] reported that Doppler-detected carotid disease increased the risk of stroke after cardiac surgery by threefold. Similarly, Brener and colleagues[28] described that a carotid stenosis greater than 50% increased the risk of stroke from 1.9% to 6.3%.

Although the presence of cerebrovascular disease is a risk factor for perioperative stroke, it does not always correlate well with the presence of significant aortic atherosclerosis.[29] Atheromatous disease of the ascending aorta, aortic arch, and descending thoracic aorta has been consistently implicated as a risk factor for stroke in cardiac surgical patients.[30–33] The widespread use of transesophageal echocardiography (TEE) and epiaortic ultrasonography has added new dimensions to the detection of aortic atheromatous disease and the understanding of its relation to stroke risk. These imaging modalities have allowed the diagnosis of atheromatous disease to be made in a more sensitive and detailed manner, contributing greatly to the information regarding potential stroke risk. The risk of cerebral embolism from aortic atheroma was described early in the history of cardiac surgery[34] and has been described repeatedly and in detail since then.[11,35–37] For example, Katz and coworkers[38] found that the incidence of stroke was 25% in patients with a mobile atheromatous plaque in the aortic arch, compared with a stroke rate of 2% in those with limited atheromatous disease. Studies have consistently reported higher stroke rates for

patients with increasing atheromatous aortic involvement (particularly the ascending and arch segments).[39] This relationship is outlined in Fig. 31.5.

Causes of Perioperative Central Nervous System Injury

Because central nervous system dysfunction represents a wide range of injuries, differentiating the individual causes of these various types of injuries becomes somewhat difficult (Box 31.1). They are frequently grouped together and superficially discussed as representing different severities on a continuum of brain injury. This likely misrepresents the different causes of these injuries. The following section addresses stroke and cognitive injury (Table 31.2), and their respective causes are differentiated when appropriate.

Cerebral Embolization

Macroemboli (eg, atheromatous plaque) and microemboli (ie, gaseous and particulate) are generated during CPB, and many emboli find their way to the cerebral vasculature.[40] Macroemboli are responsible for stroke with microemboli being implicated in the development of less severe encephalopathies. Sources for the microemboli are numerous and include those generated de novo from the interactions of blood within the CPB apparatus (eg, platelet-fibrin aggregates) and those generated within the body by the production and mobilization of atheromatous material or entrainment of air from the operative field. Other sources for emboli include lipid-laden debris that can be added by cardiotomy suction.[41] Other gaseous emboli may be generated though injections into the venous reservoir of the CPB apparatus itself.[42,43]

Numerous studies outline the relationship between emboli and cognitive decline after cardiac surgery.[44–46] However, one of the major limitations in understanding this relationship has been the relative inability to discern between gaseous and particulate microemboli.[47] Typically, Doppler ultrasonography has been used to measure cerebral embolic signals, but Doppler cannot reliably distinguish between gaseous and particulate emboli.[48] In addition to using Doppler evidence, Moody and associates[40] performed histologic analyses on brains from cardiac surgical patients and described the presence of millions of cerebral emboli represented as small capillary arteriolar dilations. More recently, the relationship between emboli and cognitive changes has been questioned.[47,49,50]

The impact of aortic atheroma on cognitive decline is incompletely understood. It is widely known from nonsurgical as well as cardiac surgical studies that there is a clear relationship between aortic atheroma and stroke,[30,51–53] but the relationship between cognitive outcome and cerebral atheroma is much less uncertain. Several studies describe different results.[54,55] Whereas some data suggest that cerebral emboli are more likely with a higher degree of atheroma in the ascending aorta,[56] there are no data to demonstrate that these atheroma correspond to cognitive decline.[54] Part of the discordance between these two findings may reflect the limitation of Doppler technology to discriminate between gaseous and particulate emboli, thereby possibly misrepresenting the true cerebral embolic load.[57]

Global Cerebral Hypoperfusion

The concept that global cerebral hypoperfusion during CPB may lead to neurologic and neurocognitive complications originates from the earliest days of cardiac surgery, when significant (in degree and duration) systemic hypotension was a relatively common event. Although

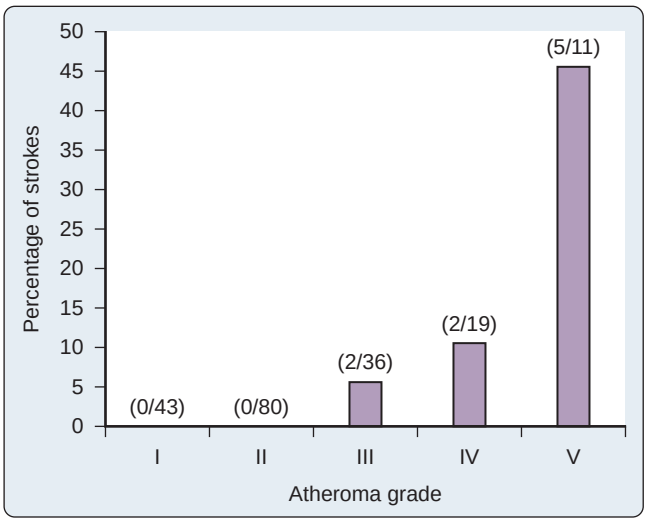

Fig. 31.5 Stroke rate 1 week after cardiac surgery as a function of atheroma severity. Atheroma was graded by transesophageal echocardiography as follows: I, normal; II, intimal thickening; III, plaque < 5 mm thick; IV, plaque > 5 mm thick; V, any plaque with a mobile segment. *(From Hartman GS, Yao FS, Bruefach M 3rd, et al. Severity of aortic atheromatous disease diagnosed by transesophageal echocardiography predicts stroke and other outcomes associated with coronary artery surgery: a prospective study.* Anesth Analg *1996;83:701–708.)*

BOX 31.1 POTENTIAL CONTRIBUTORS TO CENTRAL NERVOUS SYSTEM COMPLICATIONS AFTER CARDIOPULMONARY BYPASS

- Cerebral emboli
- Global hypoperfusion
- Inflammation
- Cerebral hyperthermia
- Cerebral edema
- Blood-brain barrier dysfunction
- Genetics

TABLE 31.2 Potential Contributors to Causes of Cognitive Dysfunction After Cardiac Surgery

Cause	*Possible Settings*
Cerebral microemboli	Generated during cardiopulmonary bypass (CPB); mobilization of atheromatous material or entrainment of air from the operative field; gas injections into the venous reservoir of the CPB apparatus
Global cerebral hypoperfusion	Hypotension, occlusion by an atheromatous embolus leading to stroke
Inflammation (systemic and cerebral)	Injurious effects of CPB, such as blood interacting with the foreign surfaces of pump-oxygenator; upregulation of proinflammatory cyclooxygenase mRNA
Cerebral hyperthermia	Hypothermia during CPB; hyperthermia during and after cardiac surgery, such as aggressive rewarming
Cerebral edema	Edema from global cerebral hypoperfusion or increased cerebral venous pressure from cannula misplacement
Blood-brain barrier dysfunction	Diffuse cerebral inflammation; ischemia from cerebral microembolization
Genetic influences	Effects of single nucleotide polymorphisms on risk for Alzheimer disease or for acute coronary syndromes and other thrombotic disorders

this concept (ie, that hypotension would lead to global cerebral hypoperfusion) makes intuitive sense, studies that have examined the relationship between mean arterial pressure (MAP) and cognitive decline after cardiac surgery have generally failed to show any significant relationship.[16,58,59]

This is not the case for stroke, for which Hartman and investigators[37] and Gold and coworkers[60] demonstrated a link between hypotension and the presence of a significantly atheromatous aorta with an increased risk of stroke (see Fig. 31.5). This is not a clear relationship, however, and likely represents an interaction between macroembolism and global cerebral hypoperfusion. It is likely, for example, that if an area of the brain that is being perfused by a cerebral vessel becomes occluded by an atheromatous embolus, it may be more susceptible to hypoperfusion if collateral perfusion is compromised by concomitant systemic hypotension.[61] Other evidence for global cerebral hypoperfusion comes from Mutch and associates,[62] who examined magnetic resonance imaging (MRI) assessments of cerebral blood flow (CBF) showing progressive decreases in CBF during the course of experimental CPB in pigs. However, clinical demonstrations of a reduction in CBF during lengthy CPB have not been shown.[63]

Temperature-Related Factors

The various trials of hypothermia during CPB with detailed temperature monitoring have also shown that *hyperthermia* can occur during and after cardiac surgery. During rewarming from hypothermic CPB, there can be an overshoot in cerebral temperature due to aggressive rewarming generally aimed at decreasing time on CPB and overall operating room time. This cerebral hyperthermia may well be responsible for some of the injury that occurs in the brain.[64]

The postoperative period is also a critical time in which hyperthermia can contribute to brain injury.[65,66] Grocott and colleagues[65] demonstrated that the peak temperature in the postoperative period (24 hours after surgery) was related to cognitive decline 6 weeks after cardiac surgery. It is not clear whether this hyperthermia causes de novo injury or exacerbates injury that has already occurred (eg, injury that might be induced by cerebral microembolization or global cerebral hypoperfusion). It is necessary to be cautious in concluding whether these relationships are temporal or causal. However, it is assumed that the brain is injured during CPB, and because experimental brain injury is known to cause hyperthermia (resulting from hypothalamic injury[67]), the hyperthermia that is demonstrated in the postoperative period may be caused by the occurrence or extent of brain injury. However, if hyperthermia results from the inflammatory response to CPB, the hyperthermia itself may induce or exacerbate cerebral injury.

Inflammation

Although it is well known that blood interacts with the foreign surfaces of the pump-oxygenator to stimulate a profound inflammatory response,[68] the systemic end-organ effects of this inflammatory response are less clearly defined. Much of the data relating organ dysfunction in the central nervous system to the inflammatory response in the cardiac surgical patient are based on indirect experimental and clinical evidence. It is not clear whether a cerebral inflammatory response occurs as a result of CPB in humans. Hindman and coworkers[69] reported that cyclooxygenase mRNA was upregulated after CPB, suggesting that on the molecular biologic level, CPB induces overexpression of this proinflammatory gene in the brain. What is not clear is whether this was a primary event (ie, as a direct result of the proinflammatory effects of CPB) or a secondary event as a result of other injurious effects of CPB (eg, microembolization). In settings other than cardiac surgery, inflammation has been demonstrated to directly injure the brain (eg, sepsis-mediated encephalopathy),[70] but it is also known to result as a response to various cerebral injuries (eg, ischemic stroke).[71]

There is no direct evidence that inflammation causes cardiac surgery-associated adverse cerebral outcome; however, there is some supportive indirect evidence. For example, Mathew and investigators[72] demonstrated a relationship between poor cognitive outcome and an impaired immune response to circulating endotoxin, which inevitably translocates from the gut into the bloodstream as a result of alterations in splanchnic blood flow during CPB. Having a low antibody response to circulating endotoxin is paradoxically associated with an overstimulated inflammatory response,[73] thus demonstrating that the relationship between low endotoxin antibodies and poor cognitive outcome may be mediated by an augmented inflammatory response. There is increasing genetic evidence linking inflammation to adverse cerebral outcomes, both stroke and cognitive loss (see "Genetic Influences").

Cerebral Edema

Cerebral edema after CPB has been reported in several studies.[74,75] The explanation for why cerebral edema may occur early in the period after bypass is not clear. It may be caused by cytotoxic edema resulting from global cerebral hypoperfusion or possibly by hyponatremia-induced cerebral edema. Generalized cerebral edema due to increases in cerebral venous pressure caused by cannula misplacement, which frequently occurs during CPB, is another reason.[76] Specifically, use of a dual-stage venous cannula can often lead to cerebral venous congestion during the vertical displacement of the heart during access to the lateral and posterior epicardial coronary arteries. It is not clear from these studies whether the edema results because of injury that occurs during CPB, leading to cognitive decline, or whether the edema itself directly causes the injury by consequent increases in intracranial pressure with global or regional decreases in CBF and resulting ischemia. As both technology for CPB and our understanding of physiologic management improve, the occurrence of CPB-related cerebral edema becomes less likely. [77]

Blood-Brain Barrier Dysfunction

The function of the blood-brain barrier (BBB) is to aid in maintaining the homeostasis of the extracellular cerebral milieu protecting the brain against fluctuations in various ion concentrations, neurotransmitters, and growth factors that are present in the serum.[78] The impact of CPB on the function and integrity of the BBB is not clearly known. Gillinov and colleagues[79] were unable to show any changes in BBB dysfunction 2 hours after CPB in piglets as assessed using carbon 14–aminoisobutyric acid tracer techniques in post-bypass brain homogenates. However, Cavaglia and coworkers,[80] measuring the leakage of fluorescent albumin from blood vessels in brain slices after CPB, were able to demonstrate significant breaches in the BBB. Both studies looked at a single time point (ie, immediately after CPB), and it is not known whether there are temporal changes in the BBB integrity.

It is difficult to determine whether the changes in BBB integrity, if present at all, are a primary cause of brain dysfunction or simply a result of other initiating events such as ischemia (ie, from cerebral microembolization) or a diffuse cerebral inflammatory event. Changes in the BBB could cause some of the cerebral edema that has been demonstrated, or it could result from cerebral edema if the edema resulted in ischemic injury (from increases in intracranial pressure).[75]

Possible Pharmacologic Influences

Anesthetics have been demonstrated to affect cognitive loss after surgery. Experimental studies of cognitive outcome in young rats exposed to anesthetics have demonstrated that relatively brief (several hours) exposure to isoflurane can lead to long-term cognitive changes in the animals.[81,82] Coupled with the demonstration in other experimental models of necrosis in neonatal brains exposed to certain anesthetic agents (eg, isoflurane, midazolam, nitrous oxide),[83] these data suggest that corresponding proteomic changes can occur in the brain after exposure to anesthetics,[84] and the investigators highlighted this as a potential area for further research.

Genetic Influences

Genetics may play a role in modifying the degree of central nervous system injury or in the ability of the brain to recover after an injury has occurred. Several investigations have assessed the genetic influences

on cerebral outcome after CPB. The most commonly explored gene variant, or single nucleotide polymorphism (SNP), has been the ε4 allele of the apolipoprotein gene. This gene has been reported to be responsible for increasing the risk of sporadic and late-onset Alzheimer disease (as well as complicating outcome after a variety of other head injuries).[85] Although early reports suggested that this may be an important influence,[86] later reports shed some doubt on how robust this effect is.[87] A second SNP examined relates to the PLA2 receptor polymorphism. This platelet integrin receptor polymorphism is important in the cause of acute coronary syndromes and other thrombotic disorders.[88,89] A small study of patients undergoing cardiac surgery demonstrated worse impairments in the mini–mental state examination in the PLA2-positive patients compared with PLA2-negative patients.[90]

With the multitude of genes that may play a role in injury, it is important to go beyond examining the impact of single SNPs and explore the impact of multiple SNPs, alone or in combination. In a study of 2140 patients examining 26 different SNPs, the presence of the minor alleles of C-reactive protein (CRP) and interleukin (IL)-6 had a threefold increase in the risk of stroke after cardiac surgery.[91] Of note, no single (or combination of) prothrombotic genes were associated with stroke, suggesting that inflammatory, as opposed to thrombotic, mechanisms may be more important to the risk of a stroke.

With respect to cognitive dysfunction after cardiac surgery, a study by Mathew and associates[92] outlined the impact of genetics on outcome after cardiac surgery. In this study of 513 patients who were extensively genotyped (30 SNPs) and had cognitive testing after cardiac surgery, a link between SNPs of CRP and P-selectin (CRP1059G4/C and SELP1087G/A) and a reduction in cognitive deficit were found. The incidence of cognitive deficit was 16.7% in carriers of the minor alleles of both of these genes compared to 42.9% of the patients possessing these major alleles. Unique in this study was the mechanism-based genetic effect where these polymorphisms were also associated with reductions in both CRP and platelet activation, suggesting that an attenuation of perioperative inflammatory and prothrombotic states may be beneficial with respect to reducing cognitive deficits after cardiac surgery.[93]

Neuroprotective Strategies

Emboli Reduction

There are multiple sources of particulate and gaseous emboli during cardiac surgery. Within the CPB circuit itself, particulate emboli in the form of platelet-fibrin aggregates and other debris are generated. Gaseous emboli can be created in the circuit or augmented if already present by factors such as turbulence-related cavitation and potentially even by vacuum-assisted venous drainage.[94] Air in the venous return tubing is variably handled by the bypass circuit (ie, reservoir, oxygenator, and arterial filters). The ability of the circuit to prevent the transit of gaseous emboli through the oxygenator varies considerably between manufacturers and remains a significant source of emboli. The impact of perfusionist interventions on cerebral embolic load has also been studied. Borger and colleagues[43] found that after drug injections into the venous reservoir, gaseous emboli can make a rapid passage through to the arterial outflow. Reducing these perfusionist interventions reduced emboli generation and neurocognitive impairment.

Significant quantities of air can be entrained from the surgical field into the heart itself; flooding the field with carbon dioxide has been proposed as being effective in reducing this embolic source.[95] Its ability to specifically reduce cerebral injury has not been rigorously evaluated although it has been demonstrated to significantly reduce the amount of TEE-detectable bubbles in the heart after cardiac surgery.[96] Even with the use of carbon dioxide in the surgical field, significant amounts of entrained air can be present. Although the oxygenator-venous reservoir design attempts to purge this air before reaching the inflow cannula, the arterial line filter handles a great deal of what is left. The capacity of the arterial filter to remove all sources of emboli (gaseous or particulate) has significant limitations, and, despite its use, emboli can easily pass through and on into the aortic root.

The aortic cannula may be very important to reduce cerebral emboli production. Placement of the cannula into an area of the aorta with a large atheroma burden may cause the direct generation of emboli from the "sandblasting" of atherosclerotic material in the aorta.[97] The use of a long aortic cannula, where the tip of the cannula lies beyond the origin of the cerebral vessels has also been found to reduce emboli load.[98] The type of cannula itself may be an important factor. Various designs have allowed the reduction of various sandblasting-type jets emanating from the aortic cannula. Baffled cannulas and cannulas that allow the incorporation of regional brain hypothermia and diversion of emboli away from the cerebral vessels have been investigated.[99] A cannula that has a basket-like extension that can be inserted just before cross-clamp removal has also been studied.[100] However, in a large (N = 1289) study, this Embol-X cannula was unable to reduce the incidence of central nervous system dysfunction.[101] A smaller (N = 24) study paradoxically showed an increase in embolic signals with its deployment in the aorta.[102] This has been because of air bubbles trapped within the basket or abrasion of the atheromatous aortic wall. Few other emboli-reducing strategies have been studied sufficiently to determine their impact on cognitive loss after cardiac surgery. The safety of introducing new techniques also has not been thoroughly studied; the additional risk assumed when significantly altering a standard of practice to use a new device must be considered.

Blood that is returned from the surgical field though the use of the cardiotomy suction may significantly contribute to the particulate load in the CPB circuit and subsequently in the brain. The use of cell-salvage devices to process shed blood before returning it to the venous reservoir may minimize the amount of particulate- or lipid-laden material that contributes to embolization.[41,42] Most of this material is small enough or so significantly deformable (because of its high lipid content) that it can pass through standard 40-μm arterial filters. There are several issues with the cell saver, however. One is the cost that is incurred with its use, and the other is its side effects of reducing platelet and coagulation factors through its intrinsic washing processes. Modest use of cell salvage up to a certain, although as yet undefined, volume of blood is likely prudent. Despite this rationale, the results from studies examining neurologic outcome have shown variable effects of cell-saver use on cognitive outcome. A study by Djaiani and colleagues[103] demonstrated a benefit whereas a study by Rubens and coworkers[104] did not. This may have been because of differences in cell savers used that likely varied in their ability to remove lipid emboli.

Management of Aortic Atherosclerosis

The previous section dealt with issues related to reduction of emboli, many of which are likely spawned from atheromatous plaque in the aorta. Further specific management of the atheromatous aorta, particularly as it relates to stroke risk, requires special attention. The widespread use of TEE and complementary (and preferably routine) epiaortic scanning has contributed greatly to the understanding of the risks involved in managing patients with a severely atheromatous aorta. There is indisputable evidence linking stroke to atheroma.[30,51–53] However, the strength of association between atheroma and cognitive decline seen after cardiac surgery is less clear.

A small study used a combination of epiaortic scanning and atheroma avoidance techniques (with respect to cannulation, clamping, and vein graft anastomosis placement) to attempt to reduce neurocognitive deficits.[55] In that study, the incidence of cognitive decline was lower in patients who had an avoidance technique guided by epiaortic scanning compared with no epiaortic scanning. It was limited by its small size, but it identified an area that requires more investigation. Others have examined this issue and found the relationship between cognitive decline and atheroma to be doubtful.[105] Regardless of whether atheroma causes cognitive dysfunction, their contribution to cardiac surgery-associated stroke is enough to warrant specific strategies for management.

One of the difficulties in interpreting studies that have evaluated atheroma avoidance strategies is the absence of any form of blinding of the investigators. For the most part, a strategy is chosen based on

the presence of known atheroma, and the results of these patients are compared with historic controls. What constitutes the best strategy is unclear. Multiple techniques can be used to minimize atheromatous material liberated from the aortic wall from getting into the cerebral circulation. These range from optimizing placement of the aortic cannula in the aorta to an area relatively devoid of plaque to the use of specialized cannulas that reduce the sandblasting of the aortic wall. The use of alternative aortic cannulas and different locations may decrease embolization of atheromatous plaque. The avoidance of partial occlusion clamping for proximal vein graft placement by performing all of the anastomoses in a single application of an aortic cross-clamp has demonstrated a benefit.[106] Specialized cannulas that contain filtering technologies[100] and other means to deflect emboli to more distal sites have been developed and studied.[107] Technology is advancing rapidly, and proximal (and distal) coronary artery anastomotic devices are becoming increasingly available and focus on minimizing manipulation of the ascending aorta. None of these aortic manipulations has yet yielded significant neuroprotective results in large, prospective, randomized trials, but their potential holds promise.

Pulsatile Perfusion

A large body of literature has accumulated comparing the physiology of pulsatile with nonpulsatile perfusion.[108,109] Nevertheless, it remains uncertain whether pulsatile CPB has shown substantive clinical improvement in any outcome measure compared with standard, nonpulsatile CPB. Table 31.3, although by no means complete, represents this highly contradictory body of literature.[110–139] Claims of advantages to pulsatile flow are effectively offset by conflicting studies of similar design.

Nonpulsatile CPB is the most commonly practiced form of artificial perfusion. As intuitive as it may seem that this type of nonphysiologic, nonpulsatile pump flow could be injurious, there is an overall lack of data to suggest that using pulsatile flow during clinical CPB has a neurologic benefit. In a large (N = 316), double-blind, randomized investigation by Murkin and coworkers[140] examining the effect of pulsatile versus nonpulsatile CPB on neurologic and neuropsychologic outcomes, no significant benefit was demonstrated. One study of balloon pump–induced pulsatile perfusion during CPB failed to show any improvements in jugular venous oxygen saturation of regional brain oxygenation.[141] A significant limitation to most pulsatility studies is that, because of technical limitations, true "physiologic" pulsatility is almost never accomplished. Instead, variations of sinusoidal pulse waveforms are produced that do not replicate the kinetics and hydrodynamics of normal physiologic pulsation. A somewhat dated review by Hickey and associates,[109] published in 1983, offered important criticism and insight into this controversy and remains germane to recent reports. A fundamental difference between pulsatile and nonpulsatile flow is that additional hydraulic energy is required and applied to move blood when pulsatile flow is used. This extra kinetic energy is known to improve red blood cell transit, capillary perfusion, and lymphatic function.[135] The hydraulic power of pulsatile flow is the sum over time of the product of instantaneous pressure and instantaneous flow. CPB may influence many of the properties of the blood (viscosity) and the vasculature itself (arterial tone, size, and geometry) as a result of hemodilution, hypothermia, alteration of red blood cell deformability, and redistribution of flow. As a result of these changes, generation of what appears to be a normal pulsatile *pressure* waveform may not result in a normal pulsatile *flow* waveform. Simply reproducing pulsatile pressure is not sufficient to ensure reproduction of pulsatile flow, nor does it allow quantification of energetics.

Virtually no study has quantified the energetics of the pulsatile or nonpulsatile perfusion used. Few studies report representative pressure waveforms.[110–115] Even fewer give flow waveforms.[136,137] When pulsatile flow is not quantified, critical features such as vascular impedance and the hydraulic power delivered cannot be evaluated (ie, whether the pulsatile perfusion used in a particular study was really delivering more hydraulic power than the nonpulsatile perfusion with which it is compared). Grossi and investigators[137] developed two indices of pulsatility: the pulsatility index (PI), which quantitates the relative sharpness of a given waveform with respect to its mean flow, and the pulse power index (PPI), which quantifies the power of a pulsatile waveform compared with nonpulsatile equal flow. They found that despite use of a computer-controlled pulsatile pump, in every case PI or PPI was considerably less than control (non-bypass pulsatility). Only with specific combinations of pulse rate and pulsatile flow contours (which had high PI or PPI) was lactate production lower than the nonpulsatile perfusion at the same minute flow during pulsatile CPB. This study indicates that not all pulsatile perfusion is the same and that pulsatile modes are not necessarily capable of improved perfusion relative to nonpulsatile systems.

It is therefore not surprising that such a wide disparity of results should occur. We are unaware of any human study in which pulsatility has been quantitated in terms other than pulse pressures. Consequently, whether the generated pressure waveform is a sine wave or some other pattern cannot be ascertained.[115,116,119,121–125,128–130] The comparatively small size of the arterial inflow cannula can effectively filter out a large component of the pulsatile kinetic energy. Consequently, as achieved clinically, pulsatile flow may be quite similar energetically to nonpulsatile flow.

Newer pulsatile technologies may better reproduce the normal biologic state of cardiac pulsatility. Computer technologies that allow creating a more physiologic pulsatile perfusion pattern have demonstrated, at least experimentally, preservation of cerebral oxygenation. This approach showed some promise in a pig model of CPB in which pulsatile flow controlled by a computer to replicate the normal biologic variability in pulsatility was associated with significantly lower jugular venous oxygen desaturation during rewarming after hypothermic CPB.[142] However, most studies do not present convincing evidence to suggest that routine pulsatile flow during CPB, as can be achieved by widely available technology, is warranted.

Acid-Base Management: Alpha-Stat Versus pH-Stat

Optimal acid-base management during CPB has long been debated. Theoretically, alpha-stat management maintains normal CBF autoregulation with the coupling of cerebral metabolism ($CMRO_2$) to CBF, allowing adequate oxygen delivery while minimizing the potential for emboli. Although early studies[140] were unable to document a difference in neurologic or neuropsychologic outcome between the two techniques, later studies showed reductions in cognitive performance when pH-stat management was used, particularly in cases with prolonged CPB times.[143] pH-Stat management (ie, CO_2 is added to the oxygenator fresh gas flow) results in a higher CBF than is needed for the brain's metabolic requirements. This luxury perfusion risks

excessive delivery of emboli to the brain. Except for congenital heart surgery, for which most outcome data support the use of pH-stat management[144,145] because of its improvement in homogenous brain cooling before circulatory arrest, adult outcome data support the use of only alpha-stat management.

Temperature and Rewarming Strategies

The use of some hypothermia remains a mainstay of perioperative management in the cardiac surgical patient. Its widespread use relates to its putative, although not definitively proved, global organ protective effects. Although hypothermia has a measurable effect on suppressing cerebral metabolism (approximately 6% to 7% decline per 1°C),[146] it is likely that its other neuroprotective effects may be mediated by nonmetabolic actions. In the ischemic brain, for example, moderate hypothermia has multimodal effects, including blocking the release of glutamate,[147] reducing calcium influx,[148] hastening recovery of protein synthesis,[149] diminishing membrane-bound protein kinase C activity,[150] slowing the time to onset of depolarization,[151] reducing formation of reactive oxygen species,[152] and suppressing nitric oxide synthase activity.[153] Some or all of these effects in combination may convey some of the neuroprotective effects of hypothermia. Although experimental demonstrations of this are abundant, clinical examples of hypothermia neuroprotection have been elusive.[154–159]

Some of the most meaningful data on CPB temperature and cerebral outcome came from work that had its origins in the late 1980s and early 1990s. It was at that time the judicious use of warm CPB was tried because of its putative myocardial salvaging effects when used with continuous warm cardioplegia.[160–163] However, because CPB was being carried out at higher temperatures than what were considered conventional, the implications on the brain were also studied. Several large studies have been undertaken to elucidate the effects of temperature management on cerebral outcome after cardiac surgery. The Warm Heart Investigators trial,[160] a trial performed at Emory University,[164] and a later trial at Duke University,[165] although having several methodologic differences, had very similar results with respect to neurocognitive outcome[166,167] but some very divergent results with respect to stroke. None of the studies, or studies performed since, demonstrated any neuroprotective effect of hypothermia on neurocognitive outcome after cardiac surgery. However, the Emory trial did demonstrate an apparent injurious effect (as manifest by a worse stroke outcome) of what was most likely mild degrees of hyperthermia during CPB. Neither the Warm Heart Investigators trial nor the Duke trial showed any effect of temperature on stroke per se. These data suggest that active warming to maintain temperatures at (or greater than) 37°C may pose an unnecessary risk of stroke.

Just as hypothermia has some likely protective effects on the brain, hyperthermia, in an opposite and disproportionate fashion, has some injurious effects. Although the studies referred to previously[160,164,165] demonstrated no neuroprotective effect, there is emerging evidence that if some degree of neuroprotection is afforded by hypothermia, it may be negated by the obligatory rewarming period that must ensue.[64] Grigore and colleagues[64] demonstrated in a prospective trial that compared with conventional "fast" rewarming, slower rewarming resulted in a lower incidence of neurocognitive dysfunction 6 weeks after cardiac surgery. These lower rewarming rates led to lower peak cerebral temperatures during rewarming, consistent with past observations that rapid rewarming can lead to an overshoot in cerebral temperature resulting in inadvertent cerebral hyperthermia.[168] By reducing this rewarming rate, it reduces the overshoot in temperature and prevents the negative effects of cerebral hyperthermia. Consistent with the concept that preventing some of the rewarming may be protective was a study by Nathan and coworkers[169] that demonstrated an intermediate-term (3 months) neurocognitive benefit for patients who were maintained between 34°C and 36°C for a prolonged (12 hours) period postoperatively. That trial may have had its beneficial effect by the avoidance of cerebral hyperthermia during rewarming rather than the prolonged hypothermia.[169] However, the 5-year follow-up rate did not show a sustained benefit.[170]

Although there are numerous sites for monitoring temperature during cardiac surgery, several warrant special consideration. One of the lessons learned from the three warm versus cold trials, as well as from other information regarding temperature gradients between the CPB circuit, nasopharynx, and brain,[168] is that it is important to monitor (and use as a target) a temperature site relevant to the organ of interest. If it is the body, a core temperature measured in the bladder, rectum, pulmonary artery, or esophagus is appropriate. However, if the temperature of the brain is desired, barring implantation of a thermistor directly into the brain (which has been done),[171] it is important to look at surrogates of brain temperature. These include nasopharyngeal temperature and tympanic membrane temperature. More invasive surrogates of brain temperature have been obtained using a jugular bulb thermistor.[168,172] Testing these different temperature sites has demonstrated that vast temperature gradients appear across the body and across the brain. It is likely that during periods of rapid flux (eg, during rewarming), these temperature gradients are maximal.

The previous discussion is reflected in the latest guidelines on cardiac surgery–related temperature management that have been jointly published by The Society for Thoracic Surgeons and the Society for Cardiovascular Anesthesiologists.[173]

Mean Arterial Pressure Management During Cardiopulmonary Bypass

The relationship between blood pressure during CPB and CBF is pertinent to understanding whether MAP can be optimized to reduce neurologic injury. Tables 31.4 and 31.5 outline some of the pertinent studies regarding the relationship (or lack thereof) between blood pressure and neurologic outcome. Plochl and associates[174] examined the

lower threshold of the autoregulatory curve in dogs whereby further lowering blood pressure would result in inadequate CBF and oxygen delivery during CPB. In that study, the brain became perfusion pressure dependent below 50 mm Hg. The investigators also demonstrated that hypothermia did not shift this threshold leftward. Clinically, the available data suggest that in an otherwise normal patient, CBF during nonpulsatile hypothermic CPB using alpha-stat blood gas management is largely independent of MAP as long as that MAP is within or near the autoregulatory range for the patient (ie, 50–100 mm Hg).[175] Although the autoregulatory curve is traditionally considered a horizontal plateau, this plateau has a slightly positive slope, but this slight upward slope is unlikely to have a significant clinically meaningful effect. For example, Newman and investigators[16] demonstrated that under hypothermic conditions, CBF changes only 0.86 mL/100 g per minute for every 10–mm Hg change in MAP. Although this change (1.78 mL/100 g per min) was greater with normothermia,[176] these changes represent a relatively small fraction of the normal CBF of approximately 50 mL/100 g per minute. Underlying essential hypertension as a comorbidity, however, likely includes a rightward shift in the autoregulatory curve. The degree to which this rightward shift occurs, is not clear, but it would be reasonable to expect that it is at least 10 mm Hg, suggesting that the lower range of autoregulatory blood flow is more likely to be 60 than 50 mm Hg.[177] In addition, diabetes may lead to autoregulatory disturbances that make CBF more pressure passive than nondiabetics.[178,179]

Although the data relating MAP to neurologic and neurocognitive outcome after CABG surgery are inconclusive, most data suggest that MAP during CPB is not the primary predictor of cognitive decline or stroke after cardiac surgery. However, with increasing age, MAP during CPB may play a role in improving cerebral collateral perfusion to regions embolized, improving neurologic and cognitive outcome.[16]

Gold and colleagues[60] added significantly to the understanding of the influence of perfusion pressure on outcome after cardiac surgery in a study of 248 patients randomized to low (50–60 mm Hg) or high (80–100 mm Hg) MAP during CPB. Although a difference was demonstrated in their composite end point of combined adverse cardiac and neurologic outcome (4.8% high vs 12.9% low; $P = .026$), when the individual outcomes were compared, there were similar trends but no statistical differences. A secondary analysis of the same data performed by Hartman and coworkers[37] found interesting interactions among pressure, aortic atheroma, and stroke; patients who were at risk of cerebral embolic stroke (from having severely atheromatous aortas) were more likely to manifest a stroke if MAP was maintained in the lower range than in the higher range. Intuitively, this is logical. Some experimental data in the noncardiac surgical setting suggest that collateral perfusion to penumbral areas of brain suffering from ischemic injury are relatively protected by higher perfusion pressure.[61] Overall, it appears that MAP (in the normal range) has little effect on cognitive outcome, but in those with significant aortic atheroma, it may be prudent to modestly increase blood pressure.

Rather than choosing a specific or fixed (and arguably arbitrary) blood pressure threshold based on the conflicting preceding data, a more prudent approach may be to individualize the blood pressure targets based on the emerging concept of cerebral oximetry–based real-time physiologic feedback. Technologies such as near-infrared spectroscopy-based cerebral oximetry have played an important role in guiding this approach. This may allow for the determination of individual autoregulatory-driven blood pressure targets. For example, Ono and associates recently reported that the magnitude and duration of blood pressure below an individual's autoregulatory threshold was associated with major postoperative morbidity after cardiac surgery.[180] In a similar manner, managing blood pressures below an individual's lower cerebral autoregulatory limits were shown to be associated with an increased incidence of acute kidney injury,[181] as were blood pressures above the upper autoregulatory threshold with delirium.[182] This also highlights the ability of cerebral oximetry to potentially inform surgeons about noncerebral outcomes.

Glucose Management

Hyperglycemia is a common occurrence during the course of cardiac surgery. Administration of cardioplegia containing glucose and stress response–induced alterations in insulin secretion and resistance increase the potential for significant hyperglycemia.[183] Hyperglycemia has been repeatedly demonstrated to impair neurologic outcome after experimental focal and global cerebral ischemia.[184–186] The explanation for this adverse effect likely relates to the effects that hyperglycemia has on anaerobic conversion of glucose to lactate, which ultimately causes intracellular acidosis and impairs intracellular homeostasis and metabolism.[187] A second injurious mechanism relates to an increase in the release of excitotoxic amino acids in response to hyperglycemia in the setting of cerebral ischemia.[185] If hyperglycemia is injurious to the brain, the threshold for making injuries worse appears to be 180 to 200 mg/dL.[188,189]

Despite much experimental data, the role of glucose management on cerebral outcome after clinical CPB is not clear. Although Hindman and others[190] caution about the use of glucose-containing prime for CPB, Metz and Keats[191] did not find a difference in neurologic outcome in patients undergoing CPB with a glucose prime (blood glucose during CPB of 600–800 mg/dL) versus no glucose prime (blood glucose level of 200–300 mg/dL). This finding was supported by Nussmeier and colleagues,[192] who reported that use of a glucose-containing prime was not a risk factor for cerebral injury in nondiabetic or diabetic patients undergoing CABG procedures. In the largest retrospective review, outcome data from 2862 CABG patients showed no association between the intraoperative maximum glucose concentration and major adverse neurologic outcome or in-hospital mortality.[193,194]

The appropriate type of perioperative serum glucose management and whether it adversely affects neurologic outcome in patients undergoing CPB remain unclear. The major difficulty in hyperglycemia treatment is the relative ineffectiveness of insulin therapy. Using excessive amounts of insulin during hypothermic periods may lead to rebound hypoglycemia after CPB. Chaney and coworkers[195] attempted to maintain normoglycemia during cardiac surgery with the use of an insulin protocol and came to the conclusion that even with aggressive insulin treatment, hyperglycemia is often resistant and may actually predispose patients to postoperative hypoglycemia. This concern over potentially increasing adverse effects by exerting tight glycemic controls has reportedly been supported.[196,197] Attempting to mediate injury may predispose patients to additional injury.

Off-Pump Cardiac Surgery

Off-pump coronary artery bypass (OPCAB) surgery is frequently used for the operative treatment of coronary artery disease (see Chapter 20). Although its ability to optimally treat coronary disease (through the demonstration of long-term graft patency) has not yet been shown in a long-term, prospective, randomized, controlled fashion, it is clear that OPCAB and similar operations (eg, minimally invasive direct coronary artery bypass) will continue to be mainstays of cardiac surgery, although in an evolving fashion. Their impact on adverse cerebral outcomes after cardiac surgery has been variably reported.[198]

Although early data suggested less cognitive decline after OPCAB procedures, most studies have not seen it eliminated altogether. The reasons for this are unclear but likely reflect the complex pathophysiology involved. For example, if inflammatory processes play a role in initiating or propagating cerebral injury, OPCAB, with its continued use of sternotomy, heparin administration, and wide hemodynamic swings, all of which may contribute to a stress and inflammatory response, may be a significant reason why cognitive dysfunction is still seen. Ascending aortic manipulation, with its ensuing particulate embolization, is also still commonly used.

The results of the largest OPCAB study by Van Dijk and associates[199] to examine cognitive dysfunction showed that although there was a reduction in cognitive decline in the early months after surgery, at 1 year,[200] and even at 5 years,[170] there were no differences between groups. In a subset of patients from this study, jugular bulb saturation was examined. More desaturation (indicative of ischemia risk to the

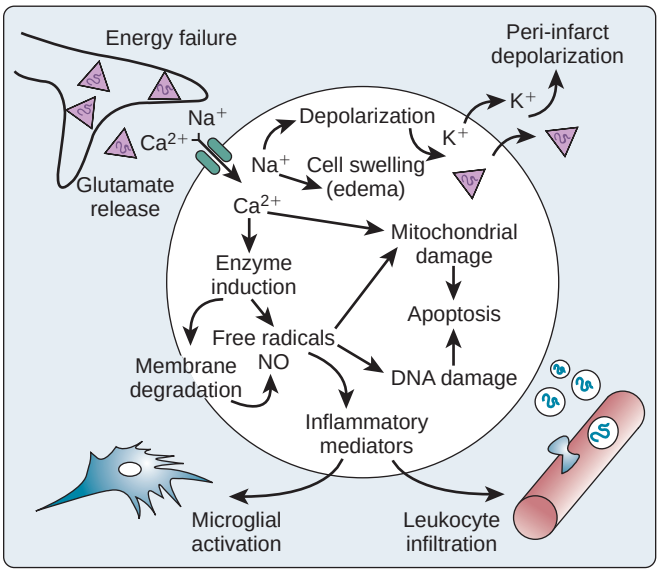

Fig. 31.6 Cerebral ischemic cascade. A simplified overview of central nervous system events that occur after energy failure in the ischemic brain. *(From Dirnagl U, Iadecola C, Moskowitz M. Pathobiology of ischemic stroke: an integrated review.* Trends Neurosci *1999;22:391–397.)*

brain) was seen in the OPCAB group. This may have been due to the low cardiac output that can be seen during manipulation of the heart, as well as jugular venous hypertension.[201] The effects of OPCAB on stroke risk have not been sufficiently analyzed, but one meta-analysis showed no beneficial effect on the incidence of stroke.[198]

Pharmacologic Neuroprotection

In addition to the improvements in CPB technology, knowledge of the molecular workings of the brain has improved significantly, revealing potential pharmacologic neuroprotective targets. The oversimplified concept that depletion of high-energy phosphates and destruction of brain tissue rapidly follow ischemia has been replaced by a considerably more complex temporal, topographic, and biochemical picture. Advanced imaging techniques have discovered spatial gradations of residual CBF in the downstream territory of an occluded cerebral vessel producing an ischemic penumbra, where CBF is critically reduced but still sufficient to prevent immediate cell death. There is a marked difference in the temporal association between the ischemic insult and eventual cell death, resulting in a therapeutic window in which intervention (particularly pharmacologic) may attenuate infarct size. This window differs between the profoundly ischemic core and the penumbra. In the ischemic core, restoration of oxygen and glucose supplies is essential where high-energy phosphates have been severely depleted. In contrast, in the penumbra, the decrease in oxygen and glucose delivery is insufficient to kill cells directly. In these regions, pharmacologic agents with little or no ability to modify CBF have been shown experimentally to effectively reduce cerebral infarct volume, even if administered after the onset of permanent focal ischemia.

The central nervous system ischemic cascade (Fig. 31.6) is triggered by reductions in CBF, globally or regionally, to the point at which the demands of cerebral metabolism can no longer be met.[202] This depletion in cerebral energy stores leads to membrane ionic pump failure, resulting in a number of injurious events mediated by the influx of sodium, the opening of voltage-dependent calcium gates, a release of stored intracellular calcium, and overall membrane depolarization. Membrane depolarization results in the release of excitatory amino acids (eg, glutamate, aspartate), with subsequent dramatic increases in intracellular calcium. This increase in cytoplasmic calcium propagates the cascade through the activation of a number of calcium-dependent enzymes, including endonucleases, nitric oxide synthase, various proteases, protein kinases, and phospholipases. If left unabated, these enzymes will result in neuronal death.

Although some of these events are potentially reversible if reperfusion is quickly reestablished, reperfusion itself initiates a number of other destructive pathways. The reestablishment of oxygen delivery provides substrate for the production of reactive oxygen species, so-called free radicals. Reperfusion initiates a number of other damaging extracellular events, including BBB breakdown, endothelial swelling, and localized thrombosis that together may culminate in microvascular occlusion and further ischemia. Each of these pathways in the ischemic cascade represents discrete groups of potential targets for neuroprotection. The ischemic cascade has formed the basis for the initiation of pharmacologic neuroprotective strategies in the setting of overt stroke and of cardiac surgery–related cerebral injury.

No pharmacologic therapies have been approved by the US Food and Drug Administration or foreign regulatory agencies for the prevention or treatment of cardiac surgery–associated cerebral injury, despite numerous previous investigations of specific pharmacologic agents in this setting (Table 31.6). The failure to discern any single compound that might protect the brain is not unique to cardiac surgery. With the exception of thrombolysis, there are no other therapies in the general medical field either.[203] However, understanding these failures is as important as any successes as it can refocus attention to pathways incompletely investigated.

The following discussion addresses many of the principal drugs that have been investigated in the setting of cardiac surgery.

TABLE 31.6 Agents Studied as Pharmacologic Neuroprotectants During Cardiac Surgery

Agent	*Study Reference*
Thiopental	57
Propofol	200
Acadesine	205
Aprotinin	209, 210
Nimodipine	220–222
GM_1 ganglioside	223
Dextromethorphan	225
Remacemide	225
Lidocaine	230
β-Blockers	232
Pegorgotein	235
C5 complement inhibitor (pexelizumab)	237
Lexiphant (platelet-activating factor antagonist)	239
Clomethiazole	244
Ketamine	251

Thiopental

Thiopental was one of the first agents investigated as a potential neuroprotective agent for patients undergoing cardiac surgery. In a study by Nussmeier and colleagues,[58] thiopental was administered (until electroencephalographic [EEG] isoelectricity was obtained) before cannulation and continued until separation from CPB. In this study, neurologic complications on postoperative day 10 were significantly reduced in the thiopental group versus controls. Based on the encouraging results of this trial, high-dose thiopental was frequently used for valvular and other open ventricular procedures. The proposed mechanism of this effect related to the suppressive effects of barbiturates on cerebral metabolism. This mechanism, along with experimental data reporting the beneficial effects of the barbiturates,[204] made it a logical choice for cardiac surgery. However, results of additional investigations of the use of thiopental were not as positive. A study by Pascoe and coworkers[205] and one by Zaidan and coworkers[206] failed to support a beneficial effect of thiopental on neurologic outcome after cardiac surgery. These negative trials and the side effects of prolonged sedation with barbiturates served to quell the optimism for barbiturates. Retrospectively examining the initial Nussmeier study,

the beneficial effects of the thiopental might not have been related to a direct neuroprotective effect but to an indirect effect on reducing emboli. The well-known cerebral vasoconstricting effects of thiopental (matching CBF with a barbiturate-induced reduction in $CMRO_2$) may have resulted in a reduction in embolic load to the brain during CPB and as a result, a beneficial effect on neurologic outcome. It has subsequently been shown that isoelectricity itself is not necessary to incur a neuroprotective benefit from barbiturates.[207] Evaluations of sub-isoelectric doses of thiopental have not been performed.

Propofol

Propofol has effects similar to those of thiopental on $CMRO_2$ and CBF and has some antioxidant and calcium channel antagonist properties.[208] Along with supportive data from experimental cerebral ischemia studies,[209–211] propofol has been evaluated as a neuroprotectant in the setting of cardiac surgery. A prospective, randomized clinical trial was conducted to determine whether propofol-induced EEG burst suppression would reduce the incidence or severity of cerebral injury during valvular surgery.[212] In a randomized trial ($N = 215$) of burst-suppression doses of propofol, there was no beneficial effect on cognitive outcome at 2 months. The investigators concluded that EEG burst-suppression doses of propofol provided no neuroprotection during valvular cardiac surgery. No other studies in nonvalve cardiac surgery have assessed the effects of propofol on the brain.

Acadesine

The adenosine-regulating agent acadesine was studied in the early 1990s with the aim of improving myocardial outcome; stroke was examined as a secondary outcome.[213] Compared with placebo, high- and low-dose infusions of acadesine resulted in a lower stroke rate ($P = .016$). Other adenosine-like agents also have provided neuroprotection in preclinical experimental settings.[214,215] Despite this positive, albeit indirect, clinical data and supportive experimental data, no further clinical neuroprotection indication for acadesine has been pursued.[216] However, studies of this drug have recently been renewed, though they have not had any beneficial effect on neurologic outcome.[217]

Aprotinin

In a large, multicenter trial of aprotinin for primary or redo CABG and valvular surgery evaluating its blood loss–reducing effects, the high-dose aprotinin group also had a lower stroke rate compared with placebo ($P = .032$).[218,219] Similarly, Frumento and investigators[220] retrospectively examined patients at high risk for stroke (because of the presence of significant aortic atheroma), and those who received aprotinin had a significantly lower stroke rate. In a small ($N = 36$) study examining the effect of aprotinin on cognitive deficit after CABG surgery, the incidence of cognitive deficit was reduced in the aprotinin group (58% aprotinin vs 94% placebo; $P = .01$).[221] However, the high rate in the placebo group, the small size of the study, and methodologic concerns limit the applicability of these results to broader populations.[222] Animal investigations in the setting of cerebral ischemia failed to show any direct benefit on functional or neurohistologic outcome after cerebral ischemia.[223]

There has been considerable investigation of the potential mechanism for aprotinin-derived neuroprotection. Initial enthusiasm focused on its antiinflammatory effects potentially preventing some of the adverse inflammatory sequelae of cerebral ischemia. However, aprotinin may have beneficial effects independent of any direct neuroprotective effect through an indirect effect of modulating cerebral emboli. Brooker and colleagues[41] identified the cardiotomy suction as a major source of cerebral emboli during CPB. By extrapolation, if a drug reduces the amount of particulate-containing blood returning from the operative field to the cardiotomy reservoir (by decreasing overall blood loss), cerebral emboli and the resulting neurologic consequences may also be decreased.

More recently, the potential adverse effects of aprotinin were reported by Mangano and coworkers in their observational study of 4374 patients.[224] In that study, patients having received aprotinin had a significantly higher rate of cerebrovascular complications ($P < .001$). The Blood Conservation Using Antifibrinolytics: A Randomized Trial (BART) reported a significant reduction in bleeding but an overall mortality risk with aprotinin compared with other antifibrinolytics.[225] However, there were no differences in the stroke rate with aprotinin compared with tranexamic acid (2.5% aprotinin vs 3.7% tranexamic acid; odds ratio [OR], 0.78; 95% confidence interval [CI], 0.45–1.35). Although the Mangano study and the BART trial contributed to the market withdrawal of aprotinin, the relevance of the potential neurologic effects of kallikrein inhibition remains. There are at least two other highly potent kallikrein inhibitors (CU-2010 and ecallantide) that have undergone clinical development, but their neurologic effects are unknown.[226–228]

Nimodipine

Calcium plays a central role in propagating cerebral ischemic injury. For this reason, as well as a demonstrated beneficial effect of the calcium channel blocker nimodipine in subarachnoid hemorrhage and experimental cerebral ischemia, a randomized, double-blind, placebo-controlled, single-center trial was undertaken to assess the effect of nimodipine on neurologic, neuro-ophthalmologic, and neuropsychologic outcomes after valvular surgery.[229–231] The trial was not completed after safety concerns regarding an increased bleeding and death rate in the nimodipine group prompted an external review board to suspend the study after enrolling 150 of 400 patients planned to be studied. There was also no neuropsychologic deficit difference between the placebo or nimodipine groups at this interim review. As a result, the true effect of this drug or similar calcium trial blockers may never be fully known in this setting.

GM_1 Ganglioside

The monosialoganglioside GM_1 ganglioside has been investigated as a potential neuroprotectant during cardiac surgery.[232] In addition to the potential beneficial effects of this type of compound on preserving neuronal membranes, some data suggest that it has a potential beneficial effect on reducing excitatory amino acid transmission.[233] In a preliminary (but underpowered) cardiac surgery study, there was no beneficial effect demonstrated. However, the study investigators used this pilot trial to describe useful statistical methodology needed to measure differences in neurocognitive outcome, thereby constituting a template for later trials. This trial highlights one of the biggest difficulties in this investigative field—the interpretation of negative but underpowered studies.

Dextromethorphan

The *N*-methyl-D-aspartate (NMDA) receptor plays a major role in cerebral ischemic injury.[202] Although human stroke trials have been limited by distressing psychomimetic side effects, a wealth of experimental data point to NMDA-receptor antagonists as being robust neuroprotective agents with a potential role in CPB-associated cerebral injury.[234] Dextromethorphan, known for its antitussive activity, has some nonspecific NMDA antagonistic properties. A small ($N = 12$) pilot study examined dextromethorphan in the setting of pediatric cardiac surgery using EEG and MRI end points to determine a difference between treatment groups, but no difference was found, probably because of the small size of the study.[235] There have been no other studies examining NMDA-receptor antagonism in the setting of pediatric cardiac surgery.

Remacemide

A second NMDA-receptor antagonist that has been evaluated for neuroprotection during CABG surgery is remacemide. In a well-designed and well-executed study by Arrowsmith and coworkers,[234] remacemide was given orally for 4 days before CABG. A neurocognitive battery was performed 1 week before and 8 weeks after CABG. A deficit was defined as a decrease in 1 standard deviation in 2 or more of the 12 tests within the neurocognitive battery. The patients were evaluated for their learning ability by subtracting the postoperative neurocognitive score

from the preoperative score (formulating a Z score). Although there was no difference between groups with respect to the dichotomous outcome of cognitive deficit (P = .6), examination of a continuous measure of learning ability showed there was a beneficial cognitive effect in the patients who received remacemide (P = .028). Despite these apparently beneficial results, because of the length of time that it took to perform this single-center trial, initial nonbeneficial preliminary results, and a prolonged period of data analysis and review for publication, this drug was not further pursued for this indication. It has highlighted, however, the potential utility of this class of drugs for this indication and ongoing investigations examining other NMDA-receptor antagonists continue.[236–238]

Lidocaine

Intravenous lidocaine, because of its properties as a sodium channel blocking agent and potential antiinflammatory effects, has been investigated as a neuroprotectant in cardiac surgery. In a study of 55 patients undergoing valvular surgery, a lidocaine infusion (in an antiarrhythmic dose of 1 mg/min) was begun preinduction and maintained for 48 hours after surgery.[239] Neurocognitive testing was performed preoperatively and 8 days, 2 months, and 6 months postoperatively. Compared with placebo, neurocognitive outcome 8 days after surgery was significantly better in the lidocaine group (P = .025). However, a much larger double-blind, randomized trial in cardiac surgery failed to replicate the finding. Mathew and associates,[240] in a study of 241 patients, found no difference in the incidence of cognitive loss with the perioperative administration of lidocaine. Interestingly, they found that in patients with diabetes, and in those receiving high doses of lidocaine, outcome was worse and may have confounded any potential benefit in the overall cohort receiving it. Lidocaine cannot be recommended at this time as a clinical neuroprotective agent in cardiac surgery, but it continues to be investigated.

β-Blockers

Although the use of β-blockers in patients with cardiac disease has been predominantly directed toward the prevention of adverse myocardial events, in a study of neurologic outcomes after cardiac surgery, β-blockers have been demonstrated to have mixed effects in neurologic outcomes. In a retrospective study of almost 3000 patients, stroke and encephalopathy were studied.[241] Patients receiving β-blocker therapy had a significantly lower incidence of neurologic deficit versus those not receiving β-blockers. Although the reasons for this potential benefit are not clear, there are several potential reasons why β-blockers may be efficacious, including the modulation of cerebrovascular tone and CPB-related inflammatory events. Support for a potential neuroprotective effect from β-blockers has come from a study of carvedilol, which is known to have mixed adrenergic antagonist effects, as well as acting as an antioxidant and inhibitor of apoptosis[242] (see Chapter 11). Any potential benefit to β-blocker therapy needs to be tempered by recent data in the non–cardiac surgery population that demonstrated neurologic harm. The POISE trial, although demonstrating a reduction in MI, demonstrated an increase in stroke rate in patients randomized to receive metoprolol perioperatively.[243] It is unclear how this information pertains to the cardiac surgical population.

Pegorgotein

The generation of reactive oxygen species is a well-described pathophysiologic mechanism of ischemic reperfusion injury. Combined with the whole-body inflammatory response associated with CPB and its own generation of reactive oxygen species, this mechanism has opened the field of neuroprotection and cardiac surgery to antioxidant therapies. Superoxide dismutase is involved in the catabolism of free radicals, and its mimetics have had beneficial results in the setting of experimental ischemia. Pegorgotein, a monomethyoxypolyethyleneglycol covalently linked to superoxide dismutase, is protective against reperfusion-mediated cardiac and neuronal injury in animal studies.[244] One study was initiated to examine whether pegorgotein would be associated with a reduced number of neurocognitive deficits after cardiac surgery.[245] In this study of 67 patients undergoing primary elective CABG surgery (n = 22 to 23 in each of three groups: placebo, 200 IU/kg of pegorgotein, or 5000 IU/kg of pegorgotein), no difference in neurocognitive outcome was found.

C5 Complement Inhibitor: Pexelizumab

The activation of complement is central to the inflammatory response seen as a response to CPB.[246] In a small (N = 18) study using a simple assessment of cognitive function, patients receiving an inhibitor to C5 (h5G1.1-scFv, pexelizumab), demonstrated fewer visuospatial deficits at hospital discharge.[247] Additional large-scale (phase III) investigations of this compound to more adequately delineate any potential longer-term neuroprotective effects from this drug in this setting have been performed. Mathew and collegues[247] assessed pexelizumab in a 914-patient study aimed at evaluating its effect on myocardial outcome and mortality. A secondary end point of neurocognitive outcome demonstrated that pexelizumab, although having no effect on global measures of cognition, appeared to have a benefit with respect to the visuospatial domain.

Platelet-Activating Factor Antagonist: Lexiphant

Platelet-activating factor antagonists have demonstrated neuroprotective effects in experimental models of cerebral ischemia.[248] Platelet-activating factor is thought to modulate postischemic injury by the release of cerebral cellular lipids and free fatty acids that may result in cellular injury and cerebral edema.[249] In an investigation of 150 cardiac surgery patients receiving placebo or one of two different doses of lexiphant, no protective effects were found in neurocognitive outcome 3 months after cardiac surgery. This study was significantly underpowered, which is a recurring and troublesome feature of many studies in this field.[250]

Clomethiazole

Clomethiazole, which enhances γ-aminobutyric acid (GABA) receptor activity, has been evaluated in CABG surgery. GABA has repeatedly been shown to be an important neuroprotective target in focal and global experimental ischemia.[251,252] However, in a relatively large, well-designed, and well-conducted study, it failed to decrease neurocognitive dysfunction in patients after cardiac surgery.[253]

Steroids

Corticosteroids have long been considered as potential cerebroprotective agents in part because of their ability to reduce the inflammatory response. Inflammation is considered an important factor in propagating ischemia-mediated brain injury.[254,255] However, with the exception of spinal cord injury,[256] steroids have never been demonstrated to possess any significant clinical neuroprotective properties. Furthermore, the administration of steroids has actually worsened cerebral outcome in a large trial (N = 10,000). The Corticosteroid Randomization after Significant Head Injury (CRASH) trial demonstrated an increased relative risk (RR) of death (RR, 1.18; 95% CI, 1.09–1.27; P = .0001) in those receiving high-dose steroids within 8 hours of injury.[257,258] Part of their lack of effect may result from the hyperglycemia that generally follows their administration. Hyperglycemia in animal models and several human studies of cerebral injury has been associated with worsened neurologic outcome.[188,259] The use of high-dose dexamethasone (1 mg/kg) in cardiac surgery was recently studied by Dieleman and colleagues.[260] In the largest ever trial of a potentially neuroprotective agent (though the trial was powered to a composite end point that included other outcomes in addition to neurologic outcome) in cardiac surgery, they were unable to show any beneficial effort in stroke, cognitive outcome, or delirium.[261,262] The administration of steroids with the intent of conferring some degree of neuroprotection during cardiac surgery cannot be recommended.

Ketamine

The neuroprotective effects of S(+D)-ketamine, a frequently used anesthetic that is also an NMDA-receptor antagonist, was evaluated in a

small ($N = 106$) study enrolling cardiac surgery patients.[263] The incidence of neurocognitive dysfunction 10 weeks after surgery trended toward being lower in the ketamine group (20% for ketamine vs 25% for controls; $P = .54$), but because the study was underpowered, it was not a significant change. There has been renewed interest in ketamine for its potential to reduce the incidence of delirium.[264] This drug awaits further large trials to determine its potential benefit. Although there is some experimental evidence supporting its role as a neuroprotectant, there is insufficient clinical evidence to support its use for this specific indication.[265]

Acute Kidney Injury

Despite concern for almost half a century over the seriousness of renal dysfunction as a complication after cardiac surgery,[266–269] acute kidney injury (AKI) persists as a prevalent and important predictor of early death.[270] Even during procedures where there is no evidence of AKI based on serum creatinine levels, more subtle markers often demonstrate renal tubular injury.[271] Increasing degrees of AKI after cardiac surgery are associated with poorer outcome, greater costs, and more short- and long-term resource utilization.[267,272–274] The degree of AKI also predicts poorer long-term survival in patients returning home.[275–277] Notably, long-term outcome is just as strongly linked to the success of renal recovery as the magnitude of the injury, incomplete return of renal function occurring in up to a third of the patients.[275–277] While some of the harm associated with AKI simply reflects its accompaniment of other serious complications as an "epiphenomenon" (eg, sepsis), there is also compelling evidence that AKI itself contributes to adverse outcome.[278–283] Accumulation of "uremic toxins" beyond creatinine has widespread adverse effects on most organ systems,[278,279,284] and where it is best studied in chronic renal disease, inadequate clearance of uremic toxins adversely affects survival.[285]

Even when postoperative dialysis is avoided, the strong relationship of AKI with adverse outcome continues to fuel the search for therapies to protect the kidney. Although practicing avoidance of the numerous recognized renal insults is a well-established approach to reducing AKI rates, the search for renoprotective strategies has otherwise been extremely disappointing. More recently, lack of progress has fueled a strategic reexamination of AKI with agreement that, compared to other conditions such as acute myocardial infarction (AMI) where advances have been made, progress in AKI therapy has been hampered by its obligate delay in diagnosis (serum creatinine accumulation takes 48 to 72 hours) and poor agreement on its definition.[286,287] Thus, strategic policies have reframed AKI along the lines of AMI, viewing it as a condition with threshold criteria, whose treatment demands prompt diagnosis and acute intervention.[286] On a positive note, consensus serum creatinine thresholds are already available to diagnose AKI and are becoming widely embraced, while tools allowing earlier diagnosis of AKI—equivalent to the ST-segment, creatine kinase MB (CK-MB), and troponin tests to diagnose AMI—may be clinically available soon.[286–290]

Clinical Course, Incidence, and Significance

The specific surgical procedure is important when considering postoperative AKI. The incidence varies widely by operation (Fig. 31.7), each

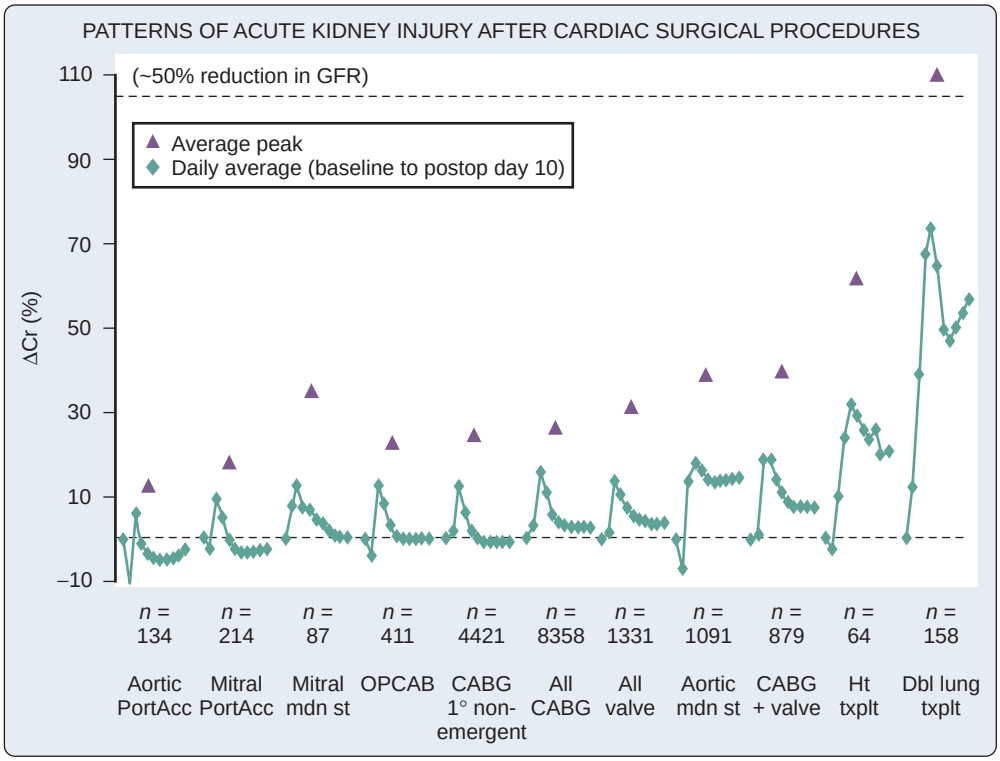

Fig. 31.7 Different cardiac surgical procedures are associated with characteristic patterns of acute kidney injury. Average daily *(diamonds)* and unadjusted average peak *(triangles)* serum creatinine values are presented. *aortic mdn st,* Median sternotomy aortic valve replacement; *aortic PortAcc,* minimally invasive parasternotomy aortic valve replacement; *CABG,* coronary artery bypass graft surgery; *dbl lung txplt,* double lung transplantation; *GFR,* glomerular filtration rate; *ht txplt,* heart transplantation; *mdn st,* median sternotomy mitral valve surgery; *1°,* nonemergent; *%ΔCr,* peak fractional serum creatinine rise; *OPCAB,* off-pump coronary artery bypass surgery; *PortAcc,* port access mitral valve surgery; *postop,* postoperative. *(Used with permission from Stafford-Smith M, Patel UD, Phillips-Bute BG, et al. Acute kidney injury and chronic kidney disease after cardiac surgery.* Adv Chronic Kidney Dis *2008;15:257–277.)*

cardiac surgery having its own characteristic renal insult and pattern of serum creatinine change. For example, creatinine often drops immediately after CABG surgery (presumably as a result of hemodilution), but then rises, typically peaking on postoperative day 2, then returning toward or even below baseline values in subsequent days. Up to 30% of CABG patients sustain sufficient insult to meet threshold AKI criteria (eg, RIFLE–injury[286]/AKIN criteria[291]: a creatinine rise > 0.3 mg/dL or 50% within the first 48 hours).[267,272,292,293] The reported incidence thus varies according to the definition of kidney injury, as well as by the institution reporting their results (Fig. 31.8). The previously mentioned RIFLE and AKIN criteria for AKI are consistent with the definitions that adhere to the KDIGO (Kidney Disease Improving Global Outcomes) criteria that also includes a urine volume definition (ie, urine volume < 0.5 mL/kg per hour).[294–296] Even among patients with similar risk factors undergoing the same procedure, however, current models poorly predict the likelihood of AKI. AKI has also been linked to accelerated long-term renal decline that may lead to end-stage disease requiring chronic dialysis.[297–302]

Of the 1% to 3% of patients sustaining AKI severe enough to require dialysis following CABG, up to 60% will die before being discharged from the hospital, and many of the survivors will require continuing dialysis or be left with chronic kidney disease.[303] Up to 20% of individuals presenting for nonemergent CABG surgery have chronic kidney disease.[304,305] While dialysis after cardiac surgery is always important, when this is associated with poor preoperative renal function, postoperative mortality rates more closely resemble those of similar patients who avoid dialysis.[306] The rate of "renal recovery" after AKI is also difficult to predict, but emerging evidence suggests it is highly associated with outcome and apparently independent of AKI.[276,307]

Risk Factors and Surgery-Related Acute Kidney Injury Pathophysiology

Numerous studies have characterized risk factors for nephropathy after cardiac surgery (Fig. 31.9).[308] Despite an increasing understanding of perioperative renal dysfunction, known risk factors account for only one-third of the observed variability in creatinine rise after cardiac surgery. Procedure-related risk factors include emergent and redo operations,[309,310] valvular procedures,[309,311,312] and operations requiring a period of circulatory arrest[310] or extended durations of CPB.[267,272,313–315] Infection and sepsis,[310,313,316] atrial fibrillation,[317] and indicators of LCOS, including need for inotropic agents and insertion of an intraaortic balloon pump during surgery, also have been associated with renal impairment.[272,309,310,313,318]

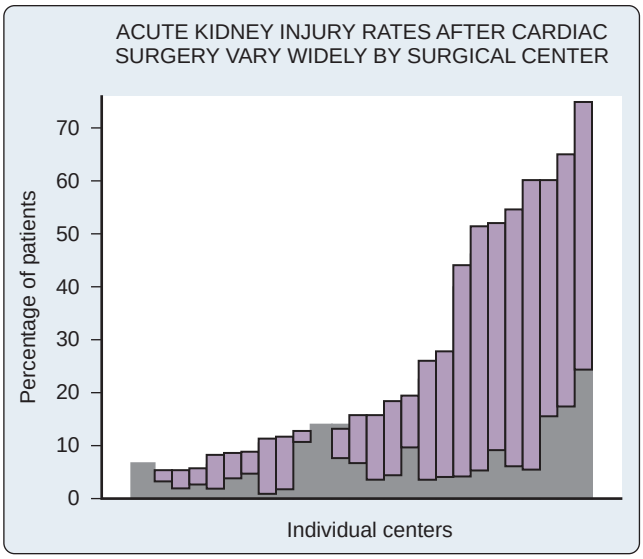

Fig. 31.8 Even after adjusting for case complexity, among institutions there is wide variation in acute kidney injury (*shaded bar* represents risk, injury, or failure according to the ADQI-RIFLE system)[286] and dialysis *(dark bar)* rates, as exemplified by Heringlake and colleagues[366] in a study of 2003 data from 26 German heart centers. *(Modified with permission from Heringlake M, Knappe M, Vargas Hein O, et al. Renal dysfunction according to the ADQI-RIFLE system and clinical practice patterns after cardiac surgery in Germany.* Minerva Anestesiol *2006;72:645–654.)*

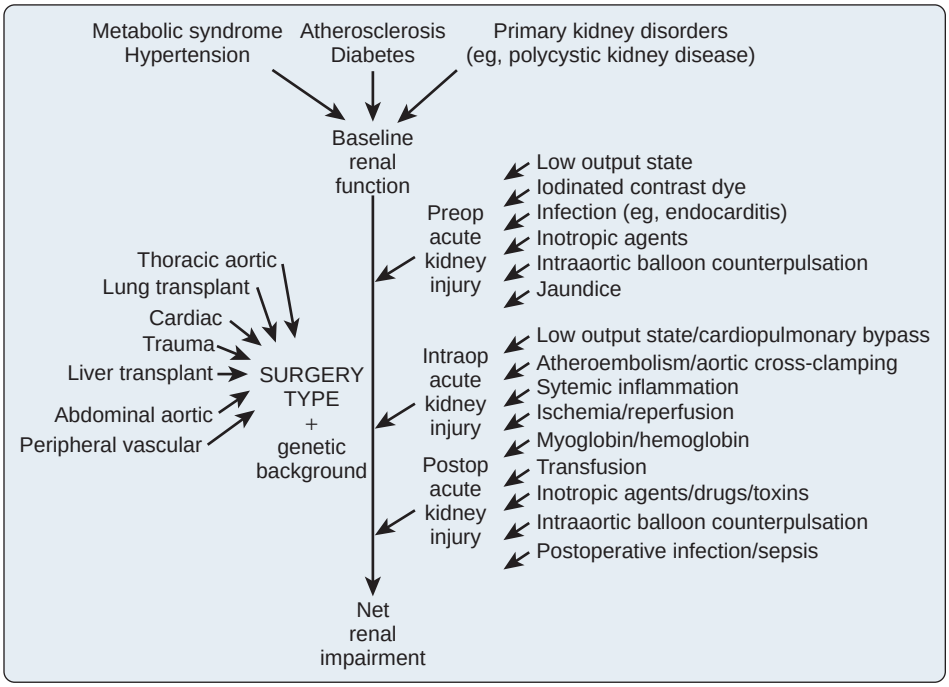

Fig. 31.9 Numerous sources of kidney insult play a variably important role for each patient during the perioperative period. *(Used with permission and modified from Stafford-Smith M, Patel UD, Phillips-Bute BG, et al. Acute kidney injury and chronic kidney disease after cardiac surgery.* Adv Chronic Kidney Dis *2008;15:257–277.)*

Preoperative demographic risk factors identified include advanced age,[267,272,310,312,318,319] increased body weight,[267] African American ethnicity,[267,320] hypertension and wide pulse pressure,[309,321,322] baseline anemia,[323] peripheral or carotid atherosclerotic disease,[267,309] diabetes, preoperative hyperglycemia, and/or elevated hemoglobin A1c in nondiabetics,[267,272,321,324,325] reduced left ventricular (LV) function, and obstructive pulmonary disease.[267,309,310,313,314] Interestingly, baseline chronic kidney disease is not a risk factor for AKI, but since even small amounts of additional renal impairment may lead to dialysis when severe renal disease is present at baseline, these individuals are at greatest risk for dialysis.

A genetic predisposition to AKI exists and explains more variation in AKI after cardiac surgery than conventional clinical risk factors alone.[326,327] A handful of candidate polymorphisms known to affect inflammation and vasoconstriction have been studied, and several, alone or in combination, demonstrate strong associations with AKI following cardiac surgery.[326,327] For example, copossession of the IL-6-572C and angiotensinogen 842C polymorphisms in Caucasians (6% of patients) predicts an approximately fourfold greater than average creatinine rise (121%) after CABG.[327] These data add credence to the idea that much of the variability in postoperative AKI may result from genetic influences[327] and suggest that wider genetic profiling and future whole genome studies may lead to useful preoperative risk prediction tools and may even provide a roadmap in the search for useful renoprotective strategies.

The development of AKI in an individual patient after cardiac surgery reflects the actual net injury from numerous potential perioperative sources known to be capable of inflicting insult (see Fig. 31.9). Many markers of renal risk hint at causes of perioperative AKI in individuals. Thus, perioperative AKI contrasts with single-insult renal injuries such as contrast nephropathy. Nonetheless, a common pathway mediates the consequences of AKI, including tubular and vascular cell dysfunction, necrosis, and apoptosis.[328] Although details of the trigger mechanisms for this reflexive component of AKI remain elusive, there is better understanding of the direct renal consequences of some insults specific to cardiac surgery. Although the physiology of perioperative renal recovery is as yet less studied, emerging data suggest this is also likely to be important. A brief overview of AKI pathophysiology focused on cardiac surgery is pertinent.

Using intraoperative epiaortic scanning, Davila-Roman and coworkers found ascending aortic atheroma burden correlates with AKI.[329] Sreeram and associates noted that postoperative AKI correlates with arterial emboli load.[330] Conlon and colleagues, however, did not see a relationship between renal artery stenosis and AKI.[331] Renal atheroembolism is sometimes a dominant source of cardiac surgical AKI[332] and often observed at autopsy.[30] Filter devices deployed before cross-clamp removal often capture macroscopic atheroemboli.[100] Plaque disruption caused by balloon pump counterpulsation is also likely a contributor to AKI.[310,333] Antiembolism strategies have been widely adopted into the conduct of cardiac surgery,[334–337] but evidence that they lead to decreased incidence of AKI is lacking. One randomized filter device trial in a post hoc analysis found less incidence of AKI in higher-risk patients.[101]

Other emboli sources may be relevant to AKI in some circumstances. Fat droplets, particulates, and bubbles are common during cardiac surgery. Renal embolic infarcts from any source are pizza wedge–shaped and involve adjacent cortex and medulla, highlighting the vascular arrangement and lack of redundancy of kidney perfusion. Incriminated particulates other than atheroma include thrombus, platelet fibrin debris, septic vegetations, and even normal vessel wall.[100,338] One-third of patients who have undergone endocarditis surgery suffer significant AKI.[339] Although sternal marrow lipid droplet reinfusion with red cell salvage is common[340] and may have effects on renal cortical blood flow,[341] its importance is unknown. Air bubbles have rarely been associated with AKI.[342] Surgical field insufflation of CO_2 reduces intravascular emboli,[343] but whether this reduces AKI rates has not been assessed.

Many cardiac surgery patients meet the criteria for systemic inflammatory response syndrome (SIRS) in the early postoperative period. AKI is a major consequence of SIRS.[344] Sepsis is a strong predictor of postoperative AKI, likely mediated through the effects of renal inflammation.[286,310,313,345] A surge of circulating proinflammatory cytokines is typical after trauma, major surgery, and CPB.[346] Local cytokine release also occurs in response to ischemia-reperfusion–mediated renal nuclear factor-κB (NF-κB) activation.[347] Finally, impaired renal filtration affects the course of any inflammatory response by influencing the primary clearance mechanism for many cytokines (eg, IL-6, IL-1β, tumor necrosis factor-α).[348]

Many elements of cardiac surgery contribute to the risk of hypoperfusion and ischemia-reperfusion–mediated AKI. Embolism, LCOS, and exogenous catecholamines can all contribute,[310,330,349] leading to cellular high-energy phosphate depletion, calcium accumulation, oxygen free radical generation, local leukocyte activation, and NF-κB activation.[350] These changes can cause apoptotic cell death through caspase activation (executioner enzymes) and/or tissue necrosis.[351] Apoptosis instigates more local inflammation and injury,[352,353] and, experimentally, inhibition of caspase or NF-κB attenuates ischemia-reperfusion AKI.

Femoral artery cannulation can be complicated by leg ischemia and has been blamed for myoglobinuric AKI.[354] Although statins can cause myopathy, these agents have not been associated with increased renal risk in vascular and major non–cardiac surgery patients.[355] Myoglobin and hemoglobin avidly bind nitric oxide and are believed to cause AKI through vasoconstrictor effects but also direct cytotoxicity and frank tubular obstruction.[356]

Withdrawal of the antifibrinolytic agent aprotinin from the market eliminates one concern of perioperative renal toxicity for cardiac surgery patients.[357] In contrast, the lysine analogue antifibrinolytics ε aminocaproic acid and tranexamic acid can raise concern because of their renal effects of small protein spillage into the urine (tubular proteinuria).[358,359] A single retrospective analysis of 1502 patients involving the introduction of ε aminocaproic acid therapy did not show an increase in AKI.[304] While tubular proteinuria often heralds tubular injury, with lysine analogue antifibrinolytics this is completely resolved within 15 minutes after the agent is discontinued.[358,359]

Other perioperative nephrotoxins include some antibiotics,[360] α-adrenergic agonist agents,[361] cyclosporine,[362] and nonsteroidal antiinflammatory agents.[363] However, the net effect on post–cardiac surgery AKI of α_1-mediated vasoconstriction and dopaminergic and α_2-mediated renal vasodilation with hemodynamic compromise is unknown. Although experimentally, even short periods of high-dose norepinephrine cause long-lasting AKI,[364] and catecholamines during cardiac surgery also predict AKI,[310,365] disentangling cause and association for these agents is problematic as they are rarely used in the absence of other major risk factors (eg, LCOS). Interestingly, in a survey of German intensive care units (ICUs) involving more than 29,000 cardiac surgery patients, centers with worse AKI rates were more likely to prefer dopamine over other inotropes and avoid norepinephrine as a vasopressor.[366]

Intravenous contrast is known to have nephrotoxic effects. Contrast-associated nephropathy is usually heralded by a significant rise in serum creatinine within 5 days after intravascular contrast injection and occurs in approximately 2% to 7% of patients.[367,368] The pathophysiology primarily results from vasoconstriction and direct renal tubular cell injury. Those at greatest risk typically have preprocedure renal impairment.[369] In a study of 27 CABG patients, Garwood and associates[370] found indicators of tubular injury to be elevated in those presenting for surgery within 5 days of cardiac catheterization relative to those further separated from an intravenous contrast injection. Use of low-osmolar contrast media and aggressive prestudy hydration have significantly reduced the risk of contrast-associated nephropathy for patients with diabetic nephropathy and other causes of chronic renal disease.

Considerable evidence has emerged with respect to the potential for colloid solutions, particularly hydroxyethyl starches, to contribute

BOX 31.2 CONTRIBUTORS TO RENAL INJURY DURING CARDIOPULMONARY BYPASS

- Emboli
- Renal ischemia
- Reperfusion injury
- Pigments
- Contrast agents
- Hydroxyethyl starches

to AKI in a number of settings (Box 31.2).[371] Cardiac surgery is no different and several studies have provided evidence suggesting that hydroxyethyl starches are one of the factors associated with renal dysfunction. For example, in a recent prospective study of 6478 cardiac surgery patients, use of a hydroxyethyl starch 134/0.4 was associated with an increased requirement for renal replacement therapy (OR, 1.46; 95% CI, 1.09–1.97).[372] When added to additional data from a meta-analysis of 15 randomized trials that evaluated hydroxyethyl starch administration in the perioperative setting, including 5 of the 15 studies being in cardiac surgery, the need for renal replacement therapy was significantly increased with the use of hydroxyethyl starch solutions (RR, 1.44; 95% CI, 1.04–2.01).[373] This was true for all the hydroxyethyl starch solutions as a class, but in particular with a hydroxyethyl starch 130/0.4 (RR, 1.47; 95% CI, 1.02–2.12).[373] As a result of these cardiac surgery studies, as well as the mounting evidence against the use of starches in other critical care settings, the avoidance of hydroxyethyl starch solutions is recommended.[374]

Strategies for Renal Protection

The sluggish serum creatinine rise consequent to sudden drops in glomerular filtration is now considered inadequate to be the signal for acute renoprotection, much as Q waves are too late to be useful for cardioprotection. When serum creatinine is employed, the obligatory delay in AKI recognition has even been suggested to explain some of the disappointing results from past renoprotection studies. Developing and validating tools for more prompt AKI diagnosis has become a priority. The hope is that early AKI biomarkers can be identified that can play a role in renal protection much like CK-MB and troponin currently serve for myocardial protection.

Nonetheless, despite its limitations as an early biomarker, serum creatinine remains an important clinical tool because of its many other uses. Indisputably, creatinine accumulation serves as a prognostic gold standard heralding AKI that is highly predictive of other major adverse outcomes, including death.[267] Validation for even the most promising of newer early AKI biomarkers is very limited or lacking in comparison. In addition to injury, serum creatinine characterizes renal recovery unlike most AKI biomarkers. Renal recovery as reflected by declining creatinine levels is highly predictive of short- and long-term outcomes beyond the magnitude of kidney insult.[276] Finally, the generalizability across studies and settings of creatinine-based consensus definitions for AKI, such as RIFLE and AKIN,[291] are gaining popularity.

Unfortunately, the lack of success in developing effective renoprotective responses and the renal monitoring challenges outlined earlier dictate that any review of renal protection still remains limited primarily to strategies to minimize or avoid AKI risk factors. Few to no interventions have consistently proven effective once AKI is established. However, there is hope that the new paradigm, viewing AKI as a threshold diagnosis much like AMI, whose recognition must be swift and intervention immediate if tissue salvage is to occur, will lead to progress in this field.

Early Acute Kidney Injury Biomarkers

Beyond serum creatinine, the race is on to identify one or more "early biomarkers" for AKI. As a condition whose treatment paradigm demands prompt intervention, AKI currently has no equivalents to CK-MB, troponin, and the ST segment for the heart.

BOX 31.3 EARLY ACUTE KIDNEY INJURY BIOMARKERS[a]

- **Serum accumulation markers:** reflect acute kidney injury (AKI) much like creatinine, serum accumulation, and decreased clearance with drop in glomerular filtration (Note: also useful to monitor renal recovery)
  Cystatin C
  Proatrial natriuretic peptide (1–98)
  Tryptophan glycoconjugate
- **Tubular enzymuria markers:** reflect AKI through leakage of cell contents into urine after tubular cell damage
  α-Glutathione S-transferase
  π-Glutathione S-transferase
  β-*N*-acetyl-β-d-glucosaminidase
  γ-Glutamyl transpeptidase
  Alkaline phosphatase
  Lactate dehydrogenase
  Ala-(leu-gly)-aminopeptidase
  Proximal renal tubular epithelial antigen
  Urinary sodium hydrogen exchanger isoform 3
- **Tubular proteinuria markers:** reflect AKI through appearance of small proteins in urine that would normally be taken up by tubular cells, reflecting tubular cell dysfunction (Note: not useful if using lysine analog antifibrinolytic agents)
  α_1-Microglobulin
  β_2-Microglobulin
  Albumin
  Adenosine deaminase binding protein
  Renal tubular epithelial antigen-1
  Retinol binding protein
  Lysozyme
  Ribonuclease
  Immunoglobulin G
  Transferrin
  Ceruloplasmin
  Lambda and kappa light chains
  Urinary total protein
- **Renal stress markers:** reflect AKI through various pathophysiologies reflecting or triggered by acute stress
  Neutrophil gelatinase-associated lipocalin
  Urinary interleukin-18
  Platelet activating factor
  Kidney injury molecule-1
  Cysteine rich protein 61
  Urinary P_{O_2}

[a]Early AKI biomarkers reflect renal insult through diverse mechanisms. Understanding of the physiology underpinning each marker can aid in understanding their potential value to improve the diagnosis of AKI.

The search for better early AKI biomarkers currently involves several contenders involving numerous physiologic mechanisms (Box 31.3). Markers such as creatinine and cystatin C that accumulate to diagnostic levels because of decreased clearance are further challenged during the perioperative period because of signal-to-noise confounders, such as hemodilution, that complicate early AKI recognition by disrupting steady state assumptions. While only a few new early biomarker candidates involve a substitute "ideal" creatinine, most involve one of three other early consequences of AKI: tubular cell damage, tubular cell dysfunction, and the adaptive stress response of the kidney. For example, damaged renal cells leak contents directly into urine; this strategy underpins tubular enzymuria AKI biomarkers, including ß-*N*-acetyl-ß-D-glucosaminidase and at least eight other candidates. Monitoring markers of the kidney's stress response provides another strategy for AKI recognition, including some frontrunners; these include neutrophil gelatinase-associated lipocalcin, urinary IL-18, and at least three other candidates. Simple urinary partial pressure of

oxygen (P_{O_2}) monitoring correlates with changes in renal medullary oxygen levels and predicts subsequent AKI in cardiac surgery patients.

Some early biomarker candidates are poorly suited specifically to perioperative AKI. So-called tubular proteinuria biomarkers, including urine α_1- and α_2-microglobulin and at least 12 other markers, manifest AKI through spillage into the urine of small filtered proteins due to impaired reuptake by the kidney. As outlined earlier, commonly used lysine analogue antifibrinolytics (ε aminocaproic acid and tranexamic acid) mimic this abnormality by selectively blocking kidney tubule receptors, causing a reversible form of this same proteinuria with apparently benign consequences; these biomarkers are considered of little value in most cardiac surgery settings.

Several large prospective observational studies are currently under way that may help identify the winner(s) of the early AKI biomarker race. It will be important for surgical and anesthesia advocates to highlight AKI biomarker issues unique to cardiac surgery lest these be overlooked in the broader pursuit of consensus AKI definitions.

Cardiopulmonary Bypass Management and the Kidney

Basic issues in the management of CPB that relate to the kidney involve the balance between oxygen supply and oxygen demand, particularly to the renal medulla. Perfusion pressure (ie, MAP during CPB) and oxygen-carrying capacity (as related to hemodilution and transfusion) address the supply issues, with the use of hypothermia being directed at modulating renal oxygen demand.

Profound hypothermia is a highly effective component of the protective strategy used during renal transplantation. Mild hypothermia during CPB would, therefore, seem to be a logical component of a perioperative renal protective strategy.[375] However, three separate studies have not found any protective benefit of mild hypothermia during CPB.[376–378] In the largest study, including 298 elective CABG patients who were randomly assigned to normothermic (35.5–36.5°C) or hypothermic (28–30°C) CPB, there was no association between normothermic (as compared with hypothermic) bypass and increased renal dysfunction after cardiac surgery.[378]

Low CPB blood pressure is typically not associated with the hypoperfusion characteristic of hypovolemic shock and LCOS, conditions that are highly associated with AKI. Studies addressing the role of perfusion pressure have not shown an association with AKI.[319,324,379,380] A retrospective, multivariable analysis of minute-to-minute CPB blood pressure data from 1404 CABG surgery procedures, including an assessment of a degree-duration integral index of MAP below 50 mm Hg, found no links between acute or extended episodes of hypotension during CPB and AKI.[324] Interestingly, some data are emerging on the interrelationship between cerebral autoregulatory limits (ie, defining individual blood pressure targets) and AKI after cardiac surgery. For example, in an observational study of patients being monitored with cerebral oximetry to determine the lower limit of cerebral autoregulation, Ono and investigators found that the duration and magnitude of blood pressure below this cerebral threshold was associated with AKI.[181]

Moderate hemodilution is thought to reduce the risk of kidney injury during cardiac surgery through blood viscosity–related improvement in regional blood flow.[381,382] However, the practice of extreme hemodilution (hematocrit < 20%) during CPB has been linked to adverse renal outcome after cardiac surgery.[383,384] Accounting for perfusion pressure, in the study of 1404 CABG patients cited in the previous paragraph,[324] independent associations were noted for both lowest hematocrit during CPB and transfusion with postoperative AKI. Other studies have reported similar patterns and suggest that profound hematocrit change (eg, >50% drop) may be even less well tolerated, highlighting the importance of a clinical strategy including transfusion only after all measures of hemodilution avoidance have been taken.[385–388]

Glycemic control during CPB has been identified as a potential opportunity to attenuate AKI. However, recent evidence has called into question the influential findings of Van den Berghe and colleagues, who reported reduced AKI and dialysis rates with postoperative therapy targeting tight serum glucose control (63% of study patients were post cardiac surgery).[389] Despite widespread adoption of these intensive insulin protocols, numerous subsequent studies have failed to reproduce Van den Berghe's findings of benefit. Wiener and coworkers performed a meta-analysis of the available randomized ICU studies involving over 3500 patients and found no reduction in AKI, dialysis rates, or mortality.[390] In a study combining Van den Berghe–like postoperative management of 400 cardiac surgery patients randomized to intensive intraoperative insulin therapy (target 80–100 mg/dL) versus usual management, Gandhi and associates found no benefit and similar dialysis rates (6/199 vs 4/201; $P = .54$), even noting an unexpected increase in 30-day mortality and stroke with tight control.[196]

Pharmacologic Intervention

There is very little in terms of interventions available to the clinician to pharmacologically prevent or treat established perioperative AKI as evidenced by a Cochrane database review.[391] Proposed changes to improve the likelihood of success in finding renoprotective strategies have included increasing the size of studies designed to see benefit should it be present and, as outlined earlier, improving timely AKI detection to allow earlier intervention. Researchers have performed meta-analyses for many prevalent therapies by combining data from their randomized clinical trials. In some cases, these reports indicate study size concerns may have been warranted. Potential optimism comes from a finding of reduced AKI in a meta-analysis of trials involving 934 cardiac surgery patients comparing various natriuretic peptides with placebo (urodilatin [two studies], brain natriuretic peptide [three studies], atrial natriuretic peptide [nine studies])[392]; however, combined evaluation of the most studied single agent, atrial natriuretic peptide, still remained inconclusive.[393] Another meta-analysis involving 20 studies assessing various methods to guide fluid and inotrope therapy to achieve hemodynamic optimization targets, involving 4220 patients, found reduced AKI and a trend toward reduced mortality.[394] Although they provide hope, neither of these meta-analyses has sufficient evidence to make practical recommendations for changes in clinical practice.

Other systematic reviews and meta-analyses of collected AKI cardiac surgery studies have been reported. For example, several meta-analyses found *N*-acetylcysteine not to have renal benefit even in large cardiac surgery populations.[395–398] A meta-analysis limited to randomized cardiac surgery trials of fenoldopam (20 studies, more than 1400 patients) concluded that a larger trial (1700–2300 patients) was needed to reconcile promising but conflicting evidence.[399] Another, less rigorous analysis of trials and observational studies of the use of fenoldopam in patients who have undergone cardiovascular surgery (1059 patients, 13 studies), by Landoni and investigators suggested reduced dialysis and death after cardiac surgery.[400]

A meta-analysis of statin therapy preceding cardiac surgery including 3 randomized and 16 observational studies (over 30,000 patients) found a reduced incidence of renal failure with this therapy.[401] A meta-analysis of 61 studies comparing "renal-dose" dopamine to placebo (3359 patients) found extremely modest benefit on day 1—with increased urine output, slight serum creatinine decline (4%), and glomerular filtration rate rise (6%).[402] However, by day 2 these gains were lost, and there was no effect on mortality, need for dialysis, or adverse events. Meta-analyses of loop diuretics trials and controlled studies in critically ill patients describe improvements in markers of renal function (urine output, oliguric period), and reduced need for dialysis but also concerning trends toward increased mortality and poorer renal recovery.[403–405] Unfortunately, because of the limitations of current research tools, most potential renoprotective therapies have not been subjected to the rigor of a large randomized trial or even meta-analysis, and none has been given the opportunity to be used immediately after the onset of AKI. Additional data, including rationale and existing studies for a number of these therapies, is outlined next.

Dopamine

Mesenteric dopamine$_1$ (D_1) receptor agonists increase renal blood flow, decrease renal vascular resistance, and enhance natriuresis and

diuresis. Despite the absence of clinical evidence of renoprotection, this rationale has been used to justify the use of low-dose ("renal-dose") dopamine (<5 μg/kg per min) for decades. However, numerous double-blind, randomized studies in several surgical and nonsurgical settings have failed to demonstrate any renal benefits.[406–408] Concerns have been raised that dopamine in cardiac surgery is not benign, including evidence suggesting impairment of hepatosplanchnic metabolism despite an increase in regional perfusion[409] and increased postoperative arrhythmias.[410] Despite the lack of benefit and accumulating concerns regarding the use of low-dose dopamine, many centers continue to use this agent for renoprotection.

Fenoldopam

Fenoldopam mesylate, a derivative of benzazepine, is a selective D_1-receptor agonist. Although first approved as an antihypertensive agent, fenoldopam has shown promise in the prevention of contrast-induced nephropathy.[411–413] There is, however, very little in the way of randomized, controlled studies to evaluate the agent as a therapy for postoperative renal dysfunction. In one prospective, randomized study involving 160 patients with preoperative renal dysfunction, improved renal function with fenoldopam versus placebo was reported after cardiac surgery; however, no long-term benefit was evaluated.[414] Other prospective, randomized, double-blind studies enrolling patients with established postoperative renal injury have proved inconclusive or even indicated possible adverse outcomes in patients with diabetes.[415] More systematic study is needed before this agent can be recommended for renoprotection in cardiac surgery.

Diuretic Agents

Diuretics increase urine generation by reducing reuptake of tubular contents. This can be achieved by numerous mechanisms, including inhibiting active mechanisms that lead to solute reuptake (eg, loop diuretics), altering the osmotic gradient in the tubular contents to favor solute remaining in the tubule (eg, mannitol), or hormonal influences that affect the balance of activities of the tubule to increase urine generation (eg, atrial natriuretic peptide). The general renoprotective principle of diuretic agents is that increasing tubular solute flow through injured renal tubules will maintain tubular patency, avoiding some of the adverse consequences of tubular obstruction, including oliguria or anuria and possibly the need for dialysis. Other agent-specific properties (eg, antioxidant effects, reduced active transport) have also been proposed to have beneficial effects in the setting of ischemic renal injury.

Loop diuretics, such as furosemide, produce renal cortical vasodilation and inhibit reabsorptive transport in the medullary thick ascending limb, causing more solute to remain in the renal tubule and increasing urine generation. In animal models, administration of furosemide and other loop diuretics has been shown to raise oxygen levels in the renal medulla,[416] presumably by reducing oxygen consumption by tubular active transport, but it also results in distal tubular hypertrophy.[417] In experimental models, loop diuretics have provided protection from renal tubular damage after ischemia-reperfusion and nephrotoxic injuries.[418–420] In contrast to evidence from animal experiments, several clinical studies have shown no benefit and possibly even harm from perioperative diuretic therapy in cardiac surgery patients.[421–423] In a double-blind, randomized, controlled trial comparing infusions of furosemide, low-dose dopamine, or placebo administered during and for 48 hours after surgery in 126 cardiac surgery patients, Lassnigg and coworkers[424] found no benefit of dopamine and a greater postoperative rise in serum creatinine in the group receiving furosemide. Although they may facilitate avoidance of dialysis in responsive patients by maintaining fluid balance, there is insufficient evidence to support the routine use of loop diuretics as specific renoprotective agents. However, in situations of severe hemoglobinuria, they may facilitate urine production and tubular clearance of this nephrotoxin.

Mannitol, an osmotic diuretic, has been evaluated in several studies of cardiac surgical patients.[376,425,426] Although an increased diuresis has been documented, very few studies have carefully assessed postoperative renal dysfunction in these patients. In an animal model of thoracic aortic clamping, mannitol did not provide evidence of improved renal function after unclamping.[427] In addition to the lack of beneficial effect on the kidney, several studies have identified a nephrotoxic potential of high-dose mannitol, especially in patients with preexisting renal insufficiency.[428]

Several studies have addressed the potential for renoprotection with natriuretic peptides. Three natriuretic peptides have received most of the attention in human trials: atrial natriuretic peptide (ANP; anaritide), urodilatin (ularitide), and brain natriuretic peptide (BNP; nesiritide).[429] Natriuretic peptides have primary effects, including receptor-mediated natriuresis and vasodilation, and are normally secreted in response to volume expansion. ANP increases glomerular filtration and urinary output by constricting efferent and dilating afferent renal arterioles.[430] In a secondary analysis of randomized data from an ICU study of 504 patients with established AKI, Allgren and colleagues noted a 24-hour intravenous infusion of ANP (0.2 μg/kg per min) was associated with improved dialysis-free survival in oliguric patients (8 vs 27%; $P = .008$) but not in nonoliguric patients (59 vs 48%; $P = .03$).[431] Unfortunately, a repeat study designed to reproduce these favorable findings did not see any benefit.[432] Few studies have evaluated urodilatin, and these have all provided inconclusive results.[433] BNP has potent vasodilating properties and is generated in response to ventricular dilatation. Evidence from cardiology studies suggest that BNP treatment may worsen renal function in patients with heart failure.[434,435] However, two randomized studies in cardiac surgery patients suggest renoprotective benefit from this agent.[436,437]

N-Acetylcysteine

N-Acetylcysteine is an antioxidant that enhances the endogenous glutathione scavenging system and has shown promise as a renoprotective agent by attenuating intravenous contrast-induced nephropathy. The weight of evidence, including four meta-analyses, suggests that potential benefits that may exist with contrast nephropathy are not pertinent to perioperative patients.[395–398,438,439]

Adrenergic Agonists

The α_1- and α_2-adrenergic receptors in the kidney modulate vasoconstrictor and vasodilatory effects, respectively. Agents that attenuate renal vasoconstriction may have potential as renoprotective drugs because vasoconstriction most likely contributes to the pathophysiology of AKI. Clonidine, an α_2-agonist, has been shown experimentally to inhibit renin release and cause diuresis, and it has been evaluated in an experimental AKI model confirming its potential as a renoprotective agent.[440–444] Similarly, two clinical trials have demonstrated some promise. A prospective, double-blind, randomized, placebo-controlled clinical trial evaluating preoperative clonidine in 48 CABG patients found that creatinine clearance decreased over the first postoperative night from 98 ± 18 (preoperatively) to 68 ± 19 mL/min ($P < .05$) in the placebo-treated group, but it remained unchanged in clonidine-treated patients (90 ± 1 to 92 ± 17 mL/min; $P < .05$).[445] The effect was transient, however, with creatinine clearance in both groups being no different at postoperative day 3. Despite being positively supported in a second trial,[446] clonidine has not gained popular acceptance as a renoprotective agent. Notably, decreased afferent α_1-adrenergic receptor–mediated vasoconstriction has been suggested as an explanation for the renal protective benefit of thoracic epidural blockade in cardiac surgery patients.[447]

Calcium Channel Blockers

Diltiazem is the calcium channel blocker that has been most evaluated as a renoprotective agent in cardiac surgery, with its ability to antagonize vasoconstricting signals and reports of beneficial effects in experimental models of toxic and ischemic acute renal failure.[448,449] However, in humans, numerous small randomized trials and a retrospective study combine to provide a confusing picture, including

evidence suggesting diltiazem therapy in cardiac surgery patients may have minor renal benefits, no benefit, or even potential harm.[450–455]

Sodium Bicarbonate

The perioperative infusion of sodium bicarbonate has recently attracted attention because of reduced AKI compared to a placebo saline infusion in 100 post–cardiac surgery patients.[456] Despite evidence that sodium bicarbonate–based hydration appears to be of benefit in other settings such as contrast-induced nephropathy, the considerable additional fluid and sodium load required with this therapy has raised concern for some clinicians.[457]

Angiotensin-Converting Enzyme Inhibitor and Angiotensin I Receptor Blockers

The renin-angiotensin-aldosterone system mediates vasoconstriction and is important in the paracrine regulation of the renal microcirculation. Angiotensin-converting enzyme (ACE) inhibitor and angiotensin I receptor blocker agents act by inhibiting steps in activation of the renin-angiotensin-aldosterone system. Although ACE inhibitor and angiotensin receptor blocker agents have demonstrated effects at slowing the progression of most chronic renal diseases,[458] their role in AKI has not been well studied.[459,460] In a study of 249 aortic surgery patients, Cittanova and coworkers[461] reported an increased risk of postoperative renal dysfunction in patients receiving preoperative ACE inhibitor therapy. Animal studies suggest that both groups of drugs have protective properties in experimental AKI.[462] In a small ($N = 18$), double-blind, placebo-controlled clinical trial enrolling CABG patients, preservation of renal plasma flow intraoperatively in patients receiving the ACE inhibitor captopril relative to placebo was demonstrated.[463] A similar study assessing perioperative enalaprilat (an angiotensin receptor blocker) therapy in 14 CABG patients demonstrated greater renal plasma flow in the enalaprilat group before CPB and on postoperative day 7, as well as greater creatinine clearance after CPB.[464,465]

Insulin-Like Growth Factor

The concept of combining AKI prevention with enhanced renal recovery is appealing given the emerging evidence; insulin-like growth factor offers the potential for the importance of the latter, with promising findings from animal AKI studies and reports in humans with chronic kidney disease of improved renal function and delayed need for dialysis.[466–468] However, unfortunately the only randomized controlled trial in 72 patients with acute renal failure found no renal benefit and a significant side effect profile.[469]

Alternate Perioperative Renoprotective Strategies

In a survey involving over 29,000 cardiac surgery patients from 26 German heart programs, Heringlake and associates reported extremely wide variation in AKI rates by center, ranging from 3.1 to 75% (mean 15.4%; see Fig. 31.9).[366] Although programs were unaware of their AKI ranking when responding to a questionnaire, centers were asked to provide case mix data and answer questions on their standard practice in patients with elevated renal risk. Groups of centers with higher and lower AKI rates had similar case mix and urgency/emergency rates, but several differences existed in their responses to standard management questions. Centers with high and low rates of AKI used loop diuretics at about the same rates but selected norepinephrine in preference to epinephrine or dopamine as a vasopressor and were less likely to prefer dopamine for either inotropy or renal prophylaxis. Using monitoring of AKI rates among centers as a tool to identify outliers and alter practice patterns was a useful strategy to improve outcomes in one study.[273]

Myocardial Injury

From the earliest days of modern cardiac surgery, perioperative myocardial dysfunction, with its associated morbidity and mortality, has been reported.[470] Evidence, including substantial subendocardial cellular necrosis, led to the conclusion that this injury resulted from an inadequate substrate supply to the metabolically active myocardium.[471] Optimizing myocardial protection during cardiac surgery involves several compromises inherent in allowing surgery to be performed in a relatively immobile, bloodless field, while preserving postoperative myocardial function. The fundamental tenets of this protection center on the judicious use of hypothermia along with the induction and maintenance of chemically induced electromechanical diastolic cardiac arrest. Bigelow and investigators[472] were the first to describe the use of hypothermia for this purpose, and this was complemented by subsequent work by Melrose and colleagues,[473] who first reported the electromechanical arrest of the heart by the administration of potassium-containing cardioplegia. Despite continued efforts directed at myocardial protection, it is clear that myocardial injury, although reduced, still remains a problem, and with it, the representative phenotype of postoperative myocardial dysfunction.

Incidence and Significance of Myocardial Dysfunction After Cardiopulmonary Bypass

Unlike other organs at risk of damage during cardiac surgery, it is assumed, because of the very nature of the target of the operation being performed, that all patients having cardiac surgery will suffer some degree of myocardial injury. Although the injury can be subclinical, represented only by otherwise asymptomatic elevations in cardiac enzymes (eg, myocardial creatine kinase isoenzyme [CK-MB]), it frequently manifests more overtly. The degree to which these enzymes are released by injured myocardium, frequently to levels sufficiently high to satisfy criteria for MI, have been related to perioperative outcome after cardiac surgery.[474–476] Chaitman[475] reported CK-MB results from the Guard During Ischemia Against Necrosis (GUARDIAN) trial in 11,950 patients with acute coronary syndromes or undergoing high-risk percutaneous intervention or CABG surgery. CK-MB values more than 10 times the upper limit of normal during the initial 48 hours after CABG were significantly associated with 6-month mortality ($P < .001$).[475]

Risk Factors for Myocardial Injury

With an increasingly sicker cohort of patients presenting for cardiac surgery,[477] many with acute ischemic syndromes (eg, often with evolving MIs) or significant LV dysfunction, the need has never been greater for optimizing myocardial protection to minimize the myocardial dysfunction consequent to aortic cross-clamping and cardioplegia.[478] The continued increase in cardiac transplantation and other complex surgeries in the heart failure patient has served to fuel the search for better myocardial protection strategies.

Pathophysiology of Myocardial Injury

Myocardial stunning represents the myocardial dysfunction that follows a brief ischemic event. It is differentiated from the reversible dysfunction associated with chronic ischemia, which is called hibernation.[479] Myocardial stunning typically resolves over the 48 to 72 hours after the ischemic event and is frequently observed after aortic cross-clamping with cardioplegic arrest.[480,481] Important factors that contribute to stunning include not only the metabolic consequences of oxygen deprivation but also the premorbid condition of the myocardium, reperfusion injury, acute alterations in signal transduction systems, and the effects of circulating inflammatory mediators.

The metabolic consequences of oxygen deprivation become apparent within seconds of coronary artery occlusion. With the rapid depletion of high-energy phosphates, accumulation of lactate and intracellular acidosis in the myocytes soon follows, with the subsequent development of contractile dysfunction. When myocyte adenosine triphosphate (ATP) levels decline to a critical level, the subsequent inability to maintain electrolyte gradients requiring active transport (eg, Na^+, K^+, Ca^{2+}) leads to cellular edema, intracellular Ca^{2+} overload, and loss of membrane integrity.

Predictably with the release of the aortic cross-clamp and the restoration of blood flow, myocardial reperfusion occurs. With reperfusion the paradox, represented by the balance of substrate delivery restoration needed for normal metabolism that also can serve as the substrate for injurious free radical production, becomes a significant issue for consideration. Reperfusion causes a rapid increase in free radical production within minutes, and it plays a major role initiating myocardial stunning. Bolli[482] identified the importance of this effect by demonstrating that antioxidants administered just before reperfusion significantly diminished myocardial stunning, an effect not observed if the same substance were introduced after reperfusion. Sun and associates[483] and Sekili and colleagues[484] subsequently demonstrated the significance of the free radical effect by demonstrating that up to 80% of myocardial stunning could be avoided with an appropriately timed regimen of free radical scavengers.

Free radical insults during myocardial reperfusion result in the near-immediate dysfunction of proteins involved in ion transport and excitation-contraction coupling, as well as injury to membranes through damage mediated through lipid peroxidation.[485] Free radical–mediated myocardial dysfunction is related to a myofilament defect manifest by an impairment in Ca-activated excitation-contraction coupling.[485] Although free radicals can directly injure these myofilament components, injury to other proteins related to ion transport and membrane integrity serve to increase intracellular calcium. Several mechanisms have been proposed to explain this impairment of myofilament function, although the most likely explanation includes physiologic downregulation of excitation-contraction coupling in response to cellular Ca^{2+} overload. The mechanisms underlying Ca^{2+} overload are not well understood, but they are thought to involve free radical–related and free radical–independent abnormalities in Ca^{2+} homeostasis. Whatever the cause, the rapid calcium influx during myocardial reperfusion can quickly overload the myocyte with Ca^{2+}.[486] The importance of Ca^{2+} overload is demonstrated by the substantial protection from reperfusion injury obtained by pretreatment with traditional Ca^{2+} blocking agents.[487]

A free radical–independent mechanism for Ca^{2+} overload involves activation of the Na^+/H^+ exchanger during reperfusion in an attempt by the cell to correct intracellular pH.[488] The resultant increase in intracellular Na^+ from activation of the Na^+/H^+ exchanger further activates the Na^+/Ca^{2+} exchanger, increasing Ca^{2+} influx.[489] Evidence for the activation of Na^+/H^+ exchangers being responsible for some of the harmful effects of reperfusion is shown by the benefits that Na^+/H^+ exchanger inhibitors have had on myocardial stunning with reductions in arrhythmias, improvement in systolic and diastolic function, and reductions in myocyte injury.[490] In addition to its role in Ca^{2+} overload, activation of the Na^+/H^+ exchanger has been linked to increased phospholipase activity, generation of prostaglandins and other eicosanoids, and activation of platelets and neutrophils—all potentially injurious processes.[488,490]

In addition to free radical upregulation, myocardial reperfusion associated with acute myocardial ischemic injury induces inflammation mediated by neutrophils and an array of humoral inflammatory components.[488,491,492] Several studies using novel neutrophil inhibitors have demonstrated a cardioprotective effect in models of myocardial stunning.[492,493] Prostaglandins are also generated during reperfusion and their adverse effects appear to be synergistic with increases in intracellular calcium. The relationship of leukotriene and cytokine release to reperfusion injury is less clear.[488,491] Consistent with a role for prostaglandins in this injury is the demonstration that inhibition of prostaglandins by nonsteroidal antiinflammatory agents can significantly diminish myocardial stunning.[494]

A potential additional mechanism for myocardial dysfunction specific to the setting of CPB relates to proposed acute alterations in β-adrenergic signal transduction.[495] Acute desensitization and downregulation of myocardial β-adrenergic receptors during CPB has been demonstrated after cardiac surgery.[495,496] Although the role of the large elevations in circulating catecholamines seen with CPB on β-adrenergic malfunction is unclear, it has been proposed that an increased incidence of post-CPB LCOS and reduced responsiveness to inotropic agents may be attributed in part to this effect.[497,498]

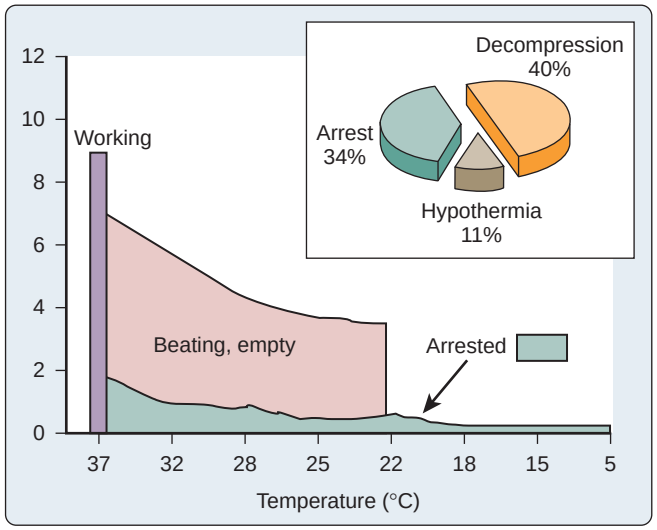

Fig. 31.10 Myocardial oxygen uptake (reflecting oxygen demand) versus temperature. Compared with the oxygen uptake of a normally beating heart, eliminating cardiac work by venting the beating heart during bypass reduces oxygen demand by 30% to 60%. Arresting the heart reduces demands by another 50%, producing a total reduction of approximately 90%. Hypothermia extends the reductions in oxygen demand. *(From Vinten-Johansen J, Thourani VH. Myocardial protection: an overview.* J Extra Corpor Technol *2000;32:38–48.)*

Myocardial Protection During Cardiac Surgery: Cardioplegia

Optimizing the metabolic state of the myocardium is fundamental to preserving its integrity. The major effects of temperature and functional activity (ie, contractile and electrical work) on the metabolic rate of the myocardium have been extensively described.[471,489,499] With the institution of CPB, the emptying of the heart significantly reduces contractile work and myocardial oxygen consumption (MvO_2). Nullifying this cardiac work reduces the MvO_2 by 30% to 60%. With subsequent reductions in temperature, the MvO_2 further decreases, and with induction of cardiac arrest and hypothermia, 90% of the metabolic requirements of the heart can be reduced (Fig. 31.10). Temperature reductions diminish metabolic rate for all electromechanical states (ie, beating or fibrillating) of the myocardium (Table 31.7).

Although cardiac surgery on the empty beating heart or under conditions of hypothermic fibrillation (both with the support of CPB) is sometimes performed, aortic cross-clamping with cardioplegic arrest remains the most prevalent method of myocardial preservation. Based on the principle of reducing metabolic requirements, the introduction of selective myocardial hypothermia and cardioplegia (ie, diastolic arrest) marked a major clinical advance in myocardial protection.[500,501] With the various additives in cardioplegia solutions (designed to optimize the myocardium during arrest and attenuate reperfusion injury) and the use of warm cardioplegia, the idea of delivering metabolic substrates (as opposed to solely reducing metabolic requirements) is also commonplace. Several effective approaches to chemical cardioplegia are employed. The clinical success of a cardioplegia strategy may be judged by its ability to achieve and maintain prompt continuous arrest in all regions of the myocardium, early return of function after cross-clamp removal, and minimal inotropic requirements for successful separation from CPB. Composition, temperature, and route of delivery constitute the fundamentals of cardioplegia-derived myocardial protection (see Chapter 32).

Composition of Cardioplegia Solutions

The composition of the various cardioplegia solutions used during cardiac surgery varies as much between institutions as it does between individual surgeons. In very general terms, cardioplegia can be classified into blood-containing and nonblood-containing (ie, crystalloid) solutions. Whereas crystalloid cardioplegia has fallen out of favor, blood cardioplegia in various combinations of temperatures and routes of delivery is the most used solution. However, even within the category of blood cardioplegia, the individual chemical constituents of the solution vary considerably with respect to the addition of numerous additives. Table 31.8 outlines the various additives to cardioplegia solutions along with their corresponding rationale for use. Although all cardioplegia solutions contain higher than physiologic levels of potassium, solutions used for the induction of diastolic arrest contain the highest concentrations of potassium as opposed to solutions used for the maintenance of cardioplegia. In addition to adjustment of electrolytes, manipulation of buffers (eg, bicarbonate, tromethamine), osmotic agents (eg, glucose, mannitol, potassium), and metabolic substrates (eg, glucose, glutamate, and aspartate) constitute the most common variations in cardioplegia content. Oxygenation of crystalloid cardioplegia before infusion is aimed at increasing aerobic metabolism, but the limited oxygen-carrying capacity of crystalloid makes a rapid decline in metabolic rate through immediate and sustained diastolic arrest critical to effective cardioprotection with this technique.

Blood cardioplegia has the potential advantage of delivering sufficient oxygen to ischemic myocardium to sustain basal metabolism or even augment high-energy phosphate stores, as well as possessing free radical scavenging properties.[502] The introduction of blood cardioplegia in the late 1970s followed recognition of the clinical utility of this technique.[503] Although low-risk cardiac surgical patients appear to do equally well with crystalloid or blood cardioplegic protection, evidence is compelling that more critically ill patients, including those with "energy-depleted" hearts (eg, cardiogenic shock, AMI before CPB), have improved outcomes using blood cardioplegia.[504,505] Patients at high risk also appear to have better recovery after a combination of antegrade and retrograde blood cardioplegia delivery, when compared with antegrade administration alone.[505]

Because an infusion of oxygenated blood cardioplegia is in many ways similar to myocardial reperfusion, it is not surprising that the composition of blood cardioplegia is based on reperfusate parameters known to minimize myocardial stunning.[506,507] These parameters include maintenance of Ca^{2+} at 1.0 mEq/L (by chelating Ca^{2+} from perfusate blood) to diminish myocyte Ca^{2+} uptake; pH between 7.6 and 7.8 (the pH of water in the hypothermic temperature range used); osmolality between 340 and 360 mOsm to minimize edema-related myocardial dysfunction after reperfusion; and hyperkalemia between 10 and 25 mEq/L to safely sustain electromechanical arrest. To create blood cardioplegia with these characteristics, blood is mixed in a ratio of 4:1 with a prepared crystalloid solution.

Infusion of a single, warm (37°C) reperfusion dose of cardioplegia (so-called hot shot) containing metabolic substrates (ie, glucose, glutamate, and aspartate) just before aortic cross-clamp removal is preferred by some clinicians. The rationale for this is evidence that normothermia maximally enhances myocardial aerobic metabolism and recovery after an ischemic period. Although, some have advocated continuous infusion of hyperkalemic warm cardioplegia throughout the period of aortic cross-clamping,[508] this technique has not gained wide popularity for CABG because of the technical challenges of grafting vessels perfused in this way and the threat of ischemia to nonperfused (warm) myocardium during grafting.

Numerous other cardioplegia additives continue to be assessed involving various buffers, osmotic agents, metabolites, ATP and precursors, enzymes controlling ATP synthesis and catabolism, oxygen radical scavengers, and antioxidants. Protection of myocardial β-adrenergic receptor function using intracoronary administration of esmolol appears to hold promise as an alternate cardioprotective method.[509] Alternative cardioplegia strategies potentially extending safe ischemic periods for heart transplantation to up to 24 hours are also being evaluated.[510–512]

Cardioplegia Temperature

The composition of cardioplegia solutions varies considerably; in contrast, myocardial temperature during cardioplegia is almost uniformly reduced to between 10°C and 12°C or less by the infusion of refrigerated cardioplegia and external topical cooling with ice slush. However, the introduction of warm cardioplegia has challenged this once universally considered necessity of hypothermia for successful myocardial protection.[160] Although hypothermic cardioplegia is the most commonly used temperature, numerous investigations have examined tepid (27–30°C) and warm (37–38°C) temperature ranges for the administration of cardioplegia. Much of the work aimed at determining the optimum temperature of the cardioplegia solution

TABLE 31.7 Influence of Temperature on Myocardial Oxygen Consumption for Different Work and Electrical Conditions

	Myocardial Oxygen Consumption (mL/100 mg per min)			
Cardiac Conditions	*37°C*	*32°C*	*28°C*	*22°C*
Beating, empty	5.5	5.0	4.0	2.9
Fibrillating, empty	6.5	3.8	3.0	2.0
K^+ cardioplegia	1.8	0.8	0.6	0.3

centered on the fact that although hypothermia clearly offered some advantages to the myocardium in suppressing metabolism (particularly when intermittent cardioplegia was delivered), it may have some detrimental effects.

The deleterious effects of hypothermia include the increased risk of myocardial edema (through ion pump activity inhibition) and the impaired function of various membrane receptors on which some pharmacologic therapy depends (such as the various additives to the cardioplegia solutions). The other disadvantages of hypothermic cardioplegia, in addition to the production of the metabolic inhibition in the myocardium, are an increase in plasma viscosity and a decrease in red blood cell deformability.[161,499,513] As a result, investigations aimed at using warmer cardioplegia temperatures have been explored.[160,514] During the initial phase of cardioplegia delivery, hypothermic temperatures, in addition to inhibiting some of the needed drug-receptor interactions, fail to optimize the metabolic rate in the myocardium. Hypothermia results in a leftward shift in the oxygen hemoglobin dissociation curve, inhibiting the release of oxygen into tissues. The myocardium is relatively ischemic during this initial induction phase of cardioplegia, with the uptake of the oxygen to this tissue being low, and, as a result, significant oxygen debt occurs.

The adverse effects of hypothermia spawned interest in using warm cardioplegia. With the warm induction of cardiac arrest, metabolic activity is maintained, ion exchanges through cellular membranes are maintained, intracellular acidosis occurring with hypothermia is eliminated, oxygen delivery is optimized by maintaining a near-normal hemoglobin-oxygen dissociation curve, hypothermia-induced changes in viscosity and blood rheology are avoided, and red blood cell deformability and resulting flow through the myocardial microvasculature are maintained. The principal differences in cold versus warm cardioplegia result from the timing and route of delivery. If the myocardium is maintained at normothermic temperature, continuous cardioplegia must be delivered to adequately supply substrate to the metabolically active myocardium. In most cases, this is done using continuous retrograde cardioplegia (discussed later).

A compromise temperature (tepid, 27–30°C) has also been proposed.[514] Ikonomidis and associates[514] compared outcomes for patients receiving warm, tepid, or cold cardioplegia. Although numerous differences were found between the various groups, the recovery of LV stroke work at 1 and 4 hours after surgery was optimal in the tepid group. The researchers concluded that tepid cardioplegia provided better overall protection with superior functional recovery.[515] Hayashida and colleagues[515] conducted a randomized trial comparing the effects of cold (9°C), tepid (29°C), and warm (37°C) cardioplegia in 42 patients undergoing CABG surgery. Overall, the investigators found that $M\dot{V}O_2$ and lactate production were greatest in the warm group, intermediate in the tepid group, and least in the cold cardioplegia group. However, early postoperative LV function was optimized in the tepid cardioplegia group.[515]

Cardioplegia Delivery Routes

If using tepid or warm cardioplegia administration, the continuous administration of this cardioplegia needs to be ensured. Retrograde cardioplegia, where a cardioplegia catheter is introduced into the coronary sinus, allows for almost continuous cardioplegia administration. Retrograde delivery is also useful in settings where antegrade cardioplegia is problematic such as with severe aortic insufficiency or during aortic root or aortic valve (and frequently, mitral) surgery (Box 31.4). It also allows the distribution of cardioplegia to areas of myocardium supplied by significantly stenosed coronary vessels. Retrograde cardioplegia has proved safe and effective in patients with coronary artery disease and in those undergoing valve surgery.[516,517] With the administration of retrograde cardioplegia, certain provisos should be considered. The acceptable perfusion pressure to limit perivascular edema and hemorrhage needs to be limited to less than 40 mm Hg.[518]

Two trials added information about cardioplegia routes of delivery. The CABG patch trial[519] enrolled high-risk CABG patients with impaired LV function and demonstrated the superiority of the combined antegrade and retrograde delivery of blood cardioplegia compared with antegrade cardioplegia alone. The limitation of this trial was that the antegrade group received crystalloid cardioplegia (as opposed to blood cardioplegia in the antegrade-retrograde group), raising questions about whether the differences in the groups were seen because of the route of administration or the constituents of the cardioplegia itself. A second trial failed to demonstrate any differences when the administration of intermittent antegrade cold blood cardioplegia was compared with a group receiving antegrade cold blood cardioplegia induction followed by retrograde cold blood maintenance in valve surgery.[520] They did find that the antegrade-retrograde approach was technically more convenient, allowing for shorter aortic cross-clamp times.

BOX 31.4 USES FOR RETROGRADE CARDIOPLEGIA

- Along with anterograde cardioplegia
- In the presence of aortic insufficiency
- For aortic (and mitral) valve surgery
- To perfuse severely diseased coronary arteries

Retrograde cardioplegia does have some limitations. Although the retrograde approach has been shown to effectively deliver cardioplegia adequately to the left ventricle, because of shunting and blood flowing into the atrium and ventricles by the thebesian veins and various arteriosinusoidal connections, the right ventricle and septum frequently receive inadequate delivery of cardioplegia. Difficulties with retrograde delivery can also occur if the coronary sinus catheter is placed beyond the great cardiac vein, or if anatomic variants occur that communicate with systemic veins, such as a persistent left superior vena cava (SVC).[518,521,522] Because retrograde cardioplegia is inefficient in producing arrest of the beating heart, induction of arrest with this technique must be achieved by a single antegrade infusion of cardioplegia before its institution.

Ischemic Preconditioning

Myocardial stunning during cardiac surgery is affected by several parameters. The preischemic state of the myocardium can influence the degree of stunning that follows an ischemic event. Ischemic preconditioning (IPC) is endogenous myocardial protection triggered by exposure to brief periods of (5–15 min) ischemia. IPC is a natural defense mechanism that permits the heart to better tolerate myocardial ischemia. Although brief ischemic episodes in themselves result in stunning, they also build up a temporary resistance to the adverse effects of subsequent, more prolonged ischemia.[523,524] IPC has been well described experimentally.[525–527] Several proposed mechanisms are responsible for IPC, including the activation of several myocardial G protein–coupled receptors, most notably A_1 adenosine and α_1-adrenergic receptors.[528] Protein kinase C appears to be a key cellular mediator of IPC, in part through activation of ATP-sensitive potassium channels.[529]

Myocardial protection strategies continue to be an active area of investigation, including assessment of IPC. Attempts to induce IPC by brief ischemia or pharmacologic means before CPB have been assessed in human cardiac surgical patients. Sevoflurane, and other frequently used volatile anesthetics, have been demonstrated to pharmacologically replicate IPC.[530] Administration of adenosine, before bypass or in cardioplegic solutions, has been studied as a pharmacologic means to induce IPC. It has been associated with reduced postoperative myocardial injury, reduced inotropic requirements, and improved myocardial recovery.[531,532] The potential for myocardial stunning after beating heart OPCAB has not been fully assessed. Intermittent coronary occlusion before beating heart OPCAB to induce IPC, although unclear as

to its effect, has had some clinical assessment,[533] but it is not usually used. See the discussion of anesthetic preconditioning in Chapters 10 and 20 for more details on OPCAB management.

Gastrointestinal Complications

Incidence and Significance

Gastrointestinal (GI) complications after cardiac surgery, although occurring relatively infrequently (0.5–5.5%), portend a significantly increased risk of overall adverse patient outcome. The variability in the reported incidence of GI complications is partly a reflection of how they are defined as well as the variable patient and operative risk factors in the studied cohorts.[534–545] As devastating as they are, because of the relative low incidence, studies of GI complications are few. Although the most commonly considered GI complications include pancreatitis, GI bleeding, cholecystitis, and bowel perforation or infarction, hyperbilirubinemia (total bilirubinemia > 3.0 mL/dL) has also been described as an important complication after cardiac surgery. In one of the largest prospective studies examining these complications after CPB, McSweeney and associates[542] studied 2417 patients undergoing CABG (with or without concurrent intracardiac procedures) in a multicenter study in the United States. The overall incidence of GI complications in this study was 5.5%, ranging from 3.7% for hyperbilirubinemia to 0.1% for major bowel perforation or infarction (Table 31.9).

In addition to their association with other morbid events, adverse GI complications are significantly associated with increased mortality after cardiac surgery.[542,546–548] The average mortality rate among subtypes of GI complications in the study by McSweeney was 19.6%, and in other reports, the mortality rate ranges from 13% to 87%, with an overall average mortality rate of 33%. Even the seemingly insignificant complication of having an increased laboratory measurement of total bilirubin was associated with a 6.6 odds ratio of death in the McSweeney study, compared with a death odds ratio of 8.4 for all adverse GI outcomes combined. Apart from the significant effect on mortality, the occurrence of an adverse GI outcome also significantly increases the incidence of perioperative MI, renal failure, and stroke, as well as significantly prolonging ICU and hospital lengths of stay.[542]

TABLE 31.9 Adverse Gastrointestinal Outcomes

	No. of Patients	*Percentage of Patients With a Gastrointestinal Event (N = 133)*	*Percentage of Total Patients (N = 2417)*
Hyperbilirubinemia, total[a]	90	67.7	3.7
3.1–5.0 mg/dL	54	40.6	2.2
5.1–9.0 mg/dL	19	14.2	0.8
>9.0 (mg/dL)	17	12.8	0.7
Gastrointestinal bleeding	28	21.0	1.2
Pancreatitis	19	14.3	0.8
Cholecystitis	7	5.3	0.3
Bowel perforation	2	1.5	0.1
Bowel infarction	2	1.5	0.1

[a]Hyperbilirubinemia was defined as maximum total bilirubin after surgery of 3.0 mg/dL.
From McSweeney ME, Garwood S, Levin J, et al. Adverse gastrointestinal complications after cardiopulmonary bypass: can outcome be predicted from preoperative risk factors? *Anesth Analg.* 2004;98:1610–1617.

Risk Factors

A long list of preoperative, intraoperative, and postoperative risk factors for GI complications have been identified in a number of studies.[540,542,549–555] As many factors are associated with one another, it is only when these risk factors are examined in multivariable analyses that a more accurate understanding of what the most significant risk factors for visceral complications after cardiac surgery are. Table 31.10 represents the most consistently reported risk factors for GI complications after cardiac surgery. Preoperatively, age (>75 years), history of congestive heart failure, presence of hyperbilirubinemia (>1.2 mg/dL), combined cardiac procedures (eg, CABG plus valve), repeat cardiac operation, preoperative ejection fraction less than 40%, preoperative elevations in partial thromboplastin time, emergency operations; intraoperatively, prolonged CPB, use of TEE, and blood transfusion; and postoperatively, requirements for prolonged inotropic or vasopressor support, IABP use for the treatment of LCOS; and prolonged ventilatory support are all risk factors. These factors identify patients at high risk, and they lend some credence to the overall pathophysiology and suspected causes of these adverse events. If there is a common link among all these risks, it is that many of these factors would be associated with impairment in oxygen delivery to the splanchnic bed.

Pathophysiology and Causative Factors

Impairments in splanchnic perfusion commonly occur during even the normal conduct of cardiac surgery. When this is superimposed on an already depressed preoperative cardiac output or is associated with prolonged postoperative LCOS, the impairment in splanchnic blood flow is further perpetuated. The systemic inflammatory response to CPB itself can be initiated by splanchnic hypoperfusion by means of translocation of endotoxin from the gut into the circulation. De novo splanchnic hypoperfusion can be a result of the humoral vasoactive substances that are released by inflammation remote from the gut.[555–557] Another causative factor for GI complications directly related to splanchnic hypoperfusion is atheroembolism. Several studies have directly attributed atheroembolism to splanchnic hypoperfusion and gut infarction.[549,553,558] Prolonged ventilator support is another causative factor for GI complications, with several lines of investigation having described a relationship between prolonged ventilation and GI

TABLE 31.10 Commonly Identified Risk Factors for Visceral Complications After Cardiac Surgery

Preoperative Risk Factors	*Type of Cardiac Surgery*	*Cardiopulmonary Bypass Factors*	*Postoperative Risk Factors*
Age	Emergency surgery	Duration of CPB	Low cardiac output, use of inotropes, vasopressors, or IABP
History of CHF or low EF	Reoperations	Cross-clamp duration	Reoperation for bleeding
Renal insufficiency	Valve or combined procedures		Loss of normal sinus rhythm
Peptic ulcer disease, chronic lung disease, recent acute myocardial infarction, diabetes mellitus, peripheral vascular disease, use of IABP[a]	Cardiac transplantation		Renal failure
			Ventilation > 24 hours
			ICU stay > 1 day
			Increased bilirubin or lactate level, mediastinitis[a]

[a]Less commonly mentioned risk factors.
CHF, Congestive heart failure; *CPB,* cardiopulmonary bypass; *EF,* ejection fraction; *IABP,* intraaortic balloon bump; *ICU,* intensive care unit.

BOX 31.5 PROTECTING THE GASTROINTESTINAL TRACT DURING CARDIOPULMONARY BYPASS

- Avoiding high doses of vasopressors
- Maintaining a high perfusion flow
- Reducing emboli-producing maneuvers

adverse events; this likely results from a direct effect of positive pressure ventilation impairing cardiac output and subsequently splanchnic perfusion.[538,540,552,559] Lung volume reduction surgery and lung transplantation also produce (approximately 9%) GI complications.[560,561]

Protecting the Gastrointestinal Tract During Cardiac Surgery

As with other aspects of organ protection, critical causative factors need to be addressed with specific targeted therapies (Box 31.5). Unfortunately, as with most other organ-protective strategies, the major limitation in making definitive recommendations is an overall lack of large, well-controlled, prospectively randomized studies to provide supportive data for any one particular technique. However, some recommendations can be made, and attention can be focused on a number of other less well-studied but potentially valid strategies.

Cardiopulmonary Bypass Management

Because CPB itself has been shown to impair splanchnic blood flow, modifications in how it is conducted may have some salutary effects on GI tract integrity. Several studies have focused on the issue of the relative importance of pressure versus flow during CPB, demonstrating that it is likely more beneficial to maintain an adequate bypass flow rate than only maintaining pressure during bypass.[562–564] The addition of significant vasoconstrictors to artificially maintain an adequate MAP in the presence of inadequate flow on CPB may lead to further compromise of splanchnic blood flow. Few definitive data offer guidance about pulsatility. Some studies have shown improvements with pulsatility by indirect measurements (ie, gastric mucosal intracellular pH [pHi]), but no studies have found definitive differences in clinical outcomes. Similarly, the optimal CPB temperature to protect the gut is also unknown. Just as aggressive rewarming can be injurious to the brain,[64] there is some evidence that rewarming can cause increases in visceral metabolism, making any overshoot in temperature suspect by adversely altering the balance of gut oxygen consumption and delivery.[565]

Emboli Reduction

Whereas microembolization and macroembolization to the splanchnic bed clearly occur during CPB and possibly even during the period after bypass, there are few data to determine whether emboli reduction strategies can alter GI outcome. Mythen and Webb[566] found a relationship between transcranial Doppler–detected emboli (used as a surrogate for overall microembolic load within the body) and adverse changes in gastric mucosal pHi. However, with respect to microembolization, a trial that used an intraaortic filter to reduce atheroemboli failed to have any influence on the rate of GI complications.[101] It remains prudent to avoid maneuvers (ie, aortic cannulation and cross-clamping) in areas of high atheroma burden, which is an overall tenet of cardiac surgery for the prevention of all complications.

Drugs

Various vasoactive drugs have been used to enhance splanchnic blood flow during CPB. It is likely that most of these drugs, such as the phosphodiesterase III inhibitors, dobutamine, and other inotropic agents, maintain or enhance splanchnic blood flow, not because of a direct effect on the vasculature but by the inherent enhancement in cardiac output. Dobutamine and dopamine have had a paradoxical detrimental effect on the splanchnic vasculature, with some evidence that they cause further mucosal ischemia.[567,568] Dopexamine has also been studied in a small group that showed an improvement in mucosal blood flow (using laser Doppler flowmetry), but there was no beneficial effect on gastric mucosal pHi.[569] An increasingly common drug in the setting of cardiac surgery is vasopressin. Although vasopressin can clearly augment systemic MAP, it does so at the cost of severe impairments to splanchnic blood flow.[570] Although there are always trade-offs when choosing which vasoactive agent to use, if having a very low MAP is going to be detrimental to other organ systems, the choice to use vasopressin should at least be made with the knowledge that it can have an adverse effect on splanchnic blood flow.

Selective Gastrointestinal Decontamination

Addressing the concept that gut translocation of endotoxin plays a role in inflammation and other organ injuries, one interesting therapy that has been tried in the setting of cardiac surgery involves the administration of oral antibiotics to selectively decontaminate the GI tract preoperatively.[571] Although examined in a small ($N = 100$) study, a combination of oral polymyxin, tobramycin, and amphotericin preoperatively for 3 days reduced the degree of endotoxemia; it was not associated with a beneficial effect on patient outcomes. One possible explanation is that there is such an overwhelmingly large depot of gram-negative organisms in the GI tract that the elimination of even a large population of these by oral antibiotics still leaves significant repositories of endotoxin in the gut. Killing these bacteria may in itself cause the release of the endotoxin, which can then be absorbed into the systemic circulation by impairment of mucosal blood flow inherent in the non-physiologic flow during CPB.

Off-Pump Cardiac Surgery

There is little evidence that the use of off-pump cardiac surgery is in any way beneficial to the GI tract. Three retrospective studies[542,550,572] have shown no differences in GI complications. One reason for this lack of apparent difference between on-pump and off-pump cardiac surgery may again be related to the common denominator of splanchnic perfusion. OPCAB surgery is fraught with hemodynamic compromise that may lead to prolonged periods of splanchnic hypoperfusion by itself or as a result of the concurrent administration of vasopressors to maintain normal hemodynamics during the frequent manipulations of the heart.

Antiinflammatory Therapies

Although the inflammatory response to CPB has been implicated as a causative factor in GI complications after cardiac surgery, few data are available to assess the ability of various antiinflammatory therapies (eg, corticosteroids, aprotinin, complement inhibitors) to reduce these types of complications (see Chapter 9).

Lung Injury During Cardiac Surgery

Incidence and Significance

Pulmonary dysfunction was one of the earliest recognized complications of cardiac surgery employing CPB.[573] However, as improvements in operative technique and CPB perfusion technologies occurred, the overall frequency and severity of this complication decreased. Juxtaposed to the improvements in cardiac surgery, which led to an overall reduction in complications, is an evolving patient population that now comprises a higher-risk group with a higher degree of pulmonary comorbidities, increasing their risks of postoperative pulmonary dysfunction. With the advent of fast-track techniques,[574] even minor degrees of pulmonary dysfunction have reemerged as significant contributors to patient morbidity and the potential need for extended postoperative ventilation. As with most postoperative organ dysfunction, there is a range of dysfunction severity. Arguably, some

degree of pulmonary dysfunction occurs in most patients after cardiac surgery; however, it manifests clinically only when the degree of dysfunction is particularly severe or the pulmonary reserve is significantly impaired.[575,576] As a result, even minor CPB-related pulmonary dysfunction can cause significant problems in some patients.

The full range of reported pulmonary complications includes simple atelectasis, pleural effusions, pneumonia, cardiogenic pulmonary edema, pulmonary embolism, and various degrees of acute lung injury ranging from the mild to the most severe (ie, acute respiratory distress syndrome [ARDS]). Although the final common pathway in all of these forms of pulmonary dysfunction complications is the occurrence of hypoxemia, these complications vary widely in their incidence, cause, and clinical significance. Understanding that the changes that occur after CPB represent a continuum, it becomes necessary to define what constitutes pulmonary dysfunction and injury.

Definitions have varied. One commonly accepted definition that was used in a large study ($N = 1461$ patients) performed in the setting of cardiac surgery defined acute pulmonary dysfunction as a patient requiring mechanical ventilation with an arterial partial pressure of oxygen (Pa_{O_2}) to fraction of inspired oxygen (F_{IO_2}) ratio of less than 150, irrespective of positive end-expiratory pressure, coupled with a chest radiograph that indicated the development of bilateral pulmonary infiltrates, assuming that other causes of hypoxia such as pneumothorax could be excluded. Using this definition, approximately 12% of patients on admission to the cardiovascular ICU after cardiac surgery met the criteria of early acute pulmonary dysfunction.[577,578] Early acute pulmonary dysfunction should be differentiated from the more severe but less common ARDS that occurs in 1% to 2% of patients.[577,579] Although these two forms likely represent similar processes with different degrees of severity, ARDS differs particularly in its timing. The definition of ARDS in the setting of cardiac surgery generally requires the presence of refractory hypoxemia, diffuse bilateral pulmonary infiltrates on chest radiograph, the requirement for mechanical ventilation with an F_{IO_2} of more than 0.40, and, most important, a duration of at least 3 days (as opposed to on admission to the ICU). This must be in the presence of a low pulmonary artery wedge pressure (PCWP < 18 mm Hg). In a study by Welsby and colleagues[580] of 2609 consecutive adult cardiac surgery patients, 7.5% of whom had pulmonary complications, the overall mortality rate was 21%, with 64% of these patients remaining in the hospital more than 10 days. In another study, the most significantly affected patients (ie, those with ARDS) had a mortality rate upward of 80%.[581] These significant morbidity and mortality rates lend credence to pulmonary complications remaining as significant and relevant today as in the early days of cardiac surgery.

Atelectasis and pleural effusions are the most common pulmonary abnormalities seen after cardiac surgery, presenting in more than 60% of patients.[582,583] Atelectasis is commonly attributed to a number of intraoperative and postoperative events. With the induction of general anesthesia, physical compression of the left lower lobe to aid exposure of the heart and facilitate in the dissection of the internal mammary artery, as well as the apnea occurring during the conduct of CPB have all been implicated.[584,585] Postoperative causes include the poor respiratory efforts by patients with impaired coughing, lack of deep inspirations, and pleural effusions.[586] Despite a high incidence of these radiographically recognized complications, the clinical significance is relatively low.[587,588]

Similar to atelectasis, pleural effusions, despite occurring commonly after cardiac surgery (40–50%), rarely cause significant perioperative morbidity. More common in the left thorax, likely as a consequence of the bleeding from the dissection of the internal mammary artery, other causes of pleural effusions relate to continued postoperative bleeding, pulmonary edema from cardiogenic and noncardiogenic causes, and pneumonia. Surgical trauma can also disrupt the normal pleural lymphatic flow through the thorax and, very rarely, direct damage to the internal thoracic duct can lead to the development of a chylothorax. Small effusions tend to resolve over time (a few months postoperatively) and rarely require any specific treatment. However, large pleural effusions that compromise the underlying lung respond well to thoracentesis and temporary chest tube placement, but if persistent, they may require decortication.

Pneumonia after cardiac surgery also has a variable incidence but a much higher significance to overall patient outcome. Reported rates of pneumonia range widely from 2% to 22%.[589–592] Pneumonia occurring early after cardiac surgery portends a very poor outcome, illustrated in one study by a mortality rate of 27%.[593] Factors that increase the risk for postoperative pneumonia include smoking, the presence of chronic obstructive pulmonary disease, other pulmonary complications requiring prolonged intubation, significant heart failure, and the transfusion of large volumes of blood products.

Risk Factors for Pulmonary Dysfunction

Rady and coworkers[577] defined preoperative, operative, and postoperative variables that represent risk factors for early pulmonary dysfunction after cardiac surgery. Although it is not entirely clear whether any of these risk factors can be modified, identifying their presence raises the level of vigilance for the subsequent development of pulmonary dysfunction.[578–593] The risk factors for the most severe ARDS syndrome as defined by Christenson and associates[579] include hypertension, current smoking, emergency surgery, heart failure (New York Heart Association classes III and IV), postoperative LCOS, and a LV ejection fraction of less than 40%. More recently, Filsoufi and investigators reported the risk factors for respiratory failure focusing on valve surgery patients.[594] They studied 2808 patients, reporting risk factors of preoperative renal failure, female gender, ejection fraction less than 30%, double valve procedures, active endocarditis, advanced age (>70 years), heart failure, reoperation, emergent procedures, previous MI, and prolonged (>180 min) CPB time.

Pathophysiology and Causative Factors

Studies have demonstrated CPB-induced changes in the mechanical properties (ie, elastance or compliance and resistance) of the pulmonary apparatus (particularly the lung as opposed to the chest wall) and changes in pulmonary capillary permeability. Impairment in gas exchange has been demonstrated to be a result of atelectasis with concomitant overall loss of lung volume.[573,595–599] Most research has focused on the development of increases in pulmonary vascular permeability (leading to various degrees of pulmonary edema) as the principal cause of the impaired gas exchange that occurs during cardiac surgery and results in a high alveolar-arterial (A-a) gradient.

The cause of pulmonary dysfunction and ARDS after cardiac surgery is complex, but largely revolves around the CPB-induced systemic inflammatory response with its associated increase in pulmonary endothelial permeability.[600,601] A central causative theme is a significant upregulation in the inflammation induced because of the interaction between the blood and foreign surfaces of the heart-lung machine or the inflammation related to the consequences of splanchnic hypoperfusion with the subsequent translocation of significant amounts of endotoxin into the circulation. Endotoxin is proinflammatory, and it has direct effects on the pulmonary vasculature.[602] Clinical studies have demonstrated an increase in circulating intracellular adhesion molecules after CPB in patients with development of acute lung injury.[603] Pathologic examination of the lungs of patients manifesting ARDS has shown extensive injury to the tissue, including swelling and necrosis of endothelial cells and type I and II pneumocytes.[604] In addition to CPB-mediated inflammation, inflammation mediated by endotoxemia has been reported. Several studies have identified transfusion of packed red blood cells (>4 units) as a risk factor for ARDS in cardiac surgical patients (see Chapter 34).[605,606]

Pulmonary Thromboembolism

Although not an injury to the lungs occurring as a direct result of CPB itself, deep vein thrombosis (DVT) and pulmonary embolism

occur with regular frequency in the cardiac surgical population. The incidence of pulmonary embolism after cardiac surgery ranges from 0.3% to 9.5%, with a mortality rate approaching 20%.[339,607,608] The incidence of pulmonary embolism appears to be lower after valve surgery compared with CABG, which may be due to the anticoagulation that is started soon after valve surgery.[608,609]

The incidence of DVT is 17% to 46%, with most cases being asymptomatic.[339,608] The higher incidences were reported from series that used lower extremity ultrasound to more comprehensively examine populations.[339] DVT has been reported for the leg from which the saphenous vein grafts were harvested and from the contralateral leg.[608,610] In a study of post-CABG patients ($N = 270$) admitted to a rehabilitation unit who underwent lower extremity ultrasound examinations, DVT was detected in 17%, with two patients subsequently developing pulmonary emboli.[611] In a postmortem study in 147 patients after cardiac surgery, pulmonary embolism was the cause of death for 4%.

The recommendations for DVT prophylaxis in cardiac surgery are aspirin and elastic gradient compression stockings in patients who ambulate within 2 to 3 days after surgery and low-molecular-weight heparin and sequential compression stockings in nonambulatory patients.[339] These recommendations are based on a randomized trial in which prophylaxis with sequential pneumatic compression stockings provided no added protection against DVT in ambulating CABG patients treated with aspirin and elastic gradient compression stockings.[612]

Pulmonary Protection

Ventilatory Strategies

Several studies have examined the use of continuous positive airway pressure (CPAP) during CPB as a means to minimize the decrement in the A-a gradient that can occur after surgery. In a small study by Gilbert and colleagues,[613] the effect of CPAP was examined in a randomized trial of 18 patients undergoing CABG surgery with CPB. CPAP did not appear to make any difference with respect to changes in measured lung resistance and elastance. In a larger ($N = 61$) study by Berry and coworkers,[614] CPAP did appear to have some transient beneficial effects on A-a gradient; however, these minor differences dissipated 4 hours after bypass. Overall, it is unlikely that CPAP plays any major role in preventing or treating the pulmonary dysfunction that occurs in the setting of cardiac surgery.

The inspired oxygen content of the gases that the lungs see during the period of apnea during CPB may have an effect on the A-a gradient, probably because of the enhanced effect of higher FIO_2 on the ability of atelectasis (so-called absorption atelectasis) on these gradients. With these findings in mind, it would be prudent to reduce the FIO_2 to room air levels during CPB. Several simple therapies can be introduced before separation from CPB, including adequate tracheobronchial toilet and the delivery of several vital capacity breaths that may reduce the amount of atelectasis that has occurred during bypass[585] (Box 31.6).

Ventilatory support of patients with acute lung injury (including ARDS) has undergone changes (see Chapter 39).[615,616] Although not studied specifically in the setting of cardiac surgery, a study authored by the Acute Respiratory Distress Syndrome Network highlighted the avoidance of ventilator-associated pulmonary mechanotrauma.[616] Delivery of repeated large tidal volumes may damage the alveoli and other small lung structures, and these mechanical stresses may activate a pulmonary inflammatory response with a local release of cytokines, further enhancing injury to the lungs. As a result, these groups of investigators randomized patients to small (approximately 6 mL/kg) or traditional tidal volumes (12 mL/kg). They demonstrated in this multicenter trial that the low tidal volume ventilation strategy could reduce mortality in patients with ARDS by up to 25%. Although this has not been specifically studied in the setting of cardiac surgery, it would be prudent to employ this beneficial ventilator strategy in cardiac surgical patients who have significant acute lung injury.

BOX 31.6 STRATEGIES TO PROTECT THE LUNGS

- Reduced fraction of inspired oxygen (FIO_2) during bypass
- Low postoperative tidal volume
- Vital capacity breath before bypass separation

Pharmacologic Pulmonary Protection

Steroids

Antiinflammatory therapies may play a role in moderating the effects of the more significant forms of pulmonary dysfunction that occur after cardiac surgery and that have inflammation as a central causative factor. However, with the exception of corticosteroids, few antiinflammatory therapies are available for routine use. Corticosteroid use can reduce the amount of systemic inflammation as measured by circulating cytokines.[617–619] However, this has not been coupled with a reduction in pulmonary dysfunction. Chaney and colleagues, in two separate studies,[195,620] demonstrated that relatively high doses of methylprednisolone actually had a detrimental effect on post-CPB pulmonary function. Both studies demonstrated no improvement or worsening in lung compliance, shunt, A-a gradient, and delays in extubation. It was speculated that the A-a gradient deterioration and delayed pulmonary extubation associated with steroid administration was attributable to steroid-induced sodium retention and vasodilation resulting in increased shunt and increased lung water content with pulmonary edema. Steroid administration led to significant hyperglycemia, which is difficult to treat during CPB.[620] In a similar study by Oliver and coworkers[619] comparing placebo to steroids or hemofiltration, the steroid-treated patients had larger increases in postoperative A-a gradients. Using a preset mechanical ventilation protocol to guide ventilation weaning, steroids again failed to reduce the time to tracheal extubation (519 ± 293 vs 618 ± 405 min; $P = .21$), confirming the findings of Chaney and colleagues.[620] However, the latest information on steroid use in cardiac surgery comes from the high-dose (1 mg/lg) dexamethasone in cardiac surgery trial.[260] The high-dose dexamethasone group, in contrast to previous studies, had a shorter duration of mechanical ventilation and pulmonary infections suggesting that if not overtly protective, then at the very least, there was no increased pulmonary risk to steroid use.

Aprotinin

The nonspecific serum protease inhibitor aprotinin was once used to reduce blood loss and transfusion after cardiac surgery, and there is some evidence that it reduced CPB-related systemic inflammation.[621–623] Aprotinin was first investigated for use in the setting of cardiac surgery as a means to protect the lungs from the whole-body inflammatory response initiated as a result of the contact activation of blood with the foreign surfaces of the CPB apparatus.[624,625] These studies serendipitously discovered aprotinin's salutary effect on preventing blood loss and transfusion in cardiac surgery.[626] After these studies, aprotinin was extensively evaluated for its blood loss and transfusion-sparing effects, with little further work focused on the pulmonary effects. Despite being a robust inhibitor of CPB-related inflammatory response, any ability to prevent the pulmonary complications of CPB has not yet been demonstrated.

Nitric Oxide

One of the consistent sequelae of pulmonary dysfunction is the development of variable degrees of elevated pulmonary vascular resistance and pulmonary hypertension. As a result, several pulmonary vasodilators have been used, most notably inhaled nitric oxide, in an attempt to reduce the pulmonary artery pressures and with it the workload of the right ventricle (see Chapter 26).[627–629]

BOX 31.7 MANAGEMENT BEFORE CARDIOPULMONARY BYPASS

- Anticoagulation
- Cannulation of the heart
- Careful monitoring to minimize organ dysfunction
- Protection of the heart
- Preparation for cardiopulmonary bypass

Nitric oxide has been used in cardiac surgery and in heart and lung transplantation as a selective pulmonary vasodilator.[630] However, there are no trials demonstrating any beneficial use for its prophylactic administration in the setting of cardiac surgery. Although it has statistically significantly reduced pulmonary artery pressures in cardiac surgery, it is unclear whether these reductions are reflected in improvements in overall outcome.

Management of Bypass

The Prebypass Period

An important objective of this phase is to prepare the patient for CPB (Box 31.7). This phase invariably involves two key steps: anticoagulation and vascular cannulation. With rare exception,[631] heparin is still the anticoagulant clinically used for CPB. Dose, method of administration, and opinions as to what constitutes adequate anticoagulation vary. Heparin must be administered before cannulation for CPB, even if cannulation must be done emergently. Failure to do so is to risk thrombosis in both the patient and extracorporeal circuit. Chapters 19, 34, and 35 offer a complete discussion of hemostasis management of cardiac surgery patients. After heparin has been administered, a period of at least 3 minutes is customarily allowed for systemic circulation and onset of effect; an activated coagulation time or heparin concentration measurement demonstrating actual achievement of adequate anticoagulation is then performed.

Vascular Cannulation

The next major step in the prebypass phase is vascular cannulation. The goal of vascular cannulation is to provide access whereby the CPB pump may divert all systemic venous blood to the pump-oxygenator at the lowest possible venous pressures and deliver oxygenated blood to the arterial circulation at pressure and flow sufficient to maintain systemic homeostasis (see Chapter 32).

Arterial Cannulation

Arterial cannulation is generally established before venous cannulation to allow volume resuscitation of the patient, should it be necessary. The ascending aorta is the preferred site for aortic cannulation because it is easily accessible, does not require an additional incision, accommodates a larger cannula to provide greater flow at a reduced pressure, and carries a lower risk of aortic dissection compared with other arterial cannulation sites (femoral or iliac arteries). Because hypertension increases the risk of aortic dissection during cannulation, the aortic pressure may be temporarily lowered (MAP < 70 mm Hg) during aortotomy and cannula insertion. Several potential complications are associated with aortic cannulation, including embolization of air or atheromatous debris, inadvertent cannulation of aortic arch vessels, aortic dissection, and other vessel wall injury.[632–637]

Reviews and clinical reports emphasize the importance of embolization as the major mechanism of focal cerebral injury in cardiac surgery patients. Barzilai and coworkers[638] and Wareing and associates[633] reported intraoperative use of two-dimensional epiaortic ultrasound imaging as a guide to selection of cross-clamping and cannulation sites. In 24% and 33% of the patients in the Barzilai and Wareing studies, respectively, ultrasonic findings led to selection of alternate cannulation sites. A femoral or axillary artery, rather than the ascending aorta, can be cannulated for systemic perfusion. These alternate sites can be used when ascending aortic cannulation is considered relatively contraindicated, as in severe aortic atherosclerosis, aortic aneurysm or dissection, or known cystic medical necrosis.[7,120,639,640] Historically, the anesthesiologist sought evidence of cannula malposition by looking for unilateral blanching of the face, gently palpating carotid pulses and checking for new unilateral diminution, and by measuring blood pressure in both arms and to check for new asymmetries. However, robust assessments of CBF symmetry can more reliably be made with the use of near-infrared spectroscopy cerebral oximetry (see Chapter 18).

Venous Cannulation

Venous cannulation can be achieved using a single atrial cannula that is inserted into the right atrium and directed inferiorly (Fig. 31.11). Drainage holes in this multistage cannula are located in the inferior vena cava (IVC) and right atrium to drain blood returning from the lower extremities and the SVC and coronary sinus, respectively. This technique has the advantage of being simpler, faster, and requiring only one incision; however, the quality of drainage can be easily compromised when the heart is lifted for surgical exposure.[641] The bicaval cannulation technique, required in cases in which right atrial access is needed, involves separately cannulating the SVC and IVC (Fig. 31.12). Loops placed around the vessels can be tightened to divert all caval blood flow away from the heart. Blood returning to the right atrium from the coronary sinus will not be drained using this technique, so an additional vent or atriotomy is necessary.

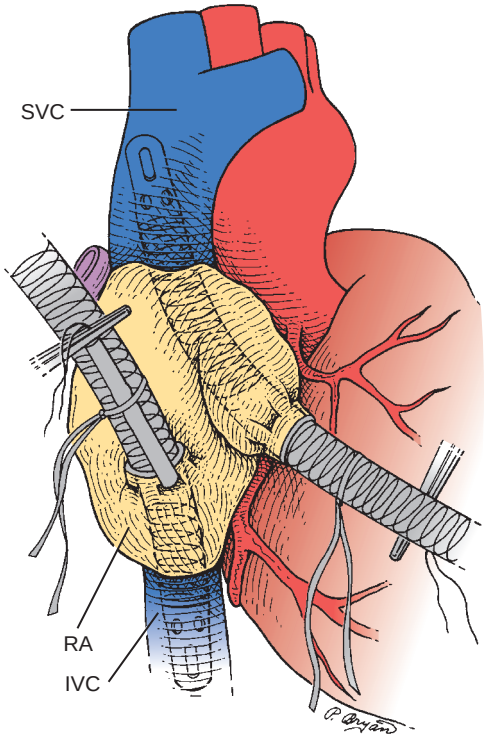

Fig. 31.12 Position of two-vessel cannulation of right atrium *(RA)* with placement of drainage holes into superior vena cava *(SVC)* and inferior vena cava *(IVC)*. The aortic cannula is not shown. *(From Connolly MW. Cardiopulmonary Bypass. New York: Springer-Verlag; 1995:59.)*

BOX 31.8 BYPASS PREPARATION CHECKLIST

1. Anticoagulation
   a. Heparin administered
   b. Desired level of anticoagulation achieved
2. Arterial cannulation
   a. Absence of bubbles in arterial line
   b. Evidence of dissection or malposition?
3. Venous cannulation
   a. Evidence of superior vena cava obstruction?
   b. Evidence of inferior vena cava obstruction?
4. Pulmonary artery catheter (if used) pulled back
5. Are all monitoring and/or access catheters functional?
6. Transesophageal echocardiograph (if used)
   a. In "freeze" mode
   b. Scope in neutral or unlocked position
7. Supplemental medications
   a. Neuromuscular blockers
   b. Anesthetics, analgesics, amnestics
8. Inspection of head and neck
   a. Color
   b. Symmetry
   c. Venous drainage
   d. Pupils

During CPB, blood will continue to return to the left ventricle from a variety of sources, including the bronchial and thebesian veins, as well as blood that traverses the pulmonary circulation. Abnormal sources of venous blood include a persistent left SVC, systemic-to-pulmonary shunts, and aortic regurgitation. It is important to avoid LV filling and distention during CPB to prevent myocardial rewarming, minimize LV wall tension, and limit myocardial oxygen demand.[642] This can be accomplished with the use of a vent placed in the left ventricle via the left superior pulmonary vein. Alternate sites include the pulmonary artery, the aortic root, or directly in the left ventricle via the ventricular apex.

Venous cannulas, using a multistage or bicaval cannula, are large and can impair venous return from the IVC or SVC. Superior vena caval obstruction is detected by venous engorgement of the head and neck, conjunctival edema, and elevated SVC pressure. Inferior vena caval obstruction is far more insidious, presenting only as decreased filling pressures because of lowered venous return.

Femoral venous cannulation is sometimes used for CPB without, or before, sternotomy or right atrial cannulation (eg, redos, ascending aortic aneurysms). Because of the femoral venous cannula's comparatively small size and long length, venous return can be impaired but is optimized when the tip of the cannula is advanced (under TEE guidance) until it is placed at the level of the SVC–right atrium junction. Kinetic or vacuum-assisted negative pressure can be applied to further enhance drainage.

Other Preparations

Once anticoagulation and cannulation are complete, CPB can be instituted. Because there usually is redundant pulmonary artery catheter length in the right ventricle, and the heart is manipulated during CPB, there is a tendency for distal migration of the catheter into pulmonary artery branches.[643] This distal migration of the catheter increases the risks of "overwedging" and pulmonary artery damage. During the prebypass phase it is advisable to withdraw the pulmonary artery catheter 3 to 5 cm to decrease the likelihood of these untoward events. It is also advisable to check the integrity of all vascular access and monitoring devices. A pulmonary artery catheter placed through an external jugular[644,645] or subclavian vein[646] can become kinked or occluded on full opening of the sternal retractor. If TEE is being used, the probe should be placed in the "freeze" mode and the tip of the scope placed in the neutral and unlocked position. Leaving the electronic scanning emitter turned on during hypothermic CPB adds heat (in some TEE models) to the esophagus and posterior wall of the ventricle.

Before initiating CPB, the anesthesiologist should assess the depth of anesthesia and adequacy of muscle relaxation. It is important to maintain paralysis to prevent patient movement that could result in dislodgment of bypass-circuit cannulas and prevent shivering as hypothermia is induced (with the attendant increases in oxygen consumption).[647] It is often difficult to determine the depth of anesthesia during the various stages of CPB. Because blood pressure, heart rate, pupil diameter, and the autonomic nervous system are profoundly affected by extracorporeal circulation (eg, the heart is asystolic, blood pressure is greatly influenced by circuit blood flow, and sweating occurs with rewarming), these variables do not reliably reflect the anesthetic state. Although hypothermia decreases anesthetic requirements, it is necessary to provide analgesia, hypnosis, and muscle relaxation during CPB. Useful adjuncts to assessing depth of anesthesia are available in the form of processed EEG devices. For example, the bispectral index has proven useful in preventing awareness during cardiac surgery.[648] With the initiation of CPB and hemodilution, blood levels of anesthetics and muscle relaxants acutely decrease. However, plasma protein concentrations also decrease, which increases the free-fraction and active drug concentrations. Every drug has a specific kinetic profile during CPB, and kinetics and pharmacodynamics during CPB vary greatly among patients. Many clinicians administer additional muscle relaxants and opioids at the initiation of CPB. A vaporizer for potent inhalation drugs may be included in the bypass circuit. Hall and investigators[649] offer an extended discussion of pharmacokinetics and bypass. A final inspection of the head and neck for color, symmetry, adequacy of venous drainage (neck vein and conjunctiva engorgement), and pupil equality is reasonable to serve as a baseline for the anesthetic state. A summary of preparatory steps to be accomplished during the prebypass phase is given in Box 31.8.

Initiation and Discontinuation of Bypass Support: An Overview

Initiation of Cardiopulmonary Bypass

Uncomplicated Initiation

Once all preparatory steps have been taken, the perfusionist progressively increases delivery of oxygenated blood to the patient's arterial system, as systemic venous blood is diverted from the patient's right side of the heart, maintaining the pump's venous reservoir volume. After full flow is achieved, all systemic venous blood is (ideally) draining from the patient to the pump reservoir. An on-bypass checklist of issues to address shortly after initiation of bypass can serve as a valuable safety tool (Box 31.9). The central venous pressure (CVP) and pulmonary arterial pressure should decrease to near zero (2–5 mm Hg), whereas systemic flow, arterial pressure, and oxygenation are maintained at desired values.

Hypotension With Onset of Bypass

Systemic arterial hypotension (MAP, 30–40 mm Hg) is relatively common on initiation of CPB. Gordon and colleagues[650] proposed that much of this could be explained by the acute reduction of blood viscosity that results from hemodilution with nonblood priming solutions. These investigators proposed systemic vascular resistance (SVR = MAP − CVP/CO) to be the product of blood viscosity (η) and inherent systemic vascular hindrance: SVR = η × SVH. MAP increases with initiation of hypothermia-induced vasoconstriction, along with levels of endogenous catecholamines and angiotensin. The hemodilution also results in the loss of nitric oxide binding by hemoglobin[651]; the excess free nitric oxide can lead to further vasodilation. Treatment with α-agonists is *usually* not necessary if the hypotension is brief (<60 s). Of concern is the potential for myocardial and cerebral ischemia because hypothermia has not yet been achieved.

Until the aortic cross-clamp is applied, the coronary arteries are perfused with hemodiluted, nonpulsatile blood. Schaff and coworkers[652] showed that subendocardial ischemia occurred in the distribution of critical coronary stenosis when MAP was less than 80 mm Hg in the normothermic empty beating heart. If placement of the aortic cross-clamp is delayed, MAP should be maintained in the range of 60 to 80 mm Hg to support myocardial perfusion, especially in the presence of known coronary stenosis or ventricular hypertrophy. This arterial pressure is likely adequate to maintain CBF until hypothermia is induced.

Unless pulsatile perfusion is used, once at full flow, the arterial pressure waveform should be nonpulsatile except for small (5–10 mm Hg) sinusoidal deflections created by the roller pump heads. Continued pulsatile arterial pressure indicates that the left ventricle is receiving blood from some source.

Pump Flow and Pressure During Bypass

Pump flow during CPB represents a careful balance between the conflicting demands of surgical visualization and adequate oxygen delivery. Two theoretical approaches exist. The first is to maintain oxygen delivery during CPB at normal levels for a given core temperature. Although this may limit hypoperfusion, it increases the delivered embolic load. The second approach is to use the lowest flows that do not result in end-organ injury. This approach offers the potential advantage of less embolic delivery as well as potential improved myocardial protection and surgical visualization.[653,654] However, some of these advantages are not seen when the left ventricle is vented during CPB.[655]

During CPB, pump flow and pressure are related through overall arterial impedance, a product of hemodilution, temperature, and arterial cross-sectional area. This is important because the first two factors, hemodilution and temperature, are critical determinants of pump flow requirements. Pump flows of 1.2 L/min per m^2 perfuse most of the microcirculation when the hematocrit is near 22% and hypothermic CPB is being employed.[656] However, at lower hematocrits or periods of higher oxygen consumption, these flows become inadequate.[657–659] Because of changes in oxygen demand with temperature and the plateauing of oxygen consumption with increasing flow, a series of nomograms have been developed for pump flow selection (Fig. 31.13).

In addition to use of these nomograms, most perfusion teams also monitor mixed venous oxygen saturation, targeting levels of 70% or greater. Unfortunately, this level does not guarantee adequate perfusion of all tissue beds, because some (muscle, subcutaneous fat) may be functionally removed from the circulation during CPB.[659] Hypothermic

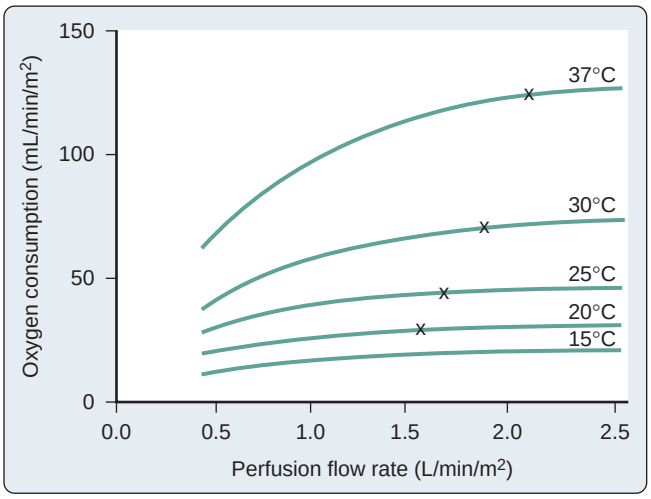

Fig. 31.13 Nomogram depicting the relationship of oxygen consumption (VO_2) to perfusion flow rate and temperature. The *x* on the curves represents common clinically used flow rates at the various temperatures. *(From Kirklin JW, Barratt-Boyes BG. Cardiac Surgery. New York: Wiley; 1986:35.)*

BOX 31.9 BYPASS PROCEDURE CHECKLIST

1. Assess arterial inflow.
   a. Is arterial perfusate oxygenated?
   b. Is direction of arterial inflow appropriate?
   c. Evidence of arterial dissection?
   d. Patient's arterial pressure persistently low?
   e. Inflow line pressure high?
   f. Pump/oxygenator reservoir level falling?
   g. Evidence of atrial cannula malposition?
   h. Patient's arterial pressure persistently high or low?
   i. Unilateral facial swelling, discoloration?
   j. Symmetrical cerebral oximetry?
2. Assess venous outflow.
   a. Is blood draining to the pump/oxygenator's venous reservoir?
   b. Evidence of SVC obstruction?
   c. Facial venous engorgement or congestion, CVP elevated?
3. Is bypass complete?
   a. High CVP/low PA pressure?
   b. Impaired venous drainage?
   c. Low CVP/high PA pressure?
   d. Large bronchial venous blood flow?
   e. Aortic insufficiency?
   f. Arterial and PA pressure nonpulsatile?
   g. Desired pump flow established?
4. Discontinue drug and fluid administration.
5. Discontinue ventilation and inhalation drugs to patient's lungs.

CVP, Central venous pressure; *PA*, pulmonary artery; *SVC*, superior vena cava.

venous saturation may overestimate end-organ reserves.[660] Slater and associates[564] characterized the hierarchy of regional blood flows during CPB at 27°C. Animals were perfused at pump blood flows of 1.9, 1.6, 1.3, and 1.0 L/min per m^2. Regional perfusion of various end-organs (brain, kidney, small intestine, pancreas, and muscle) was quantified with a fluorescent microsphere technique. CBF was unchanged at the three greatest pump flows. Renal perfusion was maintained at flows of 1.9 and 1.6 L/min per m^2. Perfusion to the pancreas was constant at all flows studied, and small bowel perfusion varied linearly with pump flow. Muscle bed flows were decreased at all flows. This study confirmed previous work regarding end-organ perfusion during CPB and highlighted the vulnerability of the kidneys to reduced flows at moderate hypothermia.

During CPB, most of the outcomes studied in relation to pump flow are those related to the organs at high risk for ischemic injury (ie, kidney and brain). Much work has been applied to examining the relationship between renal dysfunction and pump flow.[314,319,661,662] Preexisting renal disease is a consistent predictor of postoperative renal dysfunction, the incidence of which ranges between 3% and 5%. Renal function appears unaltered when pump flows greater than 1.6 L/min per m^2 are employed,[661] but whether this management will affect outcomes in patients with preexisting renal dysfunction is less clear.[662] Because of autoregulation, most studies,[175,663] but not all,[664] suggest that CBF is unaltered by variation in pump flow. At low-flow states, CBF is probably more dependent on perfusion pressure.[665–667] Discussion regarding organ-specific relationships of pressure to organ dysfunction are included in the previous section on end-organ effects of CPB.

Preparation for Separation

Before discontinuation of CPB, conditions that optimize cardiac and pulmonary function must be restored. To a great extent this is achieved by reversing the processes and techniques used to initiate and maintain CPB (Box 31.10).

BOX 31.10 PREPARATION FOR SEPARATION FROM BYPASS CHECKLIST

1. Air clearance maneuvers completed
2. Rewarming completed
   a. Nasopharyngeal temperature 36–37°C
   b. Rectal/bladder temperature ≥35°C, but ≤37°C
3. Address issue of adequacy of anesthesia and muscle relaxation
4. Obtain stable cardiac rate and rhythm (use pacing if necessary)
5. Pump flow and systemic arterial pressure
   a. Pump flow to maintain mixed venous saturation ≥70%
   b. Systemic pressure restored to normothermic levels
6. Metabolic parameters

Potential for Patient Awareness

It is not uncommon for patients to sweat during rewarming. This is almost certainly caused by perfusion of the hypothalamus (ie, the thermoregulatory site) with blood that is warmer than the latter organ's set-point (37°C). The brain is a high-flow organ and can be assumed to equilibrate fairly quickly (10 to 15 minutes) with cerebral perfusate temperature (ie, nasopharyngeal temperature). A less likely, but more disturbing, possibility is that restoration of brain normothermia with decreased anesthetic concentration may result in an inadequate depth of anesthesia and the potential for awareness. It is estimated that awareness occurs during cardiac surgery in approximately 0.1% of patients.[648]

The following suggestions are made to attempt to limit the possibility and sequelae of awareness during cardiac surgery with CPB. During the preoperative evaluation, the possibility of awareness and why it could occur should be discussed with the patient. Use of volatile agents for their amnestic properties should be considered. During the postoperative visit, a mechanism whereby the patient can freely communicate perioperative experiences should be provided. Necessary support, including counseling, to minimize potential long-term psychologic problems should awareness be reported should be provided.

Patient movement before discontinuation of CPB is, at the least, extremely disruptive and may be genuinely life-threatening if it results in cannula dislodgment or disruption of the procedure. Additional muscle relaxant should be administered. If awareness is suspected, supplemental amnestics or anesthetics should be administered during rewarming. Because sweating stops almost immediately on discontinuation of CPB, continued sweating after emergence from CPB may be a sign of awareness. Neurologic monitors such as the bispectral index can be used to help judge the depth of anesthesia during and after weaning from CPB.[668]

Rewarming

When systemic hypothermia is used, body temperature is restored to normothermia by gradually increasing perfusate temperature with the heat exchanger. Time required for rewarming (ie, heat transfer) varies with arterial perfusate temperature, patient temperature, and systemic flow. Excessive perfusate heating is not advisable for at least three key reasons: possible denaturation of plasma proteins, possible cerebral hyperthermia, and the fact that dissolved gas can come out of solution and coalesce into bubbles if the temperature gradient is too great. Because small increases (0.5°C) in cerebral temperature exacerbate ischemic injury in the brain, it is critical to perfuse the patient with blood temperatures at or below 37°C. Although this will increase the duration of rewarming, the risk of hyperthermic brain injury is greatly increased with hyperthermic blood temperatures. Most centers now employ mild hypothermia (ie, systemic temperature 32–35°C) instead of moderate hypothermia (26–28°C), reducing the amount of heat transfer required to achieve normothermia during rewarming.

Rewarming may be enhanced by increasing pump flow, which thereby increases heat input. At levels of hypothermia routinely used (25–30°C), the patient behaves as if vasoconstricted (calculated SVR is relatively high). Increasing pump flow in this setting may result in unacceptable hypertension. There are two approaches to this problem: wait out the vasoconstriction or pharmacologically induce patient vasodilation. When rectal or bladder temperature approaches 30 to 32°C, patients appear to rapidly vasodilate. This is probably the result of decreasing blood viscosity or relaxation of cold-induced vasoconstriction with warming. Increasing pump flow at this point serves several purposes: increased heat transfer, support of systemic arterial pressure, and increased oxygen delivery in the face of increasing oxygen consumption. Often, waiting for the patient to spontaneously vasodilate is sufficient, and with subsequent increased pump flows, rewarming will be adequate at separation from CPB support. Circumstances in which more aggressive rewarming may be needed include profound hypothermia with a large hypoperfused "heat sink" and late initiation of warming by accident or design.

Skeletal muscle and subcutaneous fat are relatively hypoperfused during CPB. These tissues cool slowly and are also slow to warm. Temperatures at high-flow regions (eg, esophagus, nasopharynx) do not reflect the temperature of these tissues. Davis and investigators[669] reported that restoration of normothermia (as monitored at high-flow sites) led to a net heat deficit after CPB, with subsequent recooling after emergence (ie, afterdrop). Pharmacologic vasodilation allows an earlier increase in pump flow and delivery of warmed arterial blood to low-flow beds, making the rewarming process more uniform. Noback and Tinker[670] used sodium nitroprusside (3.5 ± 0.8 μg/kg per min) to permit increased pump flows during warming, from 4.0 to 4.5 L/min, keeping MAP at approximately 70 mm Hg. Compared with a group who were warmed without sodium nitroprusside for an equivalent period of time, the sodium nitroprusside group had much greater peripheral warming and a much smaller decline in postbypass temperature. Arteriolar vasodilators (eg, nicardipine, sodium nitroprusside) are much more likely to be effective in this process than venodilators (eg, nitroglycerin). Other aids to warming during or after CPB are sterile forced-air rewarming devices and servoregulated systems,[671] as well as heating blankets, warmed fluids,[672] heated humidified gases,[673] and increased room temperature. The issue of afterdrop is less of a concern during routine cardiac surgery but manifests frequently in patients following deep hypothermic circulatory arrest (DHCA).

Unfortunately, there is a very narrow range for acceptable systemic temperatures at the end of CPB. Just as temperatures that are "too hot" increase the risk of cerebral injury, those that are "too cool" may lead to inadequate rewarming and the problem of shivering, increased oxygen consumption and carbon dioxide production, and coagulopathies. It is imperative to prevent cerebral hyperthermia in patients undergoing CPB. Additional heat may be added to the patient *after* discontinuation of CPB with the use of external heating devices. This approach can prevent the complications of hypothermia without the use of hyperthermic blood.

Targets for rectal or bladder temperature before separation from CPB vary among institutions. Nathan and Polis[674] surveyed 28 Canadian centers regarding temperature monitoring practices during cardiac surgery and found the use of a variety of monitoring sites (Fig. 31.14). Many centers failed to use monitors likely to reflect cerebral temperatures routinely: not one center studied routinely monitored tympanic membrane temperature, and only slightly more than one-half monitored nasopharyngeal temperatures. The investigators were unable to discern any uniformity of practice regarding monitors or rewarming temperature end points. In general, temperatures measured at highly perfused tissues exceeded 37°C in most centers at the end of bypass.

Cook and colleagues[675] reported that cerebral hyperthermia occurs with rewarming. They studied 10 cardiac surgery patients requiring hypothermic CPB and measured nasopharyngeal and cerebral venous temperature (monitored at the jugular bulb). Ten minutes after the onset of rewarming from 27°C, cerebral venous temperature was 37°C, but nasopharyngeal temperature was only 34°C ± 2.9°C. After 18 minutes of rewarming, nasopharyngeal temperature reached 37°C and cerebral venous temperature was 38.2°C ± 1.1°C. Peak central venous temperature exceeded 39°C for an average of 15 minutes in all 10 patients before the termination of CPB.

Nathan and Polis[674] found a substantial difference between tympanic membrane and urinary bladder temperature in 11 patients rewarmed after hypothermic CPB (Fig. 31.15). The peak temperature for each patient was aligned at minute 0; temperatures were displayed for 30 minutes before (–30 to 0 min) and after (0 to 30 min) the peak temperature. There was a smooth increase in bladder temperature from 31.4 to 36°C, but an "overshoot" in peak tympanic membrane temperature to a mean of 38.6°C (range, 37.7–39.7°C). Because tympanic membrane temperature better reflects cerebral temperature than does bladder temperature, it is likely that all 11 patients were exposed to hyperthermic cerebral temperatures.

Restoration of Systemic Arterial Pressure to Normothermic Value

After aortic cross-clamp release, the heart is again perfused through the native coronary arteries. Until the proximal anastomoses are made, myocardial perfusion may be compromised in the presence of a low MAP. Consequently, it is advisable to gradually increase MAP during rewarming to levels of approximately 70 to 80 mm Hg.

With discontinuation of CPB, a marked discrepancy often exists between blood pressure readings measured from the radial artery and the central aorta. Radial arterial catheters may underestimate central

The management of temperature during hypothermic cardiopulmonary bypass: I. Canadian survey.* Can J Anaesth *1995;42:669–671.)*

aortic systolic pressures by 10 to 40 mm Hg. Discrepancies in MAP tend to be of a lesser magnitude (5–15 mm Hg). Such a discrepancy is not present before CPB, nor is it present after CPB in all patients. Mechanisms are undefined, but evidence supports vasodilatory and arteriovenous shunting phenomena in the forearm and hand.[676] Gravlee and coworkers[677] found that systolic pressure differences after CPB were not significantly influenced by duration of CPB, use of sodium nitroprusside or phenylephrine during the final 15 minutes of CPB, SVR, minimum CPB temperature, CPB separation temperature, or duration of rewarming. Blood pressure readings from brachial or femoral arterial catheters tend to more accurately reflect central aortic pressure. It is unknown at what point during CPB radial artery–central aortic blood pressure discrepancies develop, but most investigators report their resolution 20 to 90 minutes after discontinuation of CPB (see Chapter 13).

If measured radial arterial pressure is suspected to be low in relation to central aortic pressure, several actions can be taken. The surgeon can estimate central aortic pressure by palpation of the ascending aorta, place a small needle in the aortic lumen, use an aortic cannula to allow temporary monitoring of aortic pressure, or place a femoral arterial catheter.

Removal of Intracardiac Air

At the end of the procedure, intracardiac air is present in virtually all cases that require opening the heart (ie, valve repair or replacement, aneurysmectomy, septal defect repair, repair of congenital lesions).[678] In such cases, it is important to remove as much air as possible before resumption of ejection. Surgical techniques differ. With the aortic cross-clamp still applied, the surgeon or perfusionist can partially limit venous return and LV vent flow, causing the left atrium and left ventricle to fill with blood. Through a transventricular approach, the left ventricle can then be aspirated. The left atrium and left ventricle are balloted to dislodge bubbles, and the cycle is repeated. The operating table can be rotated from side to side and the lungs ventilated to promote clearance of air from the pulmonary veins. Rather than using transventricular aspiration, some surgeons vent air through the cardioplegia cannula or a needle vent in the ascending aorta. Before removal of the aortic cross-clamp, the patient is placed head down, so that bubbles will float away from the dependent carotid arteries. Some surgeons favor temporary manual carotid occlusion before cross-clamp removal, but safety and efficacy of this potentially dangerous maneuver are undocumented. A venting cannula is often left in the aorta at a location that should allow air pickup after resumption of ejection.

Oka and associates,[678] using TEE, showed that routine air clearance techniques are not completely effective. Transcranial Doppler studies document a high incidence of intracranial gas emboli on release of the aortic cross-clamp or resumption of ejection. Oka and associates[678] described three essential elements of air removal: mobilization of air by positive chamber filling, stretching of the atrial wall, and repeated chamber ballottement; removal of mobilized air by continuous ascending aortic venting; and proof of elimination by TEE. The investigators contended that using these techniques could completely eliminate intracardiac air. Carbon dioxide gas insufflated by gravity into open cardiac chambers during CPB helps replace nitrogen in the bubbles with a more soluble gas. Accordingly, the persistence of gas bubbles observed by TEE after release of the aortic cross-clamp was lower in patients exposed to CO_2 in the chest wound than in the controls. However, CO_2 insufflation should be used in addition to, rather than instead of, other de-airing maneuvers.[679]

Intracardiac air may be present in 10% to 30% of closed cardiac cases as well (eg, CABG).[678] Robicsek and Duncan[680] demonstrated that during aortic cross-clamping, air may enter the aorta and left ventricle retrograde through native coronary arteries opened in the course of CABG surgery, particularly when suction is applied to vent the left side of the heart or aortic root. They suggest that efforts to expel air from the left ventricle and aortic root should be routine before unclamping the aorta. It is unclear to what extent gas emboli originating from the heart and aorta contribute to neurologic injury. Oka and associates[678] found that most patients in whom LV microbubbles were detected were free of major neurologic injury. This result is in agreement with the findings of several investigators who detected LV and cerebral microbubbles for various periods after CPB without apparent neurologic sequelae. However, microembolic load correlates with magnitude of cognitive dysfunction.[681] Other studies report that air ejected from the left ventricle can also travel to the coronary arteries, resulting in sudden and sometimes extreme myocardial ischemia and failure after separation from bypass (see Chapter 36).

Defibrillation

Before discontinuation of CPB, the heart must have an organized rhythm that is spontaneous or pacer induced. Ventricular fibrillation, common after cross-clamp release and warming, will often spontaneously convert to some other rhythm. Prolonged ventricular fibrillation is undesirable during rewarming for at least three reasons: subendocardial perfusion is compromised in the presence of normothermic ventricular fibrillation; myocardial oxygen consumption is greater with ventricular fibrillation compared with a beating heart at normothermia; and, if the left ventricle receives a large amount of blood (aortic insufficiency or bronchial return) in the absence of mechanical contraction, the left ventricle may distend. LV distention increases wall tension and further compromises subendocardial perfusion. On the other hand, early resumption of mechanical contraction may make some surgical procedures difficult (eg, modification of distal anastomoses).

Defibrillation, when necessary, is accomplished with internal paddles at much lower energies than would be used for external cardioversion. In the adult, starting energies of 5 to 10 J are routine. Defibrillation is less effective when the heart has not fully rewarmed, and it is rarely successful if myocardial (perfusate) temperature is less than 30°C.[682] Repeated attempts at defibrillation, particularly with escalating energy levels, can lead to myocardial injury. If defibrillation is not successful after two to four attempts, options include further warming, correction of blood gas and electrolyte abnormalities if present (high P_{O_2} and high normal serum potassium [K^+] seem favorable), increased MAP, and antiarrhythmic therapy. Bolus administration of 100 mg of lidocaine before the release of the cross-clamp significantly lowers the incidence of reperfusion ventricular fibrillation.[683] Increasing coronary perfusion by increased MAP is believed to result in myocardial reperfusion and recovery of the energy state. Larger loading doses of antiarrhythmics will be needed to achieve therapeutic concentrations, because of the larger CPB volume of distribution.

Restoration of Ventilation

With discontinuation of CPB, the venous outflow line is gradually occluded and pulmonary arterial blood flow restored. Researchers disagree as to the nature and magnitude of pulmonary dysfunction after CPB, and various aspects of this problem were discussed earlier. Some studies have found evidence of increased dead space–to–tidal volume ratio (V_d/V_t) after CPB, whereas others have not.[684] Increased V_d/V_t would result in less effective alveolar ventilation than prebypass, which would result in elevated $PaCO_2$. Other studies report modest increases in pulmonary shunt fraction after CPB, which leads to less effective oxygenation and decreased PaO_2. Catastrophic bypass-induced pulmonary injury with severe hypoxemia immediately on discontinuation of CPB is exceedingly uncommon in adults.

Before discontinuation of CPB, the lungs must be reinflated. Positive pressure (20–40 cm H_2O) is repeatedly applied until all areas of atelectasis are visually reinflated. Attention is specifically directed at the left lower lobe, which seems more difficult to reexpand. Fluid that has collected in the thoracic cavities during CPB is removed by the surgeon, and if the pleural cavity has not been opened, evidence of pneumothorax is also sought. The ventilatory rate can be increased 10% to 20% above prebypass values to compensate for increased V_d/V_t if present. Ventilation is resumed with 100% oxygen and subsequent adjustments in F_{IO_2} are made based on arterial blood gas analysis and pulse oximetry.

Correction of Metabolic Abnormalities and Arterial Oxygen Saturation

When rewarming is nearly complete and separation from CPB is anticipated to occur in 10 to 15 minutes, an arterial blood sample is taken and analyzed for acid-base status, P_{O_2}, partial pressure of carbon dioxide (P_{CO_2}), hemoglobin or hematocrit, potassium, and ionized calcium.

Oxygen-Carrying Capacity

Generally, a hematocrit of at least 20% to 25% is sought before bypass is discontinued. The primary compensatory mechanism to ensure adequate systemic oxygen delivery in the presence of normovolemic anemia is increased CO. Increased CO results in an increased myocardial oxygen need, which is met by increased coronary oxygen delivery by coronary vasodilation. The lower limit of the hematocrit, below which increased CO can no longer support systemic oxygen needs, is reported to be 17% to 20% in dogs with completely healthy hearts.[685] With increases in systemic V_{O_2}, such as occur with exercise, fever, or shivering, higher values of the hematocrit are required. Patients with good ventricular function and good coronary reserve (or good revascularization) might be expected to tolerate hematocrit values in the 20s. When ventricular function is impaired or revascularization is incomplete, hematocrit above 25% may aid in support of the systemic circulation and concomitantly lower myocardial oxygen requirements on discontinuation of bypass.

When pump or oxygenator reservoir volume is in excess, the hematocrit can be increased by use of hemofiltration. As described by Klineberg and colleagues,[686] application of a hydrostatic pressure gradient across a porous membrane results in transport of water and low-molecular-weight solutes (molecular weight, 500–50,000). Ultrafiltrate composition is similar to glomerular filtrate with solute concentrations identical to that of plasma water (see Chapter 32).

Arterial pH

Considerable debate has centered on the extent to which acidemia affects myocardial performance and whether correction of arterial pH with sodium bicarbonate is advantageous or deleterious to the heart.[687] Studies have challenged long-held beliefs that acidemia impairs myocardial performance. Nevertheless, most in vivo and clinical studies have found metabolic acidosis impairs contractility and alters responses to exogenous catecholamines.[688] Hemodynamic deterioration is usually mild above pH 7.2 because of compensatory increases in sympathetic nervous system activity.[688] Attenuation of sympathetic nervous system responses by ß-blockade or ganglionic blockade increases the detrimental effect of acidosis. The ischemic myocardium has been found to be particularly vulnerable to detrimental effects of acidosis. Patients with poor contractile function or reduction of myocardial sympathetic responsiveness (eg, chronic LV failure), those treated with β-blockers, or those with myocardial ischemia are especially susceptible to the adverse effects of acidosis. For these reasons arterial pH is corrected to near-normal levels before discontinuation of CPB, using sodium bicarbonate. Concerns regarding carbon dioxide generation and acidification of the intracellular space can be obviated by slow administration and appropriate adjustment of ventilation, both of which are easily achieved during CPB.

Electrolytes

Electrolytes most commonly of concern before discontinuation of CPB are potassium and calcium. Serum potassium concentration may be acutely low because of hemodilution with nonpotassium priming solutions, large-volume diuresis during CPB, or the use of insulin to treat hyperglycemia. More commonly, potassium concentration is elevated as a result of systemic uptake of potassium-containing cardioplegic solution; values exceeding 6 mEq/L are not uncommon. Other potential causes of hyperkalemia that must be considered are hemolysis, tissue ischemia or necrosis, and acidemia. Hypokalemia can be rapidly corrected during CPB with relative safety because the heart and systemic circulation are supported. Increments of 5 to 10 mEq of KCl over 1- to 2-minute intervals can be given directly into the oxygenator by the perfusionist, and potassium subsequently is rechecked. Depending on severity and urgency of correction, elevated potassium can be treated or reduced by any of several standard means: alkali therapy, diuresis, calcium administration, or insulin and glucose. Alternatively, hemofiltration can be used to lower serum potassium. While the patient is still on CPB, potassium-containing extracellular fluid is removed and replaced with fluid not containing potassium.

Ionized calcium is involved in the maintenance of normal excitation-contraction coupling and therefore in maintaining cardiac contractility and peripheral vascular tone. Low concentrations of ionized calcium lead to impaired cardiac contractility and lowered vascular tone. Concerns have been raised about the contribution of calcium administration to myocardial reperfusion injury and to the action of various inotropes.[689] Some investigators argue in favor of measuring ionized calcium before discontinuation of CPB and to administer calcium in patients with low concentrations to optimize cardiac performance.[690] Although they routinely measure ionized calcium before discontinuation of bypass, calcium salts are not routinely administered. When confronted with poor myocardial or peripheral vascular responsiveness to inotropes or vasopressors after bypass in the presence of a low level of ionized calcium, calcium salts should be administered to restore ionized calcium to normal (not elevated) levels in the hope of restoring responsiveness. The same strategy can be used for measuring and administering magnesium.

Other Final Preparations

Before the patient is separated from CPB, all monitoring and access catheters should be checked and calibrated. The zero-pressure calibration points of the pressure transducers are routinely checked. Not uncommonly, finger pulse oximeter probes do not have a good signal after CPB. In those cases, a nasal or ear probe is placed to obtain reliable oximetry. Intravenous infusions are restarted before separation from CPB, and their flow characteristics are assessed for evidence of obstruction or disconnection.

During warming and preparation for separation, an assessment should be made of the functional status of the heart and peripheral vasculature based on visual inspection, hemodynamic indices, and metabolic parameters. Based on this assessment, inotropes, vasodilators, and vasopressors thought likely to be necessary for successful separation from CPB should be prepared and readied for administration.

Separation From Bypass

After all preparatory steps are taken (see Box 31.10), CPB can be discontinued. Venous outflow to the pump or oxygenator is impeded by slowly clamping the venous line, and the patient's intravascular volume and ventricular loading conditions are restored by transfusion of perfusate through the aortic inflow line. When loading conditions are optimal, the aortic inflow line is clamped, and the patient is separated from CPB.

At this juncture it must be determined whether oxygenation, ventilation, and, more commonly, myocardial performance (systemic perfusion) are adequate. A discussion of these issues no longer involves CPB per se, but rather applied cardiopulmonary physiology. Consequently, a discussion of this extremely important topic is detailed in Chapters 36 and 38. Should separation fail for any reason, CPB can simply be reinstituted by unclamping the venous outflow and arterial inflow lines and restoring pump flow. This allows for support of systemic oxygenation and perfusion while steps are taken to diagnose and treat those problems that precluded successful separation.

Perfusion Emergencies

Accidents or mishaps occurring during CPB can quickly evolve into life-threatening emergencies (Box 31.11). Many of the necessary conditions of CPB (cardiac arrest, hypothermia, volume depletion) preclude the ability to resume normal cardiorespiratory function if an accident

TABLE 31.11 Comparison of the Five Most Common Accidents From the Three Perfusion Surveys

BOX 31.11 PERFUSION EMERGENCIES

- Arterial cannula malposition
- Aortic dissection
- Massive air embolism
- Venous air lock
- Reversed cannulation

threatens the integrity of the extracorporeal circuit. Fortunately, major perfusion accidents occur infrequently and are rarely associated with permanent injury or death (Table 31.11). However, all members of the cardiac surgery team must be able to respond to perfusion emergencies to limit the likelihood of perfusion-related disasters. Some of the most common emergencies are discussed in the subsequent sections.

Arterial Cannula Malposition

Ascending aortic cannulas can be malpositioned such that the outflow jet is directed primarily into the innominate artery,[691–693] the left common carotid artery (rare),[694,695] or the left subclavian artery (rare).[696] The latter two can occur with the use of long arch-type cannulas. In the first two circumstances, unilateral cerebral *hyperperfusion*, usually with systemic hypoperfusion, occurs, whereas flow directed to the subclavian artery results in global cerebral *hypoperfusion*. Despite the fact that not all combinations of arterial pressure monitoring site and cannula malposition produce systemic hypotension, it is commonly regarded as a cardinal sign of cannula malposition. For example, right arm blood pressure monitoring and innominate artery cannulation,[691] or left arm monitoring and left subclavian artery cannulation,[696] may result in *high* arterial pressure on initiation of bypass. With other positioning and monitoring combinations, investigators report persistently low systemic arterial pressure (MAP, 25–35 mm Hg), which is poorly responsive to increasing pump flow or vasoconstrictors. Over time (minutes), signs of systemic hypoperfusion (eg, acidemia, oliguria) develop.[694] Because a variable period of systemic hypotension with CPB initiation is nearly always seen with hemodilution, hypotension alone is not significant evidence to establish a diagnosis of arterial cannula malposition. Ross and coworkers[694] described a case of accidental left common carotid cannulation with unilateral facial and conjunctival edema accompanied by rhinorrhea, otorrhea, and signs of systemic hypoperfusion. In a similar case, Sudhaman[695] found left facial congestion, whereas the right side was pale. Watson[691] described a case of innominate artery cannulation. On initiation of CPB, the skin over the carotid vessels on the right was colder than on the left. Three cases of innominate cannulation produced dramatic unilateral facial blanching with onset of CPB due to perfusion with nonblood-containing priming solution.[692,693] On initiation of CPB and periodically thereafter, it is advisable to inspect the face for color change and edema, rhinorrhea, or otorrhea and to palpate the neck with onset of cooling for temperature asymmetry. EEG monitoring was first advocated as a method of detecting cannula malposition. In one study, cannula malposition, detected by EEG asymmetry, occurred in 3 (3.5%) of 84 patients.[697] However, transcranial Doppler, and more commonly available cerebral oximetry, is the monitor of choice to detect malperfusion secondary to cannula complications (see Chapter 18).

Two other arterial cannula malpositions are possible: abutment of the cannula tip against the aortic intima, which results in high line pressure, poor perfusion, or even acute dissection when CPB is initiated, and the cannula tip directed caudally toward the aortic valve. This may result in acute aortic insufficiency, with sudden LV distention and systemic hypoperfusion on bypass. If the aortic inflow cannula is soft, aortic cross-clamping will occlude the arterial perfusion line, which can rupture the aortic inflow line. Suspicion of any cannula malposition must immediately be brought to the attention of the surgeon.

Aortic or Arterial Dissection

Signs of arterial dissection, often similar to those of cannula malposition, must also be sought continuously, especially on initiation of CPB. Dissection may originate at the cannulation site, aortic cross-clamp site, proximal vein graft anastomotic site, or partial occlusion (side-biting) clamp site. Dissections are due to intimal disruption or, more distally, to fracture of atherosclerotic plaque. In either case, some systemic arterial blood flow becomes extraluminal, being forced into the arterial wall. The dissection propagates mostly but not exclusively in the direction of the systemic flow. Extraluminal blood compresses the luminal origins (take-offs) of major arterial branches such that vital organs (heart, brain, kidney, intestinal tract, spinal cord) may become ischemic. Because systemic perfusion may be low, and origins of the innominate and subclavian arteries may be compressed, probably the best sign of arterial dissection is persistently low systemic arterial pressure.[698] Venous drainage to the pump decreases (blood is sequestered), and arterial inflow "line pressure" is usually inappropriately high. The surgeon may see the dissection if it involves the anterior or lateral ascending aorta (bluish discoloration), or both.[698,699] It is possible the surgeon may *not* see any sign of dissection, because the dissection is out of view (eg, posterior ascending aorta, aortic arch, descending aorta). A careful TEE examination at this time may show the dissection and its extent. Dissection can occur at any time before, during, or after CPB. As with cannula malposition, a suspicion of arterial dissection must be brought to the attention of the surgeon. The anesthesiologist must not assume that something is suddenly wrong with the arterial pressure transducer but should "think dissection."

After a dissection of the ascending aorta is diagnosed, immediate steps to minimize propagation must be taken. If it has occurred before CPB, the anesthesiologist should take steps to reduce MAP and the rate of rise of aortic pressure (dP/dt). If it occurs during CPB, pump flow and MAP are reduced to the lowest acceptable levels. Arterial perfusate is frequently cooled to profound levels (14–19°C) as rapidly as possible to decrease metabolic demand and protect vital organs.[699] A different arterial cannulation site is prepared (eg, the femoral artery is cannulated or the true aortic lumen is cannulated at a site more distal on the aortic arch). Arterial inflow is shifted to that new site with the intent that perfusing the true aortic lumen will reperfuse vital organs.[699] The ascending aorta is cross-clamped just below the innominate artery, and cardioplegia is administered (into the coronary ostia or coronary sinus). The aorta is opened to expose the site of disruption, which is then resected and replaced. Reimplantation of the coronary arteries or aortic valve replacement, or both, may be necessary. The false lumina at both ends of the aorta are obliterated with Teflon buttresses, and the graft is inserted by end-to-end suture.[639] With small dissections it is sometimes possible to avoid open repair by application of a partial occlusion clamp with plication of the dissection and exclusion of the intimal disruption.[699] Troianos and associates[700] described three cases of arterial dissection during CPB in which TEE was found useful. Although provisional diagnoses were made on the basis of traditional signs, TEE allowed assessment of the origin and extent of dissection. Diagnosis of arterial dissection has also been assisted by presence of EEG[701] and cerebral oximetry asymmetry.[702]

Arterial dissections originating from femoral cannulation also necessitate reductions in arterial pressure, systemic flow, and temperature. If the operation is near completion, the heart may be transfused and CPB discontinued; otherwise, the aortic arch must be cannulated and adequate systemic perfusion restored to allow completion of the operation.[698]

Massive Arterial Gas Embolus

Macroscopic gas embolus is a rare but disastrous CPB complication. Two independent studies in 1980 reported incidences of recognized massive arterial gas embolism of 0.1% to 0.2%.[703,704] The current incidence is probably lower because of the widespread use of reservoir-level alarms and other bubble detection devices. Between 20% and 30% of affected patients died immediately, with another 30% having transient or nondebilitating neurologic deficits, or both. Circumstances that most commonly contributed to these events were inattention to oxygenator blood level, reversal of LV vent flow, or unexpected resumption of cardiac ejection in a previously opened heart. Rupture of a pulsatile assist device[705] or intraaortic balloon pump[706] may also introduce large volumes of gas into the arterial circulation.

The pathophysiology of cerebral gas embolism (macroscopic and microscopic) is not well understood. Tissue damage after gas embolization is initiated from simple mechanical blockage of blood vessels by bubbles.[707,708] Although gas emboli may be absorbed or pass through the circulation within 1 to 5 minutes,[707–710] the local reaction of platelets and proteins to the blood gas interface or endothelial damage is thought to potentiate microvascular stasis,[710–715] prolonging cerebral ischemia to the point of infarction. Areas of marginal perfusion, such as arterial boundary zones, do not clear gas emboli as rapidly as well-perfused zones,[707] producing patterns of ischemia or infarction difficult to distinguish from those due to hypotension or particulate emboli.

Recommended treatment for massive arterial gas embolism includes immediate cessation of CPB with aspiration of as much gas as possible from the aorta and heart, assumption of steep Trendelenburg position, and clearance of air from the arterial perfusion line. After resumption of CPB, treatment continues with implementation or deepening of hypothermia (18–27°C) during completion of the operation and clearance of gas from the coronary circulation before emergence from CPB.[704,705,716,717] In many reports of patients suffering massive arterial gas embolus, seizures occurred postoperatively and were treated with anticonvulsants.[128,717–719] Because seizures after ischemic insults are associated with poor outcomes, perhaps because of hypermetabolic effects, prophylactic phenytoin seems reasonable. Hypotension has been shown to lengthen the residence time of cerebral air emboli and worsen the severity of resulting ischemia.[720] Maintenance of moderate hypertension therefore is reasonable and clinically attainable to hasten clearance of emboli from the circulation and, hopefully, improve neurologic outcome.

Many clinicians have reported dramatic neurologic recovery when hyperbaric therapy was used for arterial gas embolism, even if delayed up to 26 hours after the event.[705,715,716,721] Spontaneous recovery from air emboli has also been reported,[712,717,719,721] and no prospective study of hyperbaric therapy in the cardiac surgery setting has been performed.[722] Few institutions that do cardiac surgery have an appropriately equipped and staffed hyperbaric chamber to allow expeditious and safe initiation of hyperbaric therapy. Nonetheless, immediate transfer by air is often possible and should seriously be considered. It seems reasonable to expect that institutions that perform cardiac surgery should have policies regarding catastrophic air embolism.

In 1980, Mills and Ochsner[704] suggested venoarterial perfusion as an alternative to hyperbaric therapy. Retrograde perfusion through the SVC cannula at 1.2 L/min at 20°C for 1 to 2 minutes was used in five of their eight patients with massive gas embolism. The goal was to flush air from the cerebral arterial circulation. None of the patients so treated had evidence of neurologic injury. Other reports using this technique have followed.[723,724] Hendriks and investigators,[725] in a porcine model of venoarterial perfusion, found that only 50% of injected gas (nitrogen) could be recovered from the aorta. Ninety-eight percent of the removable gas was collected from the aorta in the first 7 to 10 minutes of retrograde perfusion. Although no animal (clinically or pathologically) appeared to sustain neurologic injury, the investigators concluded that venoarterial perfusion did not adequately remove embolized gas, and hyperbaric therapy remained the treatment of choice. The timing of the embolism is also a major consideration. For example, if massive air embolism occurs during connection, serious consideration should be given to abandoning the procedure in order to allow immediate therapy and awakening the patient to assess neurologic status. Air embolism and its subsequent cerebral ischemia are likely worsened by the nonphysiologic nature of CPB as well as its inherent inflammatory processes.

Venous Air Lock

Air entering the venous outflow line can result in complete cessation of flow to the venous reservoir, and this is called *air lock*. Loss of venous outflow necessitates immediate slowing, even cessation of pump flow, to prevent emptying the reservoir and subsequent delivery of air to the patient's arterial circulation. After an air lock is recognized, a search for the source of venous outflow line air must be undertaken (eg, loose atrial purse-string suture, atrial tear, open intravenous access) and repaired before reestablishing full bypass.

Reversed Cannulation

In reversed cannulation, the venous outflow limb of the CPB circuit is incorrectly connected to the arterial inflow cannula, and the arterial perfusion limb of the circuit is attached to the venous cannula. On initiation of CPB, blood is removed from the arterial circulation and returned to the venous circulation at high pressure. Arterial pressure is found to be extremely low by palpation and arterial pressure monitoring. Very low arterial pressures can also (more commonly) be due to dissection in the arterial tree. In the latter case, the perfusionist will rapidly lose volume, whereas with reversed cannulation, the perfusionist will have an immediate gross excess of volume. If high pump flow is established, venous or atrial rupture may occur. The CVP will be dramatically elevated, with evidence of facial venous engorgement.

Line pressure is the pressure in the arterial limb of the CPB circuit. Because arterial cannulas are much smaller than the aorta, there is always a pressure drop across the aortic cannula. Arterial inflow line

pressure will always be considerably higher than systemic (patient) arterial pressure. The magnitude of the pressure drop depends on cannula size and systemic flow; small cannulas and higher flows result in greater gradients. The CPB pump must generate a pressure that overcomes this gradient to provide adequate systemic arterial pressure. For a typical adult (ie, MAP of about 60 mm Hg, systemic flow of about 2.4 L/min/m^2, and a 24-Fr aortic cannula), line pressure in an uncomplicated case usually ranges from 150 to 250 mm Hg. The fittings on the arterial inflow line are plastic; the fittings and the line itself can rupture. Perfusionists typically do not want a line pressure in excess of 300 mm Hg.

CPB must be discontinued and the cannula disconnected and inspected for air. If air is found in the arterial circulation, an air embolus protocol is initiated. Once arterial air is cleared, the circuit is correctly reconnected and CPB restarted. In adults, the venous outflow limb of the CPB circuit is a larger-diameter tubing than the arterial inflow tubing, precisely to eliminate reversed cannulation. This is why reversed cannulation is rare in adults—but it has happened. In pediatric cases, the arterial inflow and venous outflow limbs of the CPB circuit are close or equal in size.

Special Patient Populations

Care of the Gravid Patient During Bypass

Studies assessing the effects of cardiac surgery and CPB on obstetric physiology and fetal well-being are lacking. However, several reviews and many case reports describe individual experience in caring for the gravid patient and fetus during cardiac surgery and extracorporeal circulation.[726–731] These surveys and anecdotal reports, along with an understanding of the well-documented physiology of pregnancy and the effects of cardiac therapeutics on fetal physiology, can serve as a basis for a rational approach to care for the pregnant patient and fetus during cardiac surgery (Box 31.12).

Several groups have published reports detailing their individual experiences or survey data on maternal and fetal outcomes after cardiac surgery and CPB.[726–731] Jacobs and colleagues[727] reported their experience with three first-trimester gravid patients. All recovered from their operative procedures and delivered normal term infants. The first survey data on pregnancy and cardiac surgery were reported in 1969 by Zitnik and coworkers[728] from the Mayo Clinic. Among the 20 patients, there was only one maternal death, but seven fetuses died before term. The study authors concluded that cardiac surgery does not increase the likelihood of death in the pregnant patient with heart disease, but it is associated with substantial fetal mortality. Lapiedra and associates[730] and Becker[729] individually published reports in the 1980s on gravid patients undergoing heart surgery. Lapiedra and associates[730] reviewed their own experiences and found only one fetal death and no instance of maternal death in their review of 23 cases. Becker[729] surveyed members of The Society of Thoracic Surgeons on their experiences with pregnant patients requiring cardiac surgery. Of the 600 surgeons responding, 119 reported on a total of 169 gravid patients undergoing cardiac surgery, 68 of whom were managed with CPB. Pomini and investigators[731] reviewed 69 case reports of gravid patients undergoing cardiac procedures and CPB. Overall, the embryo-fetal mortality rate was 20.2%, but fetal loss was reduced to 12.5% in the last 40 cases. The reported experience on maternal and fetal outcomes after cardiac procedures with CPB suggests that cardiac surgery is well tolerated by the mother, but poses a significant risk to the fetus.

Although most physicians advocate providing perioperative care that can ensure maternal well-being, appropriate investigation would enable clinicians to care optimally for mother and fetus. This section outlines recommendations for perioperative management of the gravid patient requiring cardiac surgery and CPB. The basic principles for the perioperative management of the gravid patient requiring any type of surgery are outlined by Levinson and Shnider[732]: maternal safety, avoidance of teratogenic drugs, avoidance of intrauterine asphyxia, and prevention of preterm labor (see Chapter 50).

BOX 31.12 SPECIAL PATIENTS WHO MAY NEED CARDIOPULMONARY BYPASS

- Pregnant women
- Accidental hypothermia victims
- Neurosurgical patient with an intracranial aneurysm

Considerations Before Bypass

Premedication and Patient Positioning

Premedication should be appropriate for the specific cardiac lesion and physical status of the patient. Teratogenic drugs should be avoided, especially in the first trimester of pregnancy. After the 34th week of gestation, stomach emptying is delayed and patients are at increased risk for pulmonary aspiration. Although it is not possible to ensure gastric emptying before anesthesia induction, sodium citrate and an H_2-receptor antagonist may provide some protection against aspiration pneumonia. The gravid uterus obstructs aortic flow and IVC blood return to the heart. Gravid patients should never be supine; they must be positioned with left uterine displacement throughout the perioperative period.

Maternal and Fetal Monitor Information

The pregnant patient undergoing cardiac surgery requires the usual monitors employed during cardiac surgery, as well as monitors that can assess fetal well-being. Monitors that help assess the adequacy of maternal cardiovascular performance and oxygen delivery to the fetus are of paramount importance. Little is known about the effects of cardiovascular drugs and other therapeutic measures on the pregnant cardiac patient undergoing CPB. Appropriate monitors permit the assessment of an individual therapy on maternal and fetal oxygen delivery.

Monitors for cardiac surgery and CPB are discussed in detail in other chapters. A two-lead (II, V_5) electrocardiogram (ECG), peripheral pulse oximeter, and blood pressure cuff should be placed first. These monitors provide information concerning cardiorespiratory function as other, more invasive monitors are placed. Before the induction of anesthesia, a radial artery and pulmonary artery catheter should be placed. These monitors provide beat-to-beat systemic and pulmonary artery pressure information and the ability to measure CO and arterial and mixed-venous blood gases. An oximetry pulmonary artery catheter provides continuous information on venous oxygen saturation, and an indirect, approximate measure of the adequacy of maternal tissue oxygen delivery.

Uterine activity should be monitored with a tocodynamometer applied to the maternal abdomen. This monitor transduces the tightening of the abdomen during uterine contractions. As is the case with other types of major surgery, the tocodynamometer should not interfere with the conduct of cardiac surgery; if necessary, the monitor may be intermittently displaced by the operating surgeon. The use of an intraamniotic catheter to monitor uterine activity and pressure may be inadvisable in a patient who is fully heparinized. Intraoperative uterine contractions may have a deleterious effect on fetal oxygen delivery (by causing an increase in uterine venous pressure and decrease in uterine blood flow) and signal the onset of preterm labor. Use of the tocodynamometer is imperative, as it provides important information about the state of the uterus and allows intervention if necessary. Various reports have documented the common occurrence of uterine contractions during cardiac surgery and CPB. Uterine contractions may appear at any time during the perioperative period but occur most frequently immediately after the discontinuation of CPB and in the early ICU period.[733] It is therefore important to leave the tocodynamometer in place after the completion of surgery. Although uterine contractions

occur frequently in the perioperative course, they usually are effectively treated with magnesium sulfate, ritodrine, or ethanol infusions, and they do not result in preterm labor or fetal demise.[734]

Fetal heart rate (FHR) monitors should be used in all gravid patients after 20 weeks gestation because one of the primary perioperative goals is to avoid fetal loss. Use of an FHR monitor permits recognition of fetal distress and allows the clinician to institute measures to improve fetal oxygen delivery. The FHR monitor recognizes and records the FHR, FHR variability, and uterine contractions. A spinal electrode placed in the fetal scalp gives the most reliable fetal ECG and therefore the best FHR information. However, this method may be undesirable in the presence of maternal anticoagulation. External FHR monitoring—using ultrasound, phonocardiography, or external abdominal ECG—is less exact but preferable in this clinical setting.

The cardiac surgeon, perfusionist, and cardiac anesthesiologist may not be familiar with uterine and FHR monitors. As a result, having a perinatologist or an obstetrician present during cardiac surgery is desirable to assess for preoperative fetal distress and the anticipated need for emergency cesarean section during cardiac surgery.

FHR is usually normal in the prebypass period, but decreases precipitously with the initiation of CPB and remains below normal for the entire bypass period. There are many potential causes of this observed decrease in FHR. Persistent fetal bradycardia is a classic sign of acute fetal hypoxia. However, in the CPB setting, especially when hypothermia is employed, it is difficult to ascribe fetal bradycardia to hypoxia or to decreased fetal oxygen demand. Fetal tachycardia typically occurs after the discontinuation of CPB. This tachycardia may represent a compensatory mechanism for the oxygen debt incurred during CPB. The FHR usually returns to normal by the end of the operative period.

Interventions optimizing maternal blood oxygen content, correcting any acid-base imbalance, and replenishing fetal glycogen stores may alleviate signs of fetal hypoxia. Some clinicians recommend an increase in CPB pump flow to improve fetal oxygen delivery.[729,731]

After anesthesia induction, a urinary bladder catheter with a temperature probe and TEE probe should be placed. The former provides information on fluid balance and core temperature. TEE is always helpful, but is especially important in the patient undergoing valvular or congenital heart surgery, because it can document pathologic changes and help assess the adequacy of repair.

Conducting the Bypass Procedure

The conditions of extracorporeal circulation—nonpulsatile blood flow, hypothermia, anemia, and anticoagulation—will likely have a negative impact on fetal well-being during CPB. There are no studies that recommend a particular CPB management strategy in gravid patients. Recommendations are summarized (Table 31.12) for the management of CPB in pregnant patients, based on the survey and anecdotal reports in the literature (Table 31.13).

Blood Flow

Optimal CPB blood flow in the gravid patient is unknown. However, the increase in CO associated with pregnancy is well defined, and it might be argued that high blood flows during CPB are more physiologic in the gravid patient. Becker[729] suggested that flow during CPB in the pregnant patient be maintained at a minimum of 3.0 L/min per m^2. A few reports demonstrate that increasing CPB circuit blood flow improves FHR, suggesting improvement in fetal oxygen delivery. In a report by Koh and colleagues,[735] FHR improved when pump flow was increased from 3100 to 3600 mL/min. Similarly, Werch and Lambert[736] reported an improvement in FHR when blood flow was increased from 2800 to 4600 mL/min. In another case, flow was increased from 2.3 to 2.9 L/min per m^2, with a brief, unsustained apparent improvement in fetal oxygen delivery.[736]

Blood Pressure

Under normal conditions, uterine blood flow is determined solely by maternal blood pressure, as the placental vasculature is maximally dilated. However, it is not known what factors determine uterine blood flow during the very abnormal condition of CPB. For example, catecholamine levels increase by several times during CPB; therefore, uterine vascular resistance may increase during extracorporeal circulation in response to increased levels of norepinephrine and epinephrine. However, regardless of the state of uterine vascular resistance during CPB, maternal blood pressure will be an important determinant of uterine blood flow and fetal oxygen delivery. Moderately high pressure (MAP ≥ 65 mm Hg) should be employed during perfusion in the gravid patient.[729]

There are no reports demonstrating that increasing blood pressure during CPB improves FHR or fetal oxygen delivery. Most case reports on CPB in the gravid patient do not include information on blood pressure during CPB. The few blood pressure values reported in gravid perfusion cases ranged from 55 to 95 mm Hg.[734,737]

In theory, the use of short-acting vasodilators, such as nitroglycerin or sodium nitroprusside, may counteract the effects of CPB and norepinephrine- or epinephrine-induced increases in uterine vasculature resistance. If maternal blood pressure is maintained by increasing extracorporeal circuit pump flow, uterine blood flow and fetal oxygen delivery may be increased with vasodilators. Monitoring should be conducted to assess the effect of a given therapeutic on fetal oxygen delivery during CPB.

Temperature

Controversy exists regarding temperature management during CPB in the nongravid patient, although most perfusions are conducted

TABLE 31.12 Recommendations for the Conduct of Extracorporeal Circulation in the Gravid Patient

Variable	*Recommended Value/ Characteristic*	*Rationale*
Blood flow	3.0 L/min/m^2	Cardiac index normally is increased during pregnancy.
Blood pressure (MAP)	60–70 mm Hg	Uterine blood flow depends on maternal MAP.
Temperature	32–34°C	Mild hypothermia decreases fetal oxygen requirements and is less likely to cause fetal arrhythmia.
Oxygenator type	Membrane	Membrane oxygenators are associated with fewer embolic phenomena than bubblers.
Hematocrit	25–27%	The quantity of oxygen carried in maternal blood (and therefore the oxygen available to the fetus) greatly depends on hemoglobin concentration.
Duration of perfusion	Minimized	The duration of bypass is dictated by the complexity of the operative procedure.
Cardioplegia	?	No data
Pulsatile perfusion	?	No data

MAP, Mean arterial pressure.

TABLE 31.13 Prevalence of Maternal and Fetal Mortality Following Cardiac Surgery and Cardiopulmonary Bypass in Gravid Patients

Study	*Maternal Death*	*Fetal Death*
Jacobs et al. (1965)	0/3 (0%)	0/3 (0%)
Zitnik et al. (1968)	1/20 (5%)	7/20 (35%)
Becker (1983)	1/68 (1.5%)	11/68 (16%)
Lapiedra et al. (1986)	0/23 (0%)	1/23 (4.3%)
Pomini et al. (1996)[a]	2/69 (2.9%)	8/69 (20.2%)
Pomini et al. (1996)[b]	0/40 (0%)	5/40 (12.5%)
Arnoni et al. (2003)	5/58 (8.6%)	11/58 (18.6%)

[a]All patients from 1958 to 1992.
[b]Last 40 patients in series only.

under hypothermic conditions. Similarly, there are few data and no consensus regarding temperature management in the gravid patient undergoing CPB.

There are theoretical advantages and disadvantages for normothermic and hypothermic CPB in the gravid patient. Hypothermia can cause fetal bradycardia and may lead to fetal ventricular arrhythmias, resulting in fetal wastage. Rewarming after hypothermic CPB may precipitate uterine contractions and preterm labor.[729] However, others reported the onset of uterine contractions at the time of discontinuation of CPB in spite of normothermic perfusion. Uterine contractions also occur at various times in the postbypass and postoperative periods. The association of uterine contractions with rewarming after hypothermic bypass is unclear.

Hypothermia may be protective to the fetus during extracorporeal circulation by decreasing fetal oxygen requirements. Assali and Westin[738] demonstrated that hypothermia to 28°C in gravid dogs caused an increase in uterine vascular resistance but did not result in a decrease in uterine blood flow. Hypothermia did not affect fetal survival. Pardi and colleagues,[739] using a fetal lamb model, reported that temperatures above 18°C were well tolerated. More profound hypothermia caused irreversible fetal acidosis and hypoxia. Several reports discuss the effects of deliberately induced and septicemia-associated hypothermia in gravid patients. The investigators observed that FHR decreased with maternal hypothermia but improved with maternal rewarming.[740]

Perfusion temperatures of 25 to 37°C have been used in gravid patients undergoing CPB.[729,734,737,741] Because Pomini and coworkers[731] found an apparent decrease in fetal loss when CPB temperatures were maintained at or above 36°C, they recommend normothermic temperatures during bypass. However, they acknowledge the lack of follow-up in many of the case reports they reviewed. The authors reported a case in which hypothermic CPB at 25°C was required for 2 hours 40 minutes and in which the patient underwent two periods of rewarming. Uterine contractions occurring in the early postoperative period were successfully treated with magnesium sulfate. Despite the magnitude and duration of hypothermia and two periods of rewarming, a normal infant was delivered 10 days postoperatively.[734]

In conclusion, the optimal gravida temperature during CPB has not been established. There are no data that suggest hypothermia is harmful to the mother or fetus undergoing bypass.

Accidental Hypothermia

In the early 1950s, Bigelow and colleagues demonstrated a direct relationship between metabolic rate and temperature and postulated that DHCA could facilitate cardiac surgery.[472] Although extracorporeal circulation was not used in these early cardiac cases (a tub of ice and warming coils were used to induce hypothermia and rewarm the patient), the notion that a patient could survive hypothermic arrest was established. With the introduction of CPB in the mid-1950s,[742] the induction of profound hypothermia with circulatory arrest, followed by resuscitation, was greatly facilitated by the extracorporeal circuit. It was a short leap to consider the use of CPB to resuscitate the victim suffering accidental hypothermia.

Patients with core temperatures below 32°C, and without a perfusing cardiac rhythm, are best managed with some type of extracorporeal support.[743] This section discusses the management of hypothermic patients who are optimally managed with CPB for rewarming. Danzl and Pozos[744] outlined treatment algorithms for hypothermic patients who do not require extracorporeal circulation for resuscitation (eg, patients with preserved circulation and suffering only moderate hypothermia [temperature ≥ 32°C]).

Patient Selection

Clinicians lack consensus regarding the absolute indications or contraindications for the use of CPB in the treatment of accidental deep hypothermia.[745] However, there are theoretical considerations and some data to help guide the decision-making process regarding the rewarming of accidental hypothermia patients. Phenomena that greatly limit the likelihood of successful resuscitation include the presence of asphyxia before the initiation of hypothermia, as occurs commonly in avalanche and drowning victims. Similarly, patients with severe traumatic injury, or extremely elevated potassium levels (≥10 mmol/L) are unlikely to benefit from resuscitative efforts.

One report suggests that several factors may increase the likelihood of a desirable patient outcome after accidental hypothermia managed with CPB.[746] Victims suffering profound hypothermia (without prior asphyxia), as opposed to moderate hypothermia, benefit from the substantial slowing of metabolic processes and are less likely to have severe end-organ damage. Young patients in good health are more likely to survive resuscitative efforts than are older, debilitated victims. Patients who have multiple preexisting medical problems are less likely to have a desirable outcome. Initial rescue treatment algorithms may influence the likelihood of surviving profound hypothermia. The maintenance of profound hypothermia in the rescued patient before the initiation of extracorporeal warming may greatly enhance the likelihood of successful recovery. Rewarming with CPB is the most efficient method to resuscitate the hypothermic patient. Tissue perfusion is enhanced by hemodilution, and metabolic perturbations can be easily corrected.

Caring for the Accidental Hypothermia Victim

After the decision is made to resuscitate an accidental hypothermia victim, the patient should be maintained at the hypothermic temperature and rapidly transferred to a facility that can provide extracorporeal rewarming. In the operating room, various vascular sites may be cannulated to initiate rewarming. Femoral vessels or mediastinal vasculature may serve as conduits for rewarming. Because the ventricle is noncompliant at temperatures below 32°C, sternotomy or thoracotomy may be preferable to facilitate direct cardiac massage and defibrillation. Although hypothermia reduces anesthetic requirements, the prudent use of anesthetics, analgesics, sedative-hypnotics, and volatile drugs is recommended. These agents should be administered through the extracorporeal circuit.

To treat an asystolic patient, the extracorporeal circuit must include a pump, oxygenator, and heat exchange waterbath. At flow rates of 2 to 3 L/min, with the waterbath at 37°, the patient's core temperature can increase by as much as 1 to 2°C every 3 to 5 minutes. Slowly, the flow rate can be increased as determined by venous return. Given the data regarding the adverse effects of mildly hyperthermic blood on ischemic cerebral damage, the accidental hypothermia patient should not be perfused with blood warmed to temperatures in excess of 37°C. If the victim has a perfusing cardiac rhythm, venovenous rewarming may be used. Indeed, strong arguments can be made for limiting the rewarming to only 32 to 33°C and then adhering to cardiac arrest protocols that use prolonged mild hypothermia to optimize cerebral outcomes.

One study suggests that under certain circumstances (eg, profound hypothermia before asphyxia; young, healthy patients; maintenance of hypothermia before bypass-supported rewarming) accidental hypothermia patients have an almost even chance of surviving and not suffering significant end-organ (including cerebral) deficits. Walpoth and associates[746] reviewed the hospital records of 234 patients suffering accidental hypothermia. Forty-six of these patients had core temperatures below 28°C and had circulatory arrest. Of the 32 patients rewarmed with CPB support, 15 were long-term survivors. These 15 patients were reexamined and studied an average of 7 years after their resuscitation from accidental hypothermia. The survivors were uniformly young (25.2 ± 9.9 years) and were resuscitated with CPB 141 ± 15 minutes after discovery. Although neurologic and neuropsychologic deficits were observed in all the victims in the early postresuscitation period, all patients had fully or almost completely recovered at the long-term follow-up. The investigators concluded that otherwise healthy individuals can survive accidental deep hypothermia with a preserved good quality of life.

Intracranial Aneurysm Surgery

Surgery for intracranial aneurysm represents a major challenge for the surgeon and anesthesiologist.[747] For a small number of these cases, DHCA has been applied to improve surgical access and cerebral protection. Like many areas, significant evolution in technique and application has occurred over time. Initial enthusiasm for DHCA in intracranial aneurysm surgery was tempered by the unfortunate occurrence of coagulopathies. Its use was further restricted by advances in neurosurgical microscopic techniques (aneurysm wrapping, parent vessel ligation, and use of temporary clips). Improvements in perioperative monitoring and neuroanesthesia have reserved a use for DHCA in the approach to giant aneurysms that might otherwise be inoperable.

DHCA for intracranial aneurysm requires precise integration of a remarkably large and diverse team, which includes anesthesiologists, nurses, perfusionists, cardiac surgeons, and neurosurgeons. All components and demands of the operation should be thoroughly familiar to all participants. The anesthesiologist is primarily occupied by five areas. The first area is patient selection and consent, which needs to include a careful assessment for preexisting coagulation problems or contraindications to TEE. The second area entails careful premedication and induction. This is undertaken to blunt hemodynamic responses to invasive monitor placement and intubation and to avoid respiratory depression in that subgroup of patients with elevated intracranial pressure. The third area of focus for the anesthesiologist is maintenance and monitoring. This includes TEE, EEG, and placement of defibrillator pads in addition to the routine anesthetic monitors. Next, the anesthesiologist prepares for initiation of CPB and arrest. Lastly, the anesthesiologist manages rewarming, resumption of native circulation, and correction of coagulation abnormalities. Depending on the length of arrest and adequacy of cardiac protection, these steps may proceed smoothly or be complicated by significant hemodynamic embarrassment.

DHCA has been used for intracranial aneurysm surgery with good success at a number of centers.[748–753] The high percentage of patients surviving is probably the best indicator of the value of this technique, although the relatively small number of cases performed on an annual basis make controlled outcome trials difficult to complete. Silverberg and investigators[748] reported nine operative cases with no operative deaths, although six modest perioperative complications occurred (ie, small stroke, transient cranial nerve palsy, frontal lobe hematoma, and pulmonary embolus). Baumgartner and colleagues[749] also had no reported deaths in their series, and all patients went on to live independently. Like Silverberg's series, a fair number of patients experienced modest perioperative complications (ie, four thromboembolic episodes, three strokes, three transient neurologic palsies). The other reported series[750–753] were similar in the respect that most patients went on to live independently and modest perioperative complications were in the range of 50%. Given that the overall numbers involved are small, it is very difficult to develop precise estimates for morbidity and mortality rates. However, given that DHCA in intracranial aneurysm surgery has been reserved for only the most difficult cases, the results seen are encouraging. As in most areas of cardiac surgery, continued developments have led to an evolution in neurosurgery as well and in how these intracranial aneurysms are being addressed. For example, many more are now being addressed with neurovascular radiologic coiling than are being treated open under DHCA. It is likely that this will be a continuing trend in the declining use of DHCA to treat intracranial aneurysms.

Minimally Invasive Surgery and Cardiopulmonary Bypass

In the mid-1990s, interest in minimally invasive techniques for cardiac surgery emerged. Today, coronary revascularization and mitral and aortic valvular surgery are being performed in some centers with minimally invasive approaches. The proponents of port-access cardiac surgery (PACS) suggest that this technique permits minimally invasive cardiac surgery while providing the support of CPB. This section describes the current technology and expertise with port-access CPB. Minimally invasive procedures and off-pump cardiac surgery are discussed further in Chapters 20, 21, 27, 29, 32, 33, and 37.

Port-Access Bypass Circuit

The port-access system consists of a series of catheters that are introduced through various puncture sites, including the femoral artery and vein, and threaded through the aorta and venous system to the heart. The perfusion is usually set up from the femoral vein to the oxygenator and then returned via the femoral artery. An inflatable balloon on the end of an endoaortic clamp (EAC) catheter can be used to arrest the blood flow in the aorta, and other catheters help drain and reroute the blood flow to the heart-lung machine. Through two of the catheters, cardioplegia solution can be administered to the heart (Fig. 31.16).[754,755]

The EAC is an occlusion balloon that functions as an aortic cross-clamp and permits antegrade cardioplegia infusion into the aortic root and coronary arteries. The lumen used to administer cardioplegia can also function as an aortic root–venting catheter. Some surgeons prefer to use a direct modified aortic cross-clamp inserted through a port in the right side of the chest instead of using the EAC; they depend on administration of cardioplegia in a retrograde fashion via the coronary sinus. Retrograde cardioplegia can be delivered through an endocoronary sinus catheter (ECSC) that is placed with a percutaneous approach (Fig. 31.17).

Blood returns to the CPB through the femoral venous catheter that is advanced to the level of the IVC–right atrium junction. Because extrathoracic gravity drainage is usually insufficient in providing adequate blood flow for complete CPB support, kinetic-assisted venous drainage, with controlled suction, is used to augment the drainage of blood to the heart-lung machine (see Chapter 32). Removing all air from the system at the end of surgery is challenging and must be done carefully.

Port-access CPB demands an expanded role of the anesthesiologist during CPB. The anesthesiologist is responsible for inserting the ECSC (and the even endopulmonary vent [EPV]) through introducer sheaths placed in the right internal jugular vein. The ECSC should be placed first with the assistance of both fluoroscopy and TEE. The technique was described in detail by Lebon and coworkers[756] and Miller and associates,[757] who have a combined experience of more than 600 insertions. TEE guidance is used for engaging the coronary sinus and fluoroscopy for advancing the catheter in the coronary sinus. Proper placement is judged by attaining a pressure in the coronary sinus greater than 30 mm Hg during cardioplegia administration at a rate of 150 to 200 mL/min. The mean total procedure time in the series by Lebon and coworkers was 16 ± 14 minutes. Failure can occur for a number of reasons, but the most common reason is displacement of the catheter from the coronary sinus during surgical manipulations. Complications, including perforation and dissections, have been reported in a small percentage of patients (see Chapters 13 and 15).

As with any new procedure or technology, the anesthesiologist should expect a learning curve regarding the skill of placing an ECSC and EPV. A side benefit of port-access bypass is the necessity of increased communication among members of the health care team.

Monitoring for Endovascular Clamp Bypass

Measures of venous drainage, arterial blood flow, ventricular venting, cardioplegic delivery, regional perfusion, and aortic occlusion must be carefully monitored to ensure safe and adequate CPB and myocardial protection. Although the surgical staff is positioned to assess cardioplegia delivery and LV venting, and the perfusionist monitors arterial flow and venous drainage to and from the CPB circuit, the anesthesiologist is responsible for determining the proper placement of the EAC and adequacy of CBF.[758]

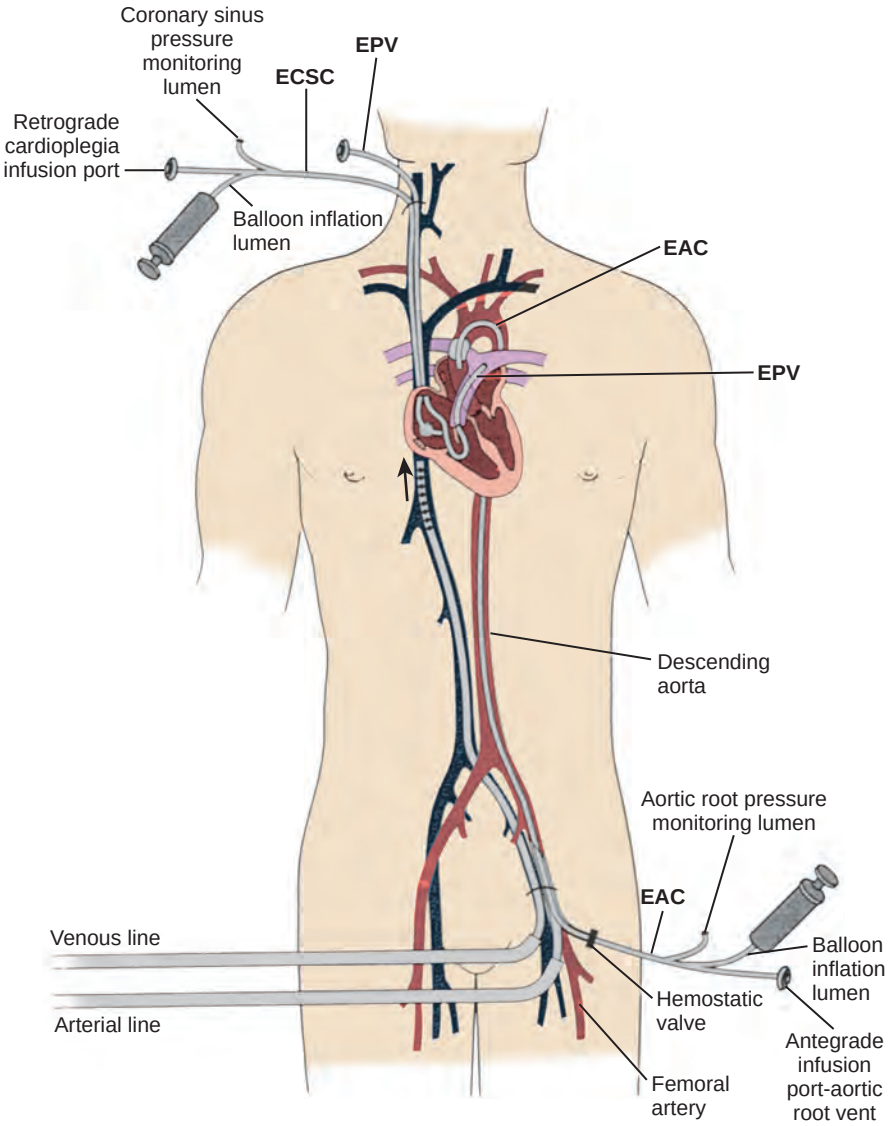

Fig. 31.16 Positioning of endovascular catheters. The femoral venous drainage catheter tip is positioned at the right atrium–superior vena cava junction by fluoroscopy and transesophageal echocardiography. *EAC,* Endoaortic clamp; *ECSC,* endocoronary sinus catheter; *EPV,* endopulmonary vent. *(From Toomasian JM, Peters SP, Siegel LC, Stevens JH. Extracorporeal circulation for port-access cardiac surgery.* Perfusion *1997;12:83–91.)*

The aorta catheter with the EAC should be positioned in the ascending aorta 2 to 4 cm distal to the aortic valve. Because cephalad migration of the endovascular aortic root clamp may compromise CBF, it is imperative to monitor endovascular clamp position continuously. There are several proposed methods to achieve this essential goal (Table 31.14). TEE and color-flow Doppler aid in visualizing the placement of the EAC balloon in the ascending aorta and in detecting any leakage of blood around the balloon. Right radial artery pressure will decrease acutely if the EAC migrates and obstructs the brachiocephalic artery. Some clinicians choose to measure blood pressure in the left and right radial arteries. The occurrence of acute difference in radial artery pressures may indicate cephalad migration of the EAC. Pulse-wave Doppler of the right carotid artery can verify cerebral perfusion but is frequently difficult to assess under the conditions of nonpulsatile blood flow. The ability of transcranial Doppler monitoring of the middle cerebral artery and cerebral oximetry techniques to determine the adequacy of CBF requires further evaluation. The TEE probe may be useful in visualizing the ascending aorta and location of the balloon; however, many clinicians report the inadequacy of this technique.

Port-Access Cardiac Surgery Outcome Data

Early advocates of PACS hoped that this new approach would provide the benefits of minimally invasive surgery with the advantage of extracorporeal support and myocardial preservation during procedures on the heart. A relatively slow learning curve exists, and multiple, unexpected complications have been reported (eg, inadequate de-airing of the ventricle before discontinuation of CPB support, aortic or femoral artery dissection, malposition of the endovascular clamp).

Coronary artery surgery can be done using PACS, but it has not become a popular technique compared with OPCAB and other minimally invasive revascularization procedures. Mohr and investigators[759] reported a 9.8% mortality rate in their series of 51 patients undergoing elective mitral valve replacement or repair with PACS. Two patients suffered femoral artery dissections (requiring conversion to conventional techniques), and three patients required second operations for repair of postoperative perivalvular leaks. Patients in the port-access group reported the same amount of pain as those undergoing sternal splitting (as measured by a visual analog pain scale), challenging the

TABLE 31.14 Potential Strategies to Monitor Cerebral Blood Flow During Port-Access Bypass

Monitor	*Limitations*	*Observation With Cephalad Migration of Endoaortic Clamp*[a]
Fluoroscopy	1. Must interrupt surgery to use monitor	EAC occluding great vessels
Transesophageal echocardiography	1. May be difficult to visualize EAC position during cardiopulmonary bypass	EAC in area of great vessels
Carotid ultrasound	1. Difficult to monitor signal continuously—depends on index of suspicion 2. Difficult to obtain signal with nonpulsatile blood flow	Sudden loss of blood flow signal
Transcranial Doppler	1. Difficult to monitor MCA blood flow continuously—depends on index of suspicion 2. Difficult to insonate MCA during nonpulsatile blood flow 3. Poor sensitivity/specificity	1. Loss of MCA blood flow velocity signal 2. Change in ratio of RMCA vs LMCA blood flow velocity 3. Change in RMCA or LMCA blood flow direction
Cerebral oximetry (R vs L signal)	1. Sensitivity/specificity?	Decrease in cerebral venous blood oxygen saturation; change in R vs L signal[b]
Electroencephalography	1. Hypothermia, anesthetics, and roller pump artifacts limit interpretation of EEG signals	EEG slowing/change in right vs left EEG signal
Right and left radial arterial pressures	1. Requires cannulation of both radial arteries; increased risk for hand ischemia 2. Left radial arterial free graft conduit not possible	Change in the ratio of right and left radial arteries measured MAP

EAC, Endoaortic clamp; *EEG,* electroencephalographic; *L,* left; *MAP,* mean arterial pressure; *MCA,* middle cerebral artery; *R,* right.
[a]Hypothetical observation; the sensitivity and specificity of these monitors in this clinical setting have not been evaluated.
[b]The rate and magnitude of change depend on many factors, including the patient's cerebral temperature, magnitude of obstruction, and collateral blood flow.

hypothesis that minimally invasive procedures result in less pain than conventional approaches (see Chapter 42). Two other large series of mitral valve surgery via right thoracotomies with PACS found the outcomes to be similar to the standard operations done via a sternotomy.[760,761] The use of robotic assistance for mitral valve repairs performed via a thoracotomy using PACS has gained popularity in some centers; results have shown good success rates, less transfusion need, and shorter hospital stays.[762]

Extracorporeal Devices and Related Technologies

ROBERT C. GROOM, MS, CCP, FPP | DAVID FITZGERALD, MPH, CCP

KEY POINTS

1. Cardiopulmonary bypass (CPB) has been described as one of the boldest and most successful feats of medicine.
2. CPB has progressed from experimental to a commonly practiced invasive high-risk procedure as evidenced by randomized trials of off-pump versus on-pump surgery that showed significantly better composite outcomes with on-pump surgery.
3. Two predominant methods of blood propulsion are used: positive displacement roller pumps and constrained vortex or centrifugal-type pumps.
4. Modern heart-lung machines are equipped with a number of alarm systems and redundant backup systems to overcome primary system failures.
5. Blood gas exchange devices have improved over time in terms of reduced blood-surface interface, improved efficiency, and improved blood device-related inflammatory response.
6. Gaseous and particulate microemboli enter the CPB circuit from entrainment in the venous inflow to the circuit and also through the cardiotomy suction system. None of the currently available CPB systems remove all of the emboli.
7. Gaseous emboli may be reduced by correcting air entrainment around venous cannulation sites, avoiding the use of excessive vacuum-assisted venous drainage (≥20 mm Hg), use of an arterial line filter, minimizing use of vent and cardiotomy suction flow, and use of a venous reservoir with a screen filter of 40 µm or less pore size.
8. Coating technology for CPB tubing and circuit components reduces inflammation and thrombus formation.
9. There is growing concern about plasticizers such as di(2-ethylhexyl) phthalate (DEHP) in polyvinyl chloride tubing. New plasticizers such as dioctyl adipate (DOA) that have less leaching are under investigation.
10. Cardioplegia delivery must be delivered accurately to prevent myocardial damage, and new pump delivery systems provide a better operator-interface for effective delivery.
11. Blood conservation is paramount, and an effective system involves proper equipment selection for the size of the patient, careful coagulation management, and the use of advanced techniques such as acute normovolemic hemodilution, retrograde and antegrade priming, ultrafiltration, and autotransfusion.
12. Numerous studies have demonstrated efficacy of techniques using miniaturized CPB circuits for coronary artery bypass and valve procedures; adoption of these techniques has been limited.
13. Despite the growing evidence regarding the efficacy of pulsatile flow during CPB, particularly in high-risk coronary artery bypass graft (CABG) patients, clinical use remains low.
14. Numerous techniques to continuously perfuse the cerebral circulation have been developed, reducing the use of deep hypothermic circulatory arrest.
15. Communication and teamwork are of paramount importance during cardiac surgery.
16. Automated perfusion recording systems that capture physiologic patient data from patient monitors and from the heart-lung machine provide a single source for collecting, recording, and displaying essential data for the perfusionist at the point of care that enhances patient safety.
17. The use of simulation and the study of human factor science are emerging areas of research that will help teams to become effective in responding to routine and nonroutine events that may occur during CPB.

The development of surgical interventions for the treatment of cardiovascular disease has resulted in enhancements in the quality of life for an indeterminate number of patients. One of the most influential areas that has aided in the evolution of this discipline has been the development of devices and techniques for extracorporeal circulation (ECC). Indeed, the sheer complexity of how blood behaves in an extravascular environment and the influence of synthetic materials on biologic processes have provided rich areas for research.

The first reported successful use of the heart-lung machine was on May 6, 1953, when John H. Gibbon, Jr., closed an atrial septal defect with the use of a heart-lung machine, the culmination of more than 20 years of his own research.[1,2] What may not be fully appreciated is the fact that at least 17 other cases were performed in the early 1950s using some form of ECC, yet only Dr. Gibbon's patient survived.[1] By the early 1950s, Gibbon had completed an extensive series of animal experiments with the heart-lung machine with survival rates of greater

than 90%. However, his first attempt in human patients was not successful. On his second attempt, the patient's circulation was supported for 27 minutes while the atrial septal defect was repaired. According to Dr. Bernard J. Miller, "Near the termination of the operation, the machine suddenly shut down—reason being, clotting of the blood on the oxygenator took place, and the automatic arterial control sensed the sudden fall in the pool at the bottom and shut the entire machine down."[3,4] However, the patient survived and was discharged from the hospital in 9 days and lived until age 65 years, when she died in 2000. Gibbon's five subsequent procedures at Jefferson Hospital were not successful, and he abandoned the use of ECC. However, his one successful case served to inspire others, including John Kirklin at The Mayo Clinic, C. Walton Lillihei at the University of Minnesota, and Denis Melrose at Hammersmith Hospital in London, to continue the further development of ECC and cardiopulmonary bypass (CPB) in the laboratory and ultimately in the clinical arena. The accomplishments of these early pioneers in cardiac surgery have been described as being "the boldest and most successful feats of man's mind."[4]

Since the 1950s, CPB has undergone a dramatic metamorphosis from a lifesaving, yet life-threatening, technique to a procedure practiced nearly 1 million times a year throughout the world. It is uncommon in today's medical environment to encounter such an invasive procedure, with such significant risk and inherent morbidity, being practiced as routine. The goal of all techniques of CPB has always been to design an integrated system that could provide nutritive solutions with appropriate hemodynamic driving force to maintain whole-body homeostasis, without causing inherent injury. A recent randomized clinical trial, the Randomized Off-Pump or on Bypass (ROOBY) trial, involving 2203 elective or urgent coronary artery bypass grafting (CABG) patients randomized to either off- or on-pump surgery is a testament to the efficacy and safety of CPB as currently practiced. At 1 year, the on-pump group had significantly better composite outcomes (death, myocardial infarction [MI], or repeat revascularization) than the off-pump group (9.9% vs 7.4%; $P = 0.04$). The overall rate of graft patency was lower in the off-pump group than in the on-pump group as well (82.6% vs 87.8%; $P< 0.01$).[5] Concordant with the ROOBY trial's overall findings, a study examining off-pump CABG for diabetic patients reported no advantage in clinical outcomes and cost over on-pump CABG.[6] A metaanalysis that included 12 randomized controlled trials (RCTs) reported a 38% increased rate of early revascularization with off-pump surgery.[7] A systematic review by Moller and colleagues that included over 15,000 subjects found no clinical benefit to off-pump CABG regarding mortality, stroke, or MI and an increased survival benefit with on-pump CABG.[8]

This chapter is a compilation of information on extracorporeal devices and techniques used in the conduct of cardiovascular perfusion. No attempt is made to chronicle or list the multitude of components and perfusion devices currently manufactured. Rather, examples have been chosen to best represent current technology. Similarly, the techniques described under perfusion practices were chosen because of the current clinical interest, with specific protocols taken from referenced sources.

Mechanical Devices

Blood Pumps

All extracorporeal flow occurs through processes that incorporate a transfer of energy from mechanical forces to a perfusate and, ultimately, to the tissue. Methods of achieving this transfer of energy include using gravitational and mechanical forces or a combination of the two. It is through the transfer of energy from an electrical power source to the motor of a pumping mechanism and on to the fluid (blood) that causes tissue perfusion.[4,9] Most extracorporeal pumps fall into one of the following categories: positive displacement (PD), centrifugal or constrained vortex, passive filling, pneumatic and electrical pulsation, and axial flow (the latter pumps are used primarily as cardiac assist or replacement devices)[10–12] and are described in Chapter 25.

Positive Displacement Pumps

The PD pump operates by occluding tubing between a stationary raceway and rotating roller(s) or occluder(s) (Fig. 32.1). The pumping mechanism is also referred to as the *pump head*, and the tubing that traverses the raceway is referred to as the *pump header*. PD pumps were first proposed for use in cardiovascular medicine in the 1930s by Gibbon.[2] In 1935, an adaptation to the PD pump was described that included tube bushings at the head of the raceway on both inlet and outlet locations to prevent tubing creepage around the roller head.[12] Melrose[13] later modified the pump to include a grooved raceway, which further reduced tubing shimmy. Both of these adaptations were important in reducing the mobility of tubing during the operation of the pump, which decreased the potential for tubing rupture in the pump head. In a PD pump, fluid is displaced in a progressive fashion from suction to discharge, with the capacity of the displacement dependent both on the volume of the tubing occluded by the rollers and on the number of revolutions per minute (rpm) of the roller. All PD roller pumps (RPs) use the volume in the pump header, which is referred to as a *flow constant* and is specific to each size of tubing referred to by the internal diameter of tubing, for calculating the flow of the pump. This is displayed on a digital readout and is referred to as the *output* (flow) of the pump. It is measured in liters per minute. Although many types of RPs have been used for CPB, the most common PD pump in use today is the twin-RP.

There are currently at least five manufacturers of PD pumps used in ECC, with each device consisting of minor variations of the twin-RP design (Box 32.1). A modern heart-lung machine consists of between

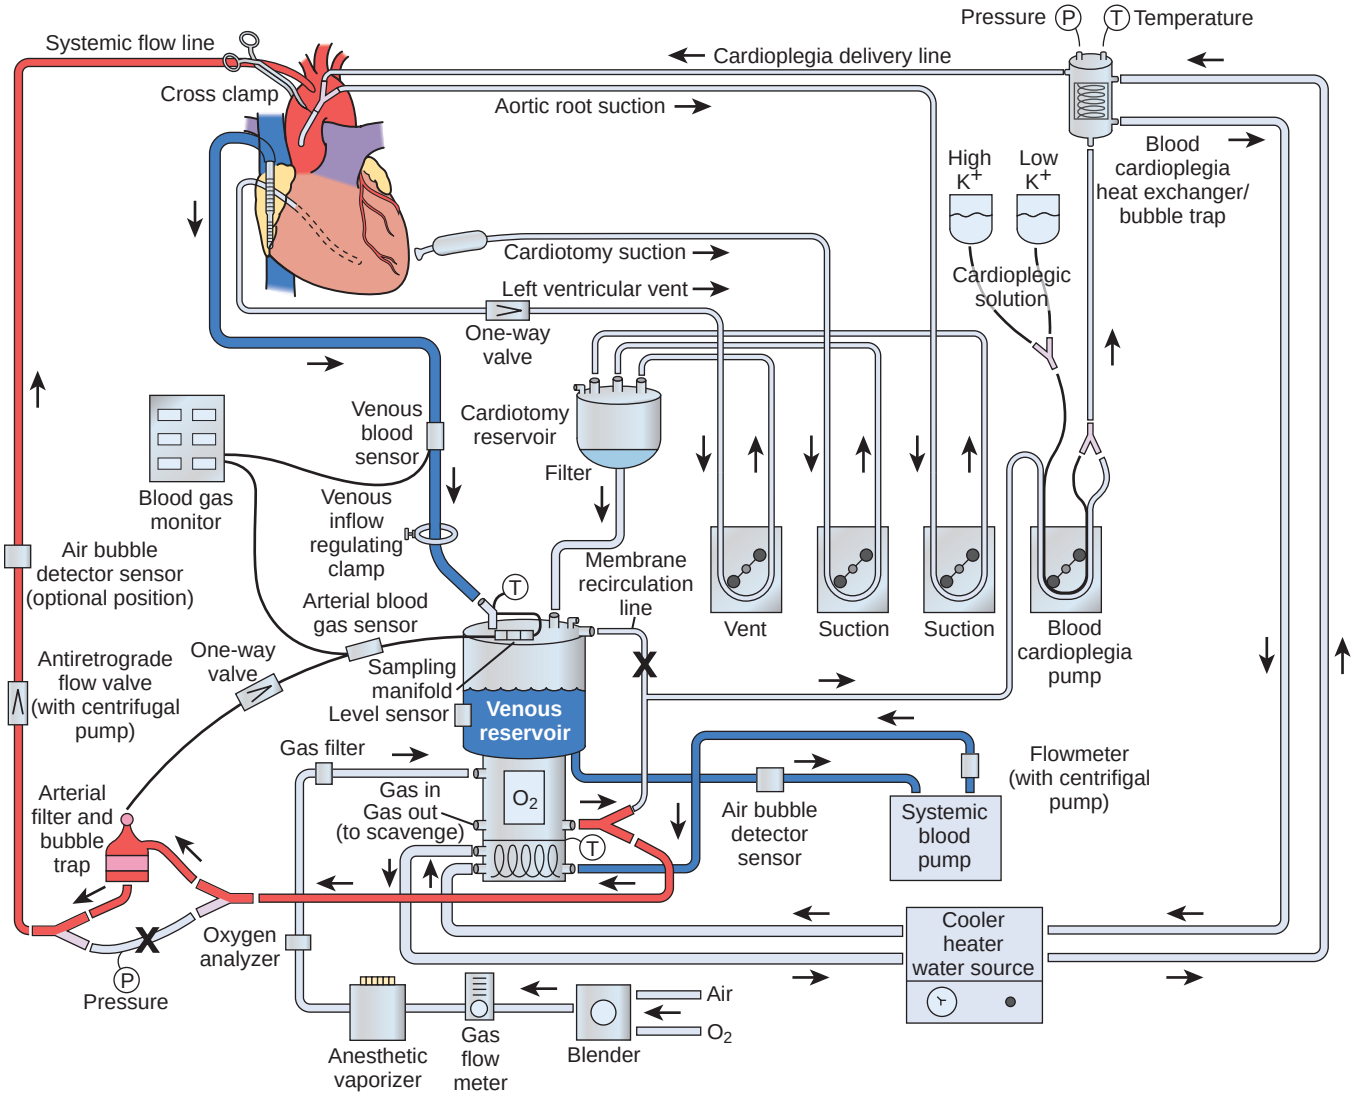

Fig. 32.2 Schematic diagram of cardiopulmonary bypass circuit, including four roller pumps (one vent pump, two suction pumps, and a cardioplegia deliver pump). A centrifugal blood pump for systemic blood propulsion is shown on the lower right. *(From Hensley FA, Martin DE, Gravlee GP.* A Practical Approach to Cardiac Anesthesia, *4th ed. Philadelphia: Lippincott Williams & Wilkins; 2008: Fig. 18.1.)*

BOX 32.1 ROLLER PUMPS

- Composed of twin rollers.
- Deliver flow using positive displacement of the fluid in the tubing.
- Blood flow is calculated using tubing stroke volume and pump revolutions per minute.
- An underocclusive roller pump may result in retrograde flow in the patient and in the cardiopulmonary bypass circuit.
- An overocclusive roller pump may increase hemolysis and produce spallation of the perfusion tubing.

four and five of these RPs positioned on a base console (Figs. 32.2 and 32.3). Most machines are modular in design, permitting the rapid change-out of a defective unit in the case of single-pump failure. It is standard practice of perfusionists to rotate the pumps along the base console in different positions so that mechanical wear is distributed evenly while maintaining equitable time utilization. Each pump is independently controlled by a rheostat that functions to regulate the rpm of the rollers. Each pump is calibrated according to specific flow constants that are calculated from the internal diameter of tubing, as well as the tubing length, placed in the pump raceway. Periodically, PD pumps are calibrated by performing a timed collection of pumped fluid to verify that after proper calibration the pump delivers the volume indicated on the pump flow display. The internal diameters for ECC tubing ranges between 1/8 and 5/8 inch/minute. For this reason, a single console can be used to perfuse a wide range of patients whose size may vary from a few kilograms to more than one hundred. This is accomplished simply by changing the raceway tubing and the shims that hold the tubing in place. The larger the internal diameter of the tubing, the lower the rpm necessary to achieve a desired pump flow. This is especially important because there is a positive correlation between red blood cell (RBC) hemolysis and the rpm of the pump rotation. The magnitude of hemolysis is related to both the time and exposure of the blood to shear forces generated by the pump. However, most of the hemolysis generated during a routine CPB procedure is not related to the occlusiveness of the arterial pump

head but rather to the air-surface interface interaction occurring with the use of suction and "vent" line components of the circuit.[14–16] An underocclusive arterial pump head will result in retrograde flow. This, in turn, will require increased rpms to ensure adequate forward flow.[17] A region of high pressure and shear force is created at the leading edge of the roller where the tubing is compressed, which is followed by a period of negative pressure as the tubing expands behind the roller. This momentary negative pressure under certain conditions may induce the cavitation of air dissolved in the solution. A further related concern is particulate emboli that may be generated by microfragmentation, so-called spallation, of the inner surface of the tubing where the roller contacts the tubing and where the fold at the edges of the tubing occurs.[14] Studies of tubing wear over time have shown that polyvinylchloride fragments generated from RPs are numerous, frequently less than 20 µm in diameter, and begin to occur during the first hour of use.[15] Overocclusive adjustment of the RP results in both hemolysis of RBCs and spallation (particulate fragmentation from the inner walls of tubing), which continues with PD pumps.[18] Kurusz[14] identified the erosive and fatiguing action of the RP as a major source for generating tubing particles in CPB circuits.

The setting of occlusion in the pump head is extremely important and varies among the pumps used on the heart-lung machine console. The arterial pump head occlusion should be set by a water-drop method that incorporates a "30-and-1" rule for setting occlusion. In this method, the occlusion of the arterial pump is set by displacing a column of water (perfusate) 30 cm above the highest water level in the venous or cardiotomy reservoir (whichever is highest) and allowing the perfusate to drop 1 cm/min. Of note, if cardioplegic solution is to be delivered through a separate RP, and/or a left ventricular drainage line (left ventricular vent) placed in a roller head, occlusion for these pumps should be set at 100% (full occlusion) with no drop in fluid movement. This ensures that during the time when cardioplegic solution is not delivered, or the left ventricular vent is turned off, the risk for negative pressure in the ascending aorta or coronary sinus, created by a slowly falling column of fluid, does not create a siphon that causes cavitation or the entrainment of air into the infusion lines. Such aspirated air could be infused directly into the patient by restarting the pump. The heart is vented during CPB to facilitate the removal of ventricular blood that accumulates from noncoronary mediastinal collateral vessels, arteriovenous sinusoids, and thebesian veins, all of which drain directly into the left atrium (LA) or left ventricle. Other anatomic locations of venting the heart include the pulmonary artery and the ascending aorta, with the latter usually drained through an antegrade cardioplegia cannula. The remaining pumps usually are referred to as "pump suctions and vents" and aspirate shed blood from the operative field (see Fig. 32.2). Additional PD pumps may be used to carry out ultrafiltration (UF) or dialysis, for topical myocardial cooling devices, or for removing air from collapsible venous reservoirs.

BOX 32.2 CENTRIFUGAL PUMPS

- Operate on the constrained vortex principle.
- Blood flow is inversely related to downstream resistance.
- Flow rate is determined using an ultrasonic flow meter.
- Increase in centrifugal pump revolutions per minute may result in heat generation and hemolysis.
- If the centrifugal pump is stopped, the line must be clamped to prevent retrograde flow.

Centrifugal Pumps

The second type of extracorporeal pump is a resistance-dependent pump termed a *centrifugal* pump (CP) or *constrained vortex* pump.[19–21] The CP conducts fluid movement by the addition of kinetic energy to a fluid through the forced centrifugal rotation of an impeller or cone in a constrained housing (Box 32.2). The greatest force, highest energy, is found at a point most distal to the center axis of rotation (Figs. 32.4–32.6). CPs operate as pressure-sensitive pumps, with blood flow directly related to downstream resistance. Blood flow is, therefore, related to both the rpm of the cones or impellers and the total resistance. This represents an important safety feature in coupling blood flow with resistance. During unexpected increases in resistance, the total energy transfer from the CP to blood will not generate forces

sufficient to cause arterial line separation. However, when downstream occlusion occurs, either through increases in afterload or through the placement of line clamps, the fluid in the pump head will be heated because of hydrodynamic processes in the magnetic coupling. This increase in temperature could result in increased blood trauma and coagulation defects.[21]

The acceptance of these devices in routine CPB has increased tremendously since first being introduced into clinical practice in 1969,[22] and it is the pump of choice during emergency bypass procedures. The CP also has been used as a ventricular assist device (VAD) because of its inherent safety features and pressure sensitivity, as well as relatively low cost. These pumps have been used extensively off-label for VADs; none of the CPs has received US Food and Drug Administration (FDA) clearance for use as systemic circulatory support for more than 6 hours. CP pumps have been used extensively off-label as VADs or in extracorporeal membrane oxygenation (ECMO) circuits. The afterload and preload sensitivity of these pumps make them particularly amenable for use for ECMO in the treatment of reversible respiratory dysfunction and postcardiotomy dysfunction.[23] The CentriMag Blood Pumping System (Thoratec Corporation, Pleasanton, CA) has a novel magnetically levitated *bearingless motor* technology designed to minimize friction and heat generation in the blood path (Fig. 32.7), which reduces stasis and minimizes blood trauma. The CentriMag is approved for use for up to 6 hours of support and is undergoing further investigation for prolonged use for patients with heart failure (HF). This device also recently received approval by the FDA for use as a right ventricular support device, for use up to 30 days to treat patients with right-HF—the first approval of this class of pump for use beyond 6 hours. The CentriMag received Conformité Européene Mark for use in patients as a ventricular support pump for days to weeks. In an in vitro study, Guan and colleagues[24] compared mechanical performance characteristics of the CentriMag pump with a conventional CP, the Rotaflow Centrifugal Pump (Maquet, Wayne, NJ) and reported better mechanical performance characteristics with the Rotaflow pump in terms of higher shutoff flow rate, maximal flow, and propensity for retrograde flow.[24] These findings deserve further study given the magnitude of cost for the CentriMag pump system's disposable components (CentriMag costs 20 to 30 times more than other CP disposable components).

When air is introduced into the CP, as in emptying of the venous reservoir, the pump head will deprime, stopping forward flow, which reduces the risk for gas embolization. However, when small quantities of air are aspirated into the pump head, these bubbles will coalesce and be passed into the outlet stream of fluid movement and potentially into the patient. Although the CP has been described as exerting less trauma to the cellular elements of blood,[25] variability in individual pump hemolytic potential has been reported.[26,27] Tamari and associates[28] have reported that the degree of hemolysis in CP is related to the hemodynamic conditions under which the pump is operated, with lower flows and higher pressure resulting in more hemolysis than similarly operated RPs. There have been reports of thrombus formation when these pumps are used with low anticoagulation or for prolonged periods.[29] Later designs possess fins and channels that prevent these areas of stasis. Improved designs have addressed issues of stasis, heat generation, and bearing wear. One contemporary design has minimal contact area for the cone and the outer housing and incorporates a series of magnets to suspend the moving rotor within the pump housing.[30] Additional advantages of CP over PD RPs include reduced mechanical trauma to extracorporeal tubing and the generation of high-volume output with moderate pressure development. A potential complication associated with nonocclusive-type pumps involves retrograde flow through the aortic cannula when the pressure in the central aorta exceeds that generated by the pump.[31] This may occur during times of power disruption or pump failure when there is an increased risk for drawing air into the arterial line via purse-string sutures placed to secure the arterial cannula (see Safety Mechanisms for Extracorporeal Flow section later in this chapter). Other uses of CPs include supported

Fig. 32.8 E-Clamp electronic line clamp works in conjunction with the Revolution centrifugal pump. The clamp is automatically deployed to clamp the line when retrograde flow is detected or if the air detector or level detector is triggered. *(Courtesy Sorin Group, Arvada, CO.)*

CPB in high-risk angioplasty patients, left-heart bypass (LHB) during repair of descending thoracic aortic aneurysms or dissections, and venovenous bypass during hepatic transplantation. Use of CPs to assist venous return for minimally invasive cardiac surgery is described as kinetic-assisted venous return.[32,33]

Currently, six manufacturers produce CPs for extracorporeal use: Biomedicus (Biomedicus-Medtronics, Minneapolis, MN), Delphin (3M Health Care, Ann Arbor, MI), Revolution Pump (Sorin Group, Arvanda, CO), Capiox-SP (Terumo Medical Corporation, Somerset, NJ), Rotoflow Maquet (Wayne, NJ), and the CentriMag Pump (Thoratec Corporation Pleasanton, CA). The operational characteristics are similar among the various systems in which the internal smooth cones or vaned impellers are connected to a central magnet (isolated from contact with blood by encasement in a polycarbonate housing), which couples with a motor by magnetic force. The centrifugal console usually is placed in the arterial pump head position on the heart-lung machine, replacing the main drive. All of the consoles currently available include their own battery backup systems in the event of power failure and a manually operated motor in case of drive motor or console failure. The Revolution pump is equipped with an electronic tubing clamp that may be programmed to deploy automatically if low, zero, or retrograde flow is sensed; if the level sensor in the venous reservoir senses a low level; if a high arterial line pressure is sensed; or if the air detector on the arterial line senses air in the circuit (Fig. 32.8). Each manufacturer markets the disposable component that is used with their pump; furthermore, some of the manufacturers have developed adaptor plates so that their disposable component may be used on another manufacturer's pump console.

A number of investigators have conducted in vitro studies comparing CPs and RPs in terms of blood handling during short-term and long-term use. Oku and colleagues,[34] Jakob and associates,[35] Englehardt and others,[36] and Hoerr and coworkers[37] reported less hemolysis with the CP when tested in vitro. Kress and associates[38] showed no difference between the two pump types in a rabbit ECMO model. Tamari and colleagues[39] examined hemolysis under various flow and pressure conditions in an in vitro model using porcine blood and concluded that the hemolysis index was related to the duration of blood exposure to shear, the ratio of pump pressure difference between the inflow and outflow, and the flow rate of the pump. From this work they provided guidelines related to pump selection based on the pressure/flow ratio likely to occur in a given application. Rawn and others[40] compared an underocclusive RP with a CP and found a significantly higher index of hemolysis in the CP (3.38 to 14.65 vs 29.58 g/100 L pumped). In a randomized trial, Salo and coworkers[41] examined inflammatory response mediators in 16 CABG patients with CPB times of less than 2 hours. These mediators included interleukin-1 beta (IL-1β), IL-2, IL-6, phospholipase A_2, endotoxin, fibronectin, and serum C Group II phospholipase A_2. These researchers found no differences in the levels of these inflammatory markers immediately post-CPB and at 24 hours after surgery. Other randomized clinical trials have been conducted to compare emboli generation, neurocognitive outcome, blood trauma, and patient charges. Wheeldon and colleagues[42] conducted a randomized, controlled trial in 16 patients, in which the only difference in equipment and technique was the type of pump used, and found significantly fewer microemboli, less complement activation, and better preservation of platelet count. Parault and Conrad[43] reported a similar significant improvement in platelet preservation in a retrospective review of 785 cases and further reported that the differences were more profound in patients older than 70 years with CPB times of longer than 2 hours. Klein and associates[44] conducted a randomized, prospective clinical study in 1000 adult cardiac patients comparing RPs with the Biomedicus CP (Medtronic, Eden Prairie, MN), using risk stratification methodology, and reported clinical benefits to the CP including blood loss, renal function, and neurologic outcomes, but no significant difference in mortality. Ashraf and others[45] examined S100 beta levels relative to pump type in a randomized, controlled trial that included 32 patients who had CABG and found no significant difference in S100 beta levels between the groups at 2 and 24 hours after bypass. Dickinson and colleagues[46] conducted a retrospective review of 102 patients examining length of stay, total patient charges, reimbursement, mortality, and major complications but could not identify a single difference. A more recent randomized control trial by Scott and others[47] subjected 103 patients to a battery of six standardized tests and found a trend toward fewer abnormal tests in the CP group; however, it failed to reach statistical significance. DeBois and coworkers[48] conducted a trial in 200 elective CABG surgery patients who were randomized to either an RP or CP and found similar patient characteristics including platelet counts, hematocrit, transfusion rate, and mortality; however, they observed differences favoring the CP with regard to weight gain, length of stay, and net hospital financial balance. Alamanni and colleaugues[49] evaluated the prevalence of major neurologic complications in 3438 consecutive patients and found the occurrence of injury to be associated with age and a history of a previous neurologic event. The authors further reported that use of the CP provided a risk reduction for the considered events ranging from 23% to 84%. Babin-Ebell[50] and associates conducted a randomized trial of CABG patients and found a significant reduction in tissue factor in the group supported with a CP; however, this did not translate into a measurable reduction in thrombin formation or other apparent clinical benefit. Baufreton and others[51] examined cytokine production (tumor necrosis factor-α, IL-6, IL-8) and circulating adhesion molecules (soluble endothelial-leukocyte adhesion molecule-1 and intercellular adhesion molecule-1) in a randomized, controlled trial of 29 CABG patients. They reported greater SC5b-9 and elastase levels in the CP group, suggesting more favorable performance from the RP with regard to complement and neutrophil activation.

Although nearly all of the randomized trials show significant benefit to systems designed with CPs, it is difficult to separate the improved performance conferred from other characteristics, such as lower prime volume, surface coating, more limited surface area, and reduced air-to-blood contact. A metaanalysis that included 18 RCTs comparing CP and RP in adult cardiac surgery suggests no significant difference for hematologic variables, postoperative blood loss, transfusions, neurologic outcomes, or mortality.[52]

CPs produce less blood damage; however, this improvement may be inconsequential given the blood trauma and inflammation related to contact activation of the blood related to cardiotomy suction, the introduction of gaseous and particulate emboli, and related factors. According to the recently published *Guidelines on Perioperative Blood Transfusion and Blood Conservation in Cardiac Surgery,* jointly endorsed by the Society of Thoracic Surgeons and the Society of Cardiovascular Anesthesiologists, *"It is not unreasonable to select a CP rather than a RP but more so for safety reasons rather than blood conservation"* (American Heart Association (AHA)/American College of Cardiology (ACC) class IIb level of evidence B).[53,54] In 2000, approximately 50% of the cardiac centers in the United States routinely used CPs for adult

CPB.[55] Exclusive use of CPs for pediatric cardiac surgery is about 5%; however, one-third of centers report occasional use of CPs.[56] The lower maximum pressure generated by CPs represents a noteworthy advantage because the likelihood of disruption of a tubing connection with the CP is negligible compared with that of an RP.

Electromagnetic transducers and Doppler ultrasonic flowmeters are the two methods of measuring CP flow, as compared with the calculated flow display of the PD pumps, which is the product of a flow constant and the rpms. Some have argued that separate flow meters should be used with PD pumps to directly measure the flow to avoid errors that may occur related to an unocclusive roller head or selection of the wrong flow constant.[57] Electromagnetic flowmeters operate under Faraday's principle, that an electric current can be produced in a wire moved through a magnetic field. Voltage is generated when an electrical conductor moves through a magnetic field if the movement is perpendicular to the magnetic lines between the poles of the magnet. Because blood is an electrical conductor, voltage is generated when it passes through a magnetic field and the voltage is directly proportional to the velocity of blood movement. The Doppler technology uses digital signal processing to transform the Doppler analog signal received from the flowmeter into digital format. Fast Fourier transformation then matches the incoming signal to recognizable patterns, which are displayed as flow rates.

Safety Mechanisms for Extracorporeal Flow

Some of the most recent advances in pump design have been a result of a heightened awareness of increasing safety associated with complex operating systems. The PD pumps are pressure independent, which means they will continue to pump regardless of downstream resistance. In a CPB circuit, the summation of resistances against which a pump must function includes the total tubing length, the oxygenator, the heat exchanger, the arterial line filter, the cannula, and the patient's systemic vascular resistance (SVR). Additional factors that influence SVR include the viscosity of the perfusate, related to the total formed element concentration, which primarily is dependent on the formed elements of blood and the temperature of the solution. According to Poiseuille's law, the greatest resistance to flow is created at the arterial cannula, where the change in the caliber of the tubing lumen declines the most. Perfusionists routinely monitor the summation of all resistances and record this value as the arterial line, or system, pressure. This always will be greater than the pressure measured at the distal end of the circuit terminating at the cannula tip because the pressure drop across each component in the series circuit will be subtracted from the summation of resistance (resistors) in the entire circuit. Bypass circuitry and components have been designed to incorporate minimal pressure drops; therefore, in routine adult perfusion, the resistance becomes a function of the patient's SVR and the pump flow rate. Establishing a normal value for arterial line resistance is difficult, although normal limits range between 100 and 350 mm Hg. Any acute change in resistance, such as unexpected clamping or kinking of the arterial line, results in an abrupt increase in arterial line pressure, which can lead to catastrophic line separation or circuit fracture anywhere on the high-pressure side of the circuit. A life-threatening event could occur on the initiation of CPB if the tip of the arterial cannula lodges against the wall of the aorta, undermining the intima of the vessel. Under these conditions, aortic dissection can occur as the vessel intima separates from the media, directing blood flow into a newly created false lumen. This dissection can extend throughout the entire length of the aorta. For this reason, perfusionists routinely check the line pressure after cannulation before the onset of CPB to ensure the presence of a pulsatile waveform, indicating proper cannula placement in the central lumen of the aorta. Either the absence of pulsatile pressure in the outflow portion of the perfusion circuit or an extremely high line pressure (>400 mm Hg when CPB is initiated) should immediately be investigated (see Chapter 31).

All heart-lung machines include a microprocessor-controlled safety interface with their pump consoles. These systems monitor and control pump function and serve as the primary mechanical safety control system for regulating extracorporeal flow. Pressure limits are set by the perfusionist and are determined by patient characteristics and the type of intervention performed. These units consist of early-warning alarms that alert the user to abrupt changes in pressure and will automatically turn off a pump when preset limits are exceeded. These safety devices have been used in both the main arterial pump and the cardioplegia pump; the latter become more important with the utilization of retrograde cardioplegia administration into the coronary sinus.[58,59] Currently, the incorporation of a safety monitor for negative pressure sensing, located on the inflow side of the arterial pump head and during pulsatile perfusion when intermittent occlusion is created, still is lacking.

Electrical failure in the operating room (OR) can be especially catastrophic in the conduct of ECC when the native heart and lungs are unable to function. When such an event occurs during CPB, it is imperative that instantaneous actions be instituted to minimize the risk for whole-body hypoperfusion. The perfusionist should be mindful of the power limitations of the electrical outlet used in the cardiac OR and also be aware of the location of the circuit breaker panel for the room and the specific number of the breaker in the panel for the outlet used for the heart-lung machine and other support equipment. Methods to ensure the safe conduct of CPB involve the incorporation of an emergency power source in the extracorporeal circuit that provides a secondary power source in the event of electrical interruption. Electrical failure during CPB was reported by 42.3% of respondents in a survey on perfusion accidents.[60] Although hospitals are equipped with emergency generators for such events, their availability may be limited to certain electrical circuits within the operating suite. Furthermore, these emergency power systems require a brief interruption in power before a generator or backup source of power is initiated. Most heart-lung machines are equipped with uninterrupted backup power, sometimes referred to as the *uninterrupted power source,* whereby there is a seamless transfer from the wall power source to an internal battery within the pump should the wall power fail. Thus with this system, there is no loss of flow from the pumps that could result in retrograde flow and entrainment of air or disruption of settings and timers. Cases of primary power failure with concurrent emergency backup failure also have been reported.[61] As a tertiary fallback measure, emergency hand cranks for CPB pumps are standard features in extracorporeal circuitry, which enable pump operation in the event of total power failure and when emergency systems fail to operate. However, care should be taken to ensure that the direction of blood flow is ascertained because hand cranking in the reverse direction of fluid flow could result in serious patient injury related to exsanguination and the entrainment of air around purse-string sutures at cannulation sites. The Retroguard valve (Quest Medical Incorporated, Allen, TX), a mechanical circuit component to prevent retrograde flow in the arterial outflow of the circuit, is available to prevent retrograde flow in the arterial line and possible entrainment of air into the circuit and into the patient's arterial circulation. It is composed of a simple duck-billed valve that adds minimal resistance to forward flow in the circuit and will close when downstream pressure is greater (Fig. 32.9).

Although the chance of infusing massive air boluses to patients has been reduced dramatically since the early days of CPB,[60] this remains a serious potential event during surgery (Box 32.3). Cannulation of the heart with aortic and venting catheters has been identified as the primary cause for air embolization during ECC.[62] Methods of air-bubble detection have improved tremendously, and the sensitivity for detecting small amounts of air has increased in modern heart-lung machines.[63] Ultrasonic and capacitance air-detection systems, used for both level sensing and air detection in arterial and cardioplegia circuit lines, represent dramatic improvements over less sensitive (photoelectric) methods.[64] Reliable level-sensing devices alert the perfusionist to rapid changes in venous reservoir levels with the ability to servoregulate blood flow, stop the arterial blood pump, or engage an electronic line clamp (see Fig. 32.9). The American Society of Extracorporeal Technology's International Consortium for Evidence-Based Practice

Fig. 32.9 Quest Medical RetroGard Valve. Blood enters from the 3/8-inch inlet, passes through a duck-billed valve, and exits through a 3/8-inch outlet. This valve prevents retrograde flow. This valve may also be placed on an inlet port of the venous reservoir to prevent pressurization of the hard shell venous reservoir. *(Courtesy Quest Medical, Allen, TX.)*

BOX 32.3 SAFETY MASSIVE AIR EMBOLISM

- Cannulation of the heart with aortic and venting catheters is a primary source of massive air embolism (MAE).
- Air detection and level-sensing safety devices should be used in the cardiopulmonary bypass circuit.
- One-way vent valves, positive pressure release valves, and filter purge line valves may prevent MAE related to reversed vent tubing or a pressurized venous reservoir.

has stated that both air-bubble detection and level-sensing devices must be used in all extracorporeal circuits.[65]

Electronic Perfusion Records

Health care providers and patients alike have benefitted from the influence of computer technology on improving the tools and techniques in the cardiovascular OR.[66] Since the first reported use of a digital computer to calculate indices of cardiopulmonary function in 1966, microprocessor-driven technologies have emerged to offer tremendous advantages in surgical device function and reliability.[67] Such systems are able to function without interruption through all processes of the procedure, with minimal downtime ensured with proper use and maintenance. The ability to transmit and store vast amounts of data confers significant advantages in decreasing delays in both clinical communication and treatment. [68]

The practice of ECC is represented by a multitude of physiologic and mechanical events, which are closely interrelated and constantly changing. The continuous generation of information during these events provides a perfect situation for data capture and processing, optimizing the conduct of perfusion.[69–71] Microprocessor connectivity between devices allows for real-time data to be quickly transmitted to a central processing system. As such, output data from the heart-lung machine (as well as information from peripheral equipment such as in-line blood gas analyzers, coagulation devices, cooler/heater units, and regional oximetry monitors) can be easily integrated into a single perioperative data management system. Electronic medical records (EMRs), when used in conjunction with physiologic patient data from the anesthesia-monitoring device, provide a single source for collecting, recording, and displaying essential data for the perfusionist at the point of care.

EMRs do not simply transmit information; they quickly compute values specific to the needs of the patient. Formulas using the patient's body surface area provide the clinician with immediate feedback on perfusion and oxygen requirements during ECC. Continuous real-time monitoring of both arterial and venous saturation values is used to calculate oxygen delivery and consumption ratios. Tracking fluid inputs (crystalloids, colloids, and blood products) and outputs (ultrafiltrate, urine output, and blood loss) provides trends on the overall fluid balance of the patient. ECC prime constituents and medications can be used to predict dilutional patient hematocrit values. At the conclusion of the surgical procedure, automated and manually inputted data collected during ECC are incorporated into the official perfusion perioperative record. These data may also be uploaded to a secure server to be used for retrospective quality assurance and improvement activities.[72] By electronically automating the generation of quality indicators for CPB, Baker and colleagues demonstrated an improved adherence to process of care guidelines and reduced practice variation when compared with a control group of clinicians that did not receive quality improvement (QI) data feedback.[73] Similar benefits have been reported at national and regional levels, as clinical registries help cardiac surgical programs benchmark and compare discrete perfusion variables to other institutions.[74,75] Clinical registry findings can then be "translated" back to key stakeholders to increase the speed at which new and effective treatments reach patients. In 2010, the Centers for Medicare and Medicaid Services (CMS) established provisions of the American Recovery and Reinvestment Act of 2009 that provide financial incentives to hospitals that successfully demonstrate meaningful use of electronic health records (EHRs).[76] These standards require CMS-eligible institutions to record and report clinical quality measures aimed to quantify health care processes and outcome. The perceived benefits of the meaningful use of EMR data will result in better clinical outcomes, increased transparency and efficiency of services, empowered individuals, and more robust research data on health systems.[76]

The newest generation of perfusion EMRs is now capable of providing real-time safety alerts to potentially dangerous events during extracorporeal support. Through the advent of continuous monitoring of critical care parameters, computer-generated notifications can alert the clinician when various physiologic parameters fall outside of the desired level of compliance. Similar to the aviation industry, these computer-guided early warning systems help perfusionists quickly diagnose potentially adverse conditions before they manifest into significant complications.[77] The Viper EMR data acquisition system (Spectrum Medical, Fort Hunt, SC) is a clinical software application that collects and interprets data in real-time by incorporating compliance threshold limits (Figs. 32.10 and 32.11). Clinicians can activate high and low threshold alarms for a multitude of physiologic parameters during ECC support. When a clinical variable falls outside the preset compliance limit, a pop-up banner alert message immediately notifies the clinician. Beck and colleagues demonstrated nearly a 10-fold decrease in perfusionist response time (3.6 vs 30 seconds) for critical values occurring for clinicians assigned to the Viper and non-alert groups, respectively.[78] The authors concluded that the use of this type of technology not only improved operator performance, but also had the ability to translate into improved patient safety and outcome. Another unique feature of the Viper system is the ability to broadcast clinical information to locations across the medical center campus.

Fig. 32.10 Viper display with table and graphical display of data. *(Courtesy of Spectrum Medical, Fort Mill, SC.)*

When coupled with compliance alert thresholds, remote monitoring can enable the perfusionist to be notified of suboptimal clinical parameters when they are not immediately available at the bedside. Fung and colleagues demonstrated the effective use of remote monitoring to diagnose and troubleshoot complications for patients on ECMO support.[79] The continued support and growth of such telehealth services could extend the clinical reach of health care providers to patients that can benefit from their expertise.

Most major perfusion hardware manufacturers offer EMR solutions for intraoperative data management and reporting. However, there is significant variation with each technology in its ability to interface with other OR devices and software applications. This limits the amount of data that can be collected and stored for QI tools. Further, the lack of device connectivity requires significant levels of manual data entry, which not only focuses the attention of the clinician away from the patient, but also limits information that can be used to make informed clinical decisions at the point of care. The Sorin CONNECT Perfusion EMR (Sorin Group, Milan, Italy) incorporates an intuitive goal-directed perfusion (GDP) technology that quantifies the adequacy of modifiable factors during ECC (Fig. 32.12). CONNECT features real-time calculations of oxygen delivery, oxygen consumption, and venous CO_2 values. Similar GDP management strategies have been shown to be associated with reductions in the incidence of postoperative acute kidney injury following cardiac surgery.[80]

As the use of EHRs continue to grow in the health information technology ecosystem, all perfusion-based patient care activities will

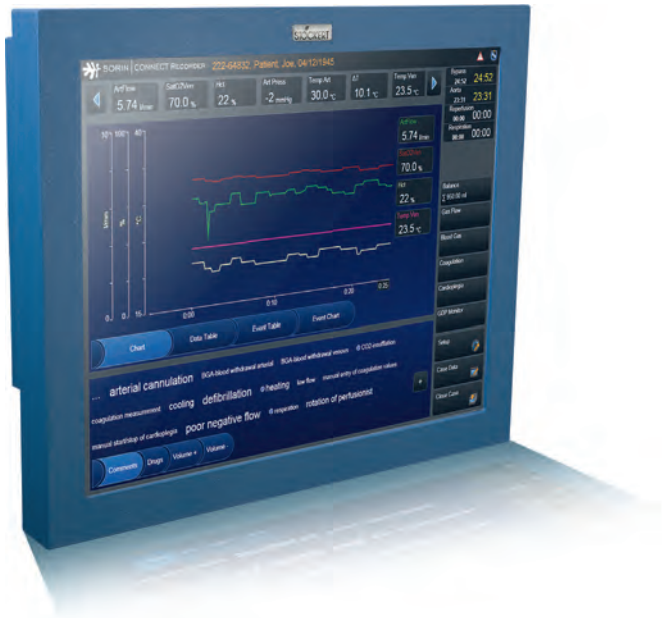

Fig. 32.12 Sorin Connect perfusion electronic medical record with goal-directed perfusion display. *(Courtesy of The Sorin Group, Arvada, CO.)*

eventfully transition away from paper to electronic data entry. However, the overall impact on positive patient care and outcome will rely on the EMR's ability to integrate with other health care systems to make the data meaningful. Choosing the right EMR solution, as opposed to the "one size fits all" platform, may offer a level of data granularity that best meets the unique needs of the cardiac surgical patient. Although a significant investment of time, money, and training is associated with implementing many EMR systems, the observed benefits of translational medicine from the bench to the bedside cannot be understated. The digital age in medicine is transforming the delivery and coordination of patient care and outcome.

BOX 32.4 MEMBRANE OXYGENATORS

- Hollow-fiber membrane oxygenators are commonly used for cardiopulmonary bypass.
- An oxygen gas mixture flows through microporous polypropylene hollow fibers.
- Blood flow is directed over the microporous hollow fibers.
- Recently nonporous polymethylpentene (PMP) hollow fibers have been developed.
- PMP fibers provided a more durable surface for prolonged oxygenation such as extracorporeal membrane oxygenation.
- PMP fibers do not permit the passage of volatile anesthetics such as isoflurane.

Extracorporeal Circuitry

Blood Gas Exchange Devices

The ECC of blood incorporating total heart-lung bypass could not be accomplished were it not for the development of devices that could replace the function of the lungs in pulmonary gas exchange. The technology of pumps to replace the mechanical action of the heart was developed well before their incorporation in ECC. Therefore the limiting factor hindering the progression of CPB was the development of an artificial lung, or BGED, commonly referred to as a *membrane oxygenator* (Box 32.4). The term *membrane* denotes the separation of blood and gas phases by a semipermeable barrier, whereas *oxygenator* refers to the change in oxygen partial pressure that occurs by the arterialization of venous blood. However, "oxygenator" is a misrepresentation of the functional ability of these systems to perform ventilatory control of carbon dioxide. Numerous engineering challenges hindered the development of BGEDs, but two of the most pressing were the design of high-capacity units for gas exchange with low rates of bioreactivity. The latter requirement, also termed *biocompatibility,* was imperative to reduce both RBC trauma and activation of the formed elements of blood.

In the 1940s, the first dialyzer membranes were made of cellulose acetate, and although intended for use in dialysis, they also had gas exchange characteristics.[1] In the 1950s, several membrane materials (including polyethylene and ethyl cellulose) were used in a flat sheet or plate configuration. At the same time, rotating disk oxygenators were introduced whereby gas exchange was accomplished by spreading venous blood in a thin film over a rotating disk, which was exposed to an oxygen-rich environment. In the 1960s, the first disposable membrane oxygenators were introduced and were made primarily of silicone rubber in either a plate or spiral wound design. Silicone offered the distinct advantage of separating both the blood and gas phases, facilitating gas exchange through a semipermeable barrier by diffusion. Teflon was introduced in the 1970s as a membrane material, together with microporous polypropylene (PPL), which first appeared in Travenol membrane devices. Today, the majority of commercially available oxygenators are made of PPL in either a pleated or folded configuration, or as capillary hollow fibers. In the United States, manufacturers develop oxygenators that meet federal regulatory guidelines for performance and biocompatibility. Those devices meeting these requirements are "cleared," approved for use for up to 6 hours of CPB, and represent the majority of oxygenators. Currently, only one oxygenator that utilizes silicone membranes is approved for long-term support such as that occurring for ECMO. However, the "off-label" use of more durable, lower prime, hollow-fiber technology membrane oxygenators and newer polymethylpentane fiber oxygenators is widely reported in the literature.

Historically, oxygenators were divided into three broad classes based on the method of gas exchange: film oxygenators, bubble devices, and membrane systems. The stationary 0.7-mm screen oxygenator used by Gibbon is an example of a film oxygenator. Blood was distributed over a screen producing a film that increases the surface area of the blood and its exposure to oxygen allowing gas to transfer by diffusion.[81] Bubble-type devices have been shown to denature plasma proteins, increase RBC fragility,[82] activate platelets,[83] and generate substantial gaseous microemboli (GME).[84–86] For these reasons, they are no longer used in most countries and are infrequently encountered in all but a few remaining places throughout the world. Bubbler systems use a direct gas-blood interface, with gas exchange occurring by the dispersion of gas, either 100% oxygen or a mixture of oxygen and carbon dioxide (carbogen), through a column of desaturated blood. Bubble devices are made of two separate compartments: an oxygenating column and a defoaming chamber. The dispersion of gas in a bubbler occurs through a sparger plate, where a thin film of blood comes in direct contact with gas. This direct blood-gas interface results in the production of foam, where gas exchange occurs. Coalescence of the foam is achieved in the defoaming chamber both through the presence of surface tension–reducing substances and by filtration. Gas exchange is affected by several factors, including the quantity of gas and the size of bubbles produced in the gas sparger.[87] Small bubbles are extremely efficient at oxygen exchange but poor at carbon dioxide exchange, whereas large bubbles are poor in oxygen but good in carbon dioxide exchange.

Membrane oxygenators are made of three distinct compartments: gas, blood, and water (see Fig. 32.10). The latter phase is also termed the *heat exchange compartment* and is used for temperature control. Gas and blood are partitioned into separate compartments with either a limited or absent gas-blood interface. Microporous membrane oxygenators initially have a blood- gas interface that becomes diminished only after the inner blood contact surface has been exposed to plasma; and a protein layer is deposited, acting as a diffusible barrier to gas exchange. The most common material in use today in membrane oxygenators is microporous PPL, which has excellent capacity for gas exchange and good biocompatibility. Membrane devices made of silicone materials transfer gas directly by diffusion across the semipermeable membrane and effectively never have a blood-gas interface.[88] Despite the improvements made to extracorporeal devices over the past several decades, once blood is exposed to synthetic surfaces, hematologic changes result. Initially, complement is activated mainly through alternative pathways, resulting in the liberation of toxic mediators such as C3a and C5a.[89,90] Both platelets and leukocytes that elicit a complex series of inflammatory and hemostatic reactions that ultimately increase the risk for postoperative complications are activated.[87]

Gas transfer in membrane oxygenators is a function of several factors that include surface area, the partial pressures of venous oxygen and carbon dioxide, blood flow, ventilation flow (called *sweep rate*), and gas flow composition. Membrane devices independently control arterial oxygen and carbon dioxide tensions (PaO_2 and $PaCO_2$). Pao_2 is a function of the FIO_2, whereas $PaCO_2$ is determined by the sweep rate of the ventilating gas. This independent control of ventilating gas results in arterial blood gas values more closely resembling normal physiologic blood gas status. However, it is common for perfusionists to maintain PaO_2 levels in the 150- to 250-mm Hg range during CPB because of the limited reserve capacity of membrane oxygenators.

A multitude of factors must be considered in the design of a membrane BGED, including total surface area, blood film thickness, diffusion residence time, gas diffusion rate, blood flow rate, blood flow geometrics, and gas flow characteristics. The most influential factors that affect blood trauma in an oxygenator are related to how blood traverses the device and are termed *shear stress* and *stasis*.[91] Design characteristics that minimize these effects by optimizing flow pattern geometry through extracorporeal devices have been generated through mathematical models termed *computational fluid dynamics*.[92] Two of the most important considerations in designing a membrane device are determining the type of membrane material and the handling of water vapor produced in the gas phase of the device. This water vapor would be synonymous with pulmonary exudate and, when excessive, mimics pulmonary edema associated with permeability changes of the alveolar capillary membrane. Another important membrane feature is how blood flows through the membrane. As fluid moves through a conduit, laminae are established, with the highest velocity of flow achieved in the center of the tube. At the same time, the outermost layers, nearest the walls of the conduit, effectively have no velocity because of the drag coefficient of the inside surface. This occurs in both the gas phase and the blood phase of membrane oxygenators. The laminar effect can be disrupted by several techniques that produce a "secondary flow," facilitating increased gas exchange.[93] In hollow-fiber membrane oxygenators, incorporating blood flow outside of the fibers, mixing is achieved by winding of the fibers, creating a crossing pattern, increasing blood exposure to the membrane surface. Laminar flow is reduced in hollow-fiber oxygenators with blood flow through the fibers by the expansion and contraction of the capillaries via the movement of blood through them, gently disrupting the boundary layers.

Estimating the total surface area of material necessary for gas exchange is a function of the predicted oxygen demands of the patient, the pattern of flow within the device. As the surface area of an oxygenator increases, the volume of solution necessary to prime the system increases. Early microporous PPL hollow-fiber membrane devices used a pattern of blood flow through the fiber. Contemporary designs have blood flow around hollow fibers with gas flowing through the fibers. Oxygenators with longer blood flow paths may require less fiber surface area. Those with shorter blood flow paths require more fiber surface area to achieve a similar oxygen transfer. Systems that use the latter design require a lower membrane surface area for gas exchange and hence result in lower prime volumes. Microporous PPL membranes have the distinct advantage of a greater gas transfer rate per surface area of membrane than that of silicone membranes.

The oxygenator represents the largest source of nonendothelialized surface area in the extracorporeal circuit, ranging in size between 0.5 and 2.5 M^2. As a consequence, it is imperative that the device is meticulously primed to remove all residual air before establishing CPB. Oxygenators have been shown to possess different abilities to remove gaseous emboli that vary according to the physical CPB conditions including temperature and pressure decline.[94–97] In an effort to reduce surface exposure and prime volume, several membrane oxygenators are now manufactured that either possess integrated arterial line filters (CAPIOX FX Oxygenator; Terumo Cardiovascular Group, Ann Arbor, MI [Fig. 32.13] and Affinity Fusion; Medtronic, Minneapolis, MN [Figs. 32.14 and 32.15]) or have an arterial line filter that is sequenced in the oxygenator (Inspire; Sorin Group, Arvada, CO [Fig. 32.16]). Some studies suggest that these devices may result in a reduction in GME.[98,99]

Numerous studies have identified the occurrence of GME during cardiac surgery with CPB.[100] Weitkemper and colleagues[101] have shown

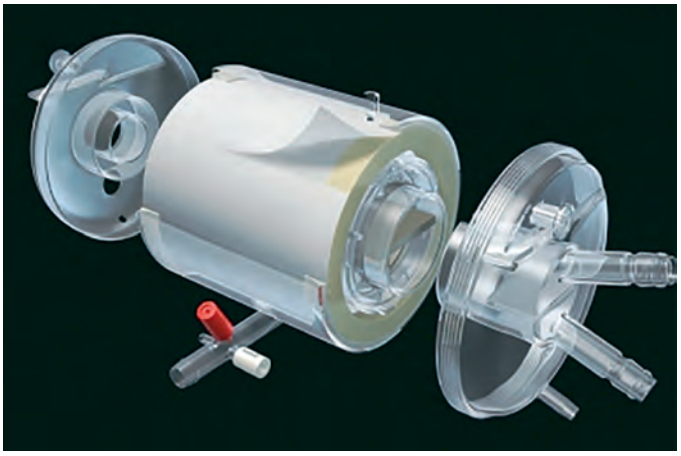

Fig. 32.13 Terumo FX Oxygenator with integral 32-micron screen filter surrounding the fiber bundle. *(Courtesy Terumo Cardiovascular Group, Ann Arbor, MI.)*

that currently used microporous membrane oxygenators have widely variable characteristics related to how they handle gas. Furthermore, the design characteristics in some cases cause partial removal of GME, as well as a change in size and numbers of microbubbles. Dickinson and associates[102] conducted an in vitro analysis that showed significant air-handling differences between the oxygenators from four different manufacturers. They demonstrated how a sonar-based system, the Embolus Detection and Classification (EDAC; Lunar Technology, Blacksburg, VA) system, could be used to evaluate perfusion systems with regard to their ability to handle gas entrained in the circuit.

A new nonporous membrane surface composed of polymethylpentene (PMP) fibers has shown improved diffusion compared with the conventional PPL hollow fibers. PPL affords improved durability and biocompatibility when used for long-term support[103,104] and for routine CPB.[105] Although oxygen and carbon dioxide gas exchange are comparable between PPL hollow fibers and the PMP nonporous fibers, it is important to note that the transfer of volatile anesthetic agents do not readily cross this membrane. Wiesenack and colleagues[106] demonstrated that the PMP fibers allow only minimal transfer of isoflurane compared with the currently used PPL microporous hollow-fiber oxygenators. A recent systematic review on anesthetic management during CPB reported the common use of volatile anesthetics through the heart-lung machine in the United States.[107] However, Europeans favor intravenous anesthetics during bypass, and European Council Directive 93/42/EEC bans the use of a vaporizer with a heart-lung machine.[108,109] During long-term support, it is not uncommon for PMP oxygenators to develop breaches in the surface that lead to plasma leaks after 40 to 90 hours of use, whereas the PPL fibers tend to be more robust, are not prone to plasma leaks, and continue to transfer oxygen and carbon dioxide after many days of use.

BOX 32.5 VENOUS RESERVOIRS

Open Systems

- Open systems have polycarbonate hard-shell reservoirs and are usually equipped with an integral cardiotomy reservoir.
- With open systems, venous return may be improved by applying regulated suction to the reservoir (vacuum-assisted venous drainage).
- With open systems, buoyant air bubbles escape to the atmosphere at the top of the reservoir.

Closed Systems

- Closed systems consist of collapsible polyvinylchloride bags.
- Closed systems require a separate cardiotomy reservoir.
- Buoyant air from the venous line accumulates in the bag and must be actively aspirated.
- Closed systems have a reduced contact surface of the blood with air or plastic.
- A separate centrifugal pump may be used to increase venous return (kinetic-assisted venous drainage).

Venous and Cardiotomy Reservoirs

There are two general categories for venous reservoirs: open and closed systems (Box 32.5). Open systems have a hard polycarbonate venous reservoir and usually incorporate a cardiotomy reservoir and defoaming compartment (see Fig. 32.13). Closed systems are collapsible polyvinylchloride bags that have a minimal surface area and often a thin single-layer screen filter, and they require a separate external cardiotomy reservoir for cardiotomy suction (Fig. 32.17). Filters and defoaming compartments in the venous reservoir and air-trapping ports located at the highest level of the blood flow path within the oxygenator are areas designed to allow passive removal of air. Studies that have examined the air-handling capabilities of oxygenators have shown that all of the currently available oxygenators do not sufficiently remove GME when challenged with air in the inflow.[102,103] The use of an open system offers several distinct advantages. Unlike collapsible reservoirs, it is not necessary to actively aspirate air, which may be entrained in the venous line during CPB. The large buoyant air migrates to the top of the reservoir and escapes through strategically placed vents on the reservoir cover. An additional benefit of the use of "open" hard-shell reservoir systems incorporates the capability of vacuum-assisted venous drainage (VAVD), although alternative methods have been implemented augmenting venous drainage to closed "bag" systems using CPs or creative vacuum applications applied to the venous line to enhance natural gravity drainage. Furthermore, a number of studies have reported a greater incidence of GME caused by air entrained in the venous line and furthermore that VAVD further increases GME counts.[105,110–114] Willcox has raised concern that VAVD has been used clinically without any significant redesign of the components of the CPB circuit to improve the gas handling performance in negative pressure conditions.[113] The prime volume may be reduced slightly because the integration of the venous reservoir with the cardiotomy eliminates connecting circuitry and may permit a smaller-bore venous line with use of VAVD. With open systems, the circulating blood is exposed to a larger and more complex surface that contains defoaming sponges and antifoam agents. Air can traverse the oxygenator into the arterial outflow of the CPB circuit and into the patient's arterial circulation, including the cerebral circulation, producing contact activation of the vascular endothelium or obstruction at the microcapillary level. Thousands of GMEs can be introduced into the patient's arterial circulation with these circuits if air becomes continuously entrained into the venous inflow, a condition that could not be tolerated with a collapsible reservoir.

VAVD also carries a risk of an accidental massive air embolism. It has been reported that occlusion of the vacuum source line can cause pressurization of the venous reservoir and introduction of a gas embolism to the patient through the venous line.[115–118] Thus it is important to monitor the reservoir pressure if vacuum-assisted venous draining is used.

Recently, several randomized clinical trials have found superior clinical outcomes with a system equipped with a closed reservoir and a centrifugal arterial pump.[119,120] Schonberger and colleagues[121] prospectively studied differences in inflammatory and coagulation activation of blood in CABG patients treated with open and closed reservoir systems. Levels of complement 3a, thromboxane B_2, fibrin degradation products, and elastase were significantly greater in open reservoir patients. Furthermore, the largest ($P < 0.001$) amount of shed blood loss, greatest ($P < 0.05$) need for colloid-crystalloid infusion, and largest (not significant) need for donor blood (0.8 ± 0.4 vs 0.2 ± 0.2 units of packed cells) were observed in the patient supported with open reservoir systems.

Aldea and associates[122] conducted a randomized, controlled trial to evaluate the effects of cardiotomy suction in CABG patients. Use of cardiotomy suction resulted in significant increases in thrombin, neutrophil, and platelet activation, as well as the release of neuron-specific enolase, after CPB. The authors suggested that limiting increases in these markers would be best accomplished by eliminating cardiotomy suction and routinely using heparin-bonded circuits whenever possible.

Miniaturized Cardiopulmonary Bypass

The principal drawbacks to the conventional CPB circuit include activation of the systemic inflammatory response, aberration in coagulation function, CPB-related gaseous embolism, and excessive hemodilution requiring blood transfusions. A principal design approach to overcome some of these problems has been the introduction of "miniaturized CPB circuits" that reduce the blood–foreign surface contact, blood-air interface, and hemodilution (Figs. 32.18 to 32.19). The currently available "mini" systems consist of either an adaptation of standard CPB components or the introduction of new devices by manufacturers that have a striking resemblance to existing devices.[123–157] The manufacturers' minisystems all use a single CP to provide kinetic venous drainage and arterial blood propulsion. All have eliminated or isolated the venous reservoir to reduce blood foreign surface contact, and all eliminated the introduction of activated blood from a cardiotomy suction system. Field shed blood is recaptured and washed by an

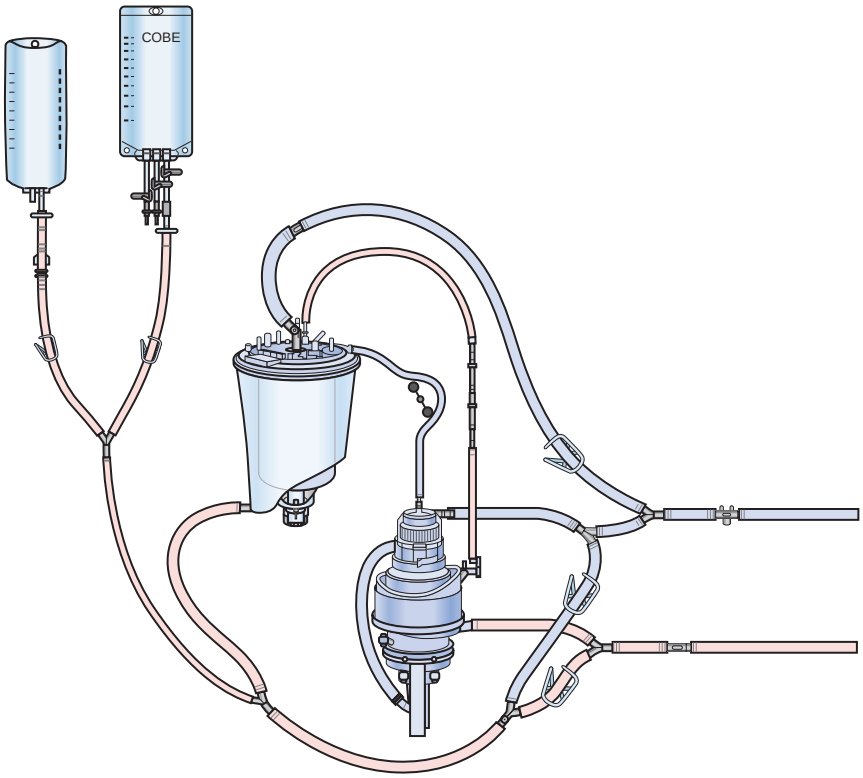

Fig. 32.18 Sorin Group Synthesis mini-bypass system. The oxygenator has an integral air detection and evacuation system and a single integral revolution centrifugal pump (providing both kinetic-assisted venous drainage and arterial blood propulsion). An integrated arterial line filter surrounds the oxygenator fiber bundle. A separate cardiotomy reservoir is incorporated into the circuit. The system may be converted to an open system by repositioning clamps and redirecting blood flow to the reservoir. *(Courtesy Sorin Group, Arvada, CO.)*

autotransfuser before reintroduction to the minisystems. Many of the systems have incorporated multisite bubble detection and innovative air removal systems to automatically remove and isolate micro and macro air entrained in the CPB circuit.

These systems lack several of the characteristics of the old standard CPB systems that made CPB simple. For example, the entrainment of air into the old systems was of little operational consequence because air could escape to the top of open reservoir systems or be aspirated by a vacuum or an RP from closed reservoir systems. Furthermore, shed blood at the surgical field could be readily collected and reintroduced into the circulation with conventional systems using the cardiotomy suction system without the use of an autotransfuser. In other words, variable venous return or excessive suction return can be easily accommodated with regular CPB systems, with minimal or no addition to the basic circuit as opposed to the minisystems currently on the market.

With most of the minisystems, minor changes in the circuit or complete major reconfiguration of the minisystem may be necessary if excessive bleeding occurs at the surgical field (addition of a venous reservoir, addition of a cardiotomy reservoir, and transfer of a massive amount of blood from the autotransfuser collection reservoir back to the minisystem). Minisystems do not facilitate emptying of the cardiac chambers as well as do conventional systems. With conventional CPB systems, the cardiac chambers can be passively emptied into a capacitance reservoir, whereas in the usual configuration, the capacity of the venous system in the presence of a minisystem is quite fixed. In minisystems, the capacitance reservoir is the patient's venous bed. To empty the heart, blood must be actively diverted to a separate reservoir or to the patient's capacitance reservoir with manipulation of the venous capacitance. Safe use of these systems requires good communication among the surgeon, anesthesiologist, and the perfusion team, together with careful monitoring. These major differences have made some centers reluctant to change to these new systems.

A metaanalysis of RCTs conducted by Zangrillo and colleagues[158] sought to determine whether the use of miniaturized CPB translates into decreased morbidity, including blood transfusion, neurologic events, and blood loss, in patients having cardiac surgery. Sixteen trials met inclusion criteria, with 1619 patients (803 to miniaturized CPB and 816 undergoing standard cardiac surgery). Miniaturized CPB proved to be beneficial in terms of decreased transfusion rate and decreased cardiac and neurologic injury. These findings are summarized in Fig. 32.20. Current use of such systems is limited. Further studies are necessary to substantiate the benefit of such systems and will likely increase the adoption of this new technology. Similarly, Harling and colleagues conducted a metaanalysis composed of 29 studies and 2355 patients, which showed no difference in mortality and neurovascular compromise and a significant favorable trend of blood loss, transfusions, and fewer arrhythmias with MECC.[159] Surprisingly, despite the preponderance of evidence, use of MECC is not widely used in the United States.

Portable Cardiopulmonary Support Systems

There has been a surge in the use of ECMO therapy for both cardiac and pulmonary support. Between 2006 and 2011 outcomes for patients supported with ECMO improved and the use of ECMO support in the United States increased by 433% [160] A variety of platforms composed of conventional CPs or RPs have been used. Maquet has designed a new system aimed to improve the safety and ease of transporting patients supported with an extracorporeal live support.[161] The Cardiohelp portable life support system (Maquet Cardiovascular, Bridgewater, NJ) is a system with a fully integrated pump and oxygenator disposable

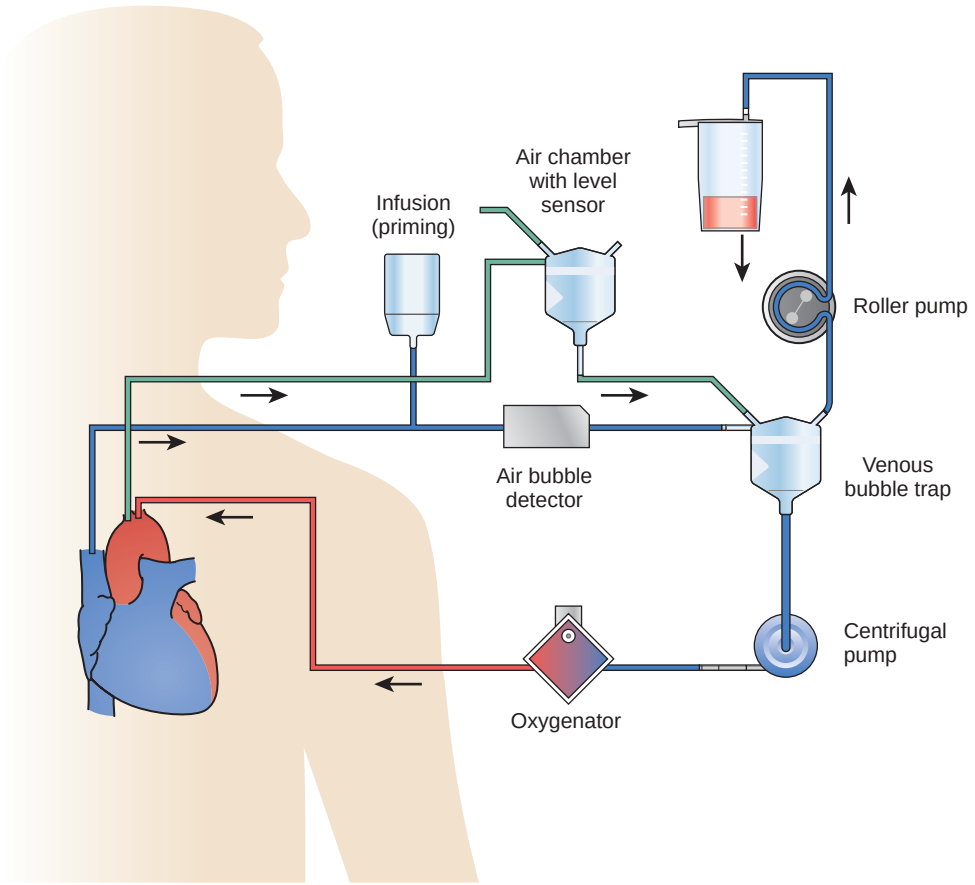

Fig. 32.19 Maquet Minimal ExtraCorporeal Circulation. cassette with a lightweight (22-lb) pump drive and control mechanism that may be used for extracorporeal perfusion resuscitation anywhere in the hospital, for ECMO support in critical care units, or for transport within or across health care facilities (Fig. 32.21). The system has a unique console design that eliminates the use of a stator motor. The system interface plate consists of a surface with a moving magnetic field that drives the integrated CP. The Cardiohelp system is an important departure from the traditional "homemade" ECMO circuits and consists of a standardized circuit and built-in pressure alarms, temperature alarms, and hemoglobin and saturation sensors. Early reported experience with this system has been favorable in terms of ease of set up, performance, and portability.[162–164]

Heat Exchangers

Patients who are exposed to ECC will become hypothermic in the absence of an external source of heat to regulate body temperature. Most CPB systems use some form of heat exchanger in the circuit to warm and/or cool the patient's blood. The majority of oxygenators contain integral heat exchangers through which blood passes before undergoing gas exchange (see Fig. 32.15). Heat exchangers may be absent from circuits used for ventricular assist or certain types of LHB. However, in either of these scenarios, external warming blankets and ambient room temperature are controlled to restrict declines in patient temperature. Heat exchangers can be made from a variety of materials, although the most often used are aluminum (anodized or silicone-coated anodized), stainless steel, and PPL. Stainless steel is the most durable and chemically inert of all commercially used heat exchangers.

Some of the basic performance features that all heat exchangers for extracorporeal blood should possess include a high degree of chemical inertness, high resistance to corrosion, smooth surfaces, and a low-energy surface where RBC and plasmatic residues do not adhere. The ideal heat exchanger must possess the following characteristics: low resistance to blood flow, freedom from defects in material that could facilitate the mixture of blood and water, low priming volume, and disposability. The effectiveness of a heat exchanger depends on several factors, including total surface area, thickness of the conductor walls, thermal conductivity, and the residence time of blood through the device. As fluid flow through a heat exchanger is increased, the performance characteristics decline, primarily as a function of decreased residence time in the device.

Heat exchanger basic design consists of two separate phases, with water passing on one side and blood, or perfusate, on the other. The direction of blood flow is routinely countercurrent to the flow of water, optimizing heat transfer. The temperature of the water entering the heat exchanger is controlled by either an external cooler/heater device or a wall source, with a temperature range from 4°C to 42°C. The majority of heat transfer occurs by the process of conduction, in which thermal energy is passed from water to blood.

Heat exchangers can be placed in the circuit in a variety of locations, although the most common location is on the proximal side of the oxygenator, often termed an *integral heat exchanger*. It is hypothesized that with proximal, or venous-side, heat exchange, there is less chance of "outgassing of solution" caused by rapid rewarming of blood after hypothermic CPB, which could generate GME. Of similar concern is the effect of rapid cooling and warming of an organ or tissue, during which temperature fluctuations would create an environment in which

the solubility of gas in blood would abruptly decline, increasing the partial pressure so that GME could be generated. Increased risk would be directly proportional to the oxygen tension of blood, which would enhance the rate solubility shifts.

Other potential risks of heat exchangers are associated with the type of material used for construction. Because stainless steel is relatively expensive, aluminum has been used most often as the material for heat exchangers. Aluminum, however, has a high toxicity in humans; when blood levels exceed 100 mg/L, careful patient monitoring is imperative and levels greater than 200 mg/L are toxic.[165] Aluminum oxide concretions were found recently in organs of neonatal patients having undergone ECMO; these concretions most likely formed from aluminum leached from the anodized aluminum heat exchangers used in the circuit.[166] In the late 1990s, Medtronic manufactured the Forte oxygenator, the first oxygenator with a PPL heat exchanger. This change in materials was considered to reduce manufacturing costs and aid in the disposal of used oxygenators. It was discovered that the oxygenator would build up a static charge of 2200 volts because the PPL would not dissipate the charge between the water and blood side of the oxygenator. Occasionally, this oxygenator would develop blood-to-water leaks

when a spark would arc across a fiber. Eventually, a grounding cable was added to prevent such leaks, but the Forte oxygenator was taken off the market because clinicians had no confidence in it.[167] However, more recently, a resurgence in the use of PPL tubes for heat exchangers has occurred. Regardless of the material used and despite careful manufacturing, heat exchangers must be tested before use. Leaks between the blood and water compartments have been reported.[168]

Heat exchanger performance standards were established in the 1982 American Association of Medical Instruments draft report.[169] Performance testing is conducted by the simultaneous measurement of three temperatures: blood inlet temperature, blood outlet temperature, and water inlet temperature. Heat exchanger performance is reflected through a coefficient for heat transfer calculated by the following equation (where a coefficient of 1 is equal to 100% efficiency):

$$HEC = (TBI - TBO)/(TWI - TBO)$$

where HEC = heat exchanger coefficient, TBI = temperature of blood inlet, TBO = temperature of blood outlet, and TWI = temperature of water inlet. The heat exchange coefficient can be calculated for various devices over steady-state conditions, which would provide comparative analysis data on heat exchanger efficiency.

Cooler/Heater Units

Cooler/heater units consist of a system that provides a thermoregulated water supply and can circulate water between 4^0 to 42^0C to the heater exchanger through a ½ -inch internal diameter water tube. The method of water delivery is a critical feature of these devices. Some systems pump water out to the heat exchanger, whereas others pull water from the cooler/heater's reservoir through the heat exchanger. The latter design is preferable in that the pressure on the water side of the oxygenator heat exchanger will then always be lower than the pressure in blood side. Should a leak be present in the oxygenator, the leak will likely be a blood-to-water leak instead of a water-to-blood leak, the latter of which would result in contamination of the patient's circulation with water and crenation and hemolysis of RBCs.[168]

Careful maintenance of the cooler/heater is critical. There have been numerous reports of mycobacterium contamination from cooler/heater unit water supplied to the oxygenator heat exchanger or to the cardioplegia delivery heat exchanger, resulting in endocarditis or death.[170–172] Mycobacterium has been detected in the water systems of cooler/heaters and in OR air samples dispersed by the air circulation from the cooling system compressor.[172] These systems require frequent maintenance, including drainage of the water supply and sanitation of the internal pump, conduits, and internal surfaces of the water tank to prevent microbial growth. Manufacturers instructions must be strictly followed to reduce patient risk.

Arterial Line Filters

Arterial line filters significantly reduce the load of gaseous and particulate emboli and should be used in CPB circuits[173,174] (Fig. 32.22). Some studies suggest that 20-µm screen filtration is superior to 40-µm filtration in the reduction of cerebral embolic counts.[174] A dose-response relation between GME and subtle neurologic injury has been reported, and some studies have demonstrated a protective effect of arterial line filtration on neurologic outcomes.[175–177] Whitaker and Stanton's[178] clinical trial showed that the use of a leukocyte-depleting arterial line filter reduced cerebral embolic count and demonstrated a trend (not statistically significant) toward improved postoperative psychometric test scores. The GME separation performance of 10 different arterial line filters in clinical use was recently evaluated.[179] All were found to be moderately effective, and rated pore size did not predict performance. A systematic review of the data related to arterial line filtration reported that the level of evidence supporting this practice was high (class I level of evidence A).[180] Filter design has been of two principal types: microporous screen filters and depth filters composed of dense fiber material packed in a polycarbonate housing patented by Swank. Screen filters are the predominant type in current use. Screen filters trap particulate and gaseous emboli that are of larger diameter than their effective pore size. The filter material is accordion pleated to provide a larger surface area within a lower prime housing. Two contemporary filter designs consist of a larger flat screen surface that is located concentrically around the oxygenator fiber bundle. The Terumo F series filter incorporates the screen material concentrically surrounding the fiber bundle. This design reduces CPB circuit prime volume because the filter media is incorporated into the oxygenator housing, eliminating the prime volume of the separate arterial filter housing.[181] Preston and colleagues[182] found that the F05 series oxygenator released more emboli than a similar model oxygenator used in combination with a separate 32-µm arterial filter, although the difference was not statistically significant. Sorin Group has incorporated a concentric filter design that surrounds the fiber bundle. The screen forms an envelope around the fiber bundle (see Fig. 32.16). This design does not effectively reduce prime volume; however, the larger housing provides an effective bubble trap (Box 32.6).

BOX 32.6 ARTERIAL LINE FILTERS

- Have been shown to reduce the rate of neurocognitive dysfunction.
- Reduce the load of gaseous and particulate microemboli to the patient.
- Typical pore size ranges between 20 and 40 µm.
- There is a trend towards integration of the arterial filter into the oxygenator.

Cannulae and Tubing

The major devices of CPB are those that replace the systems from which the heart-lung machine has derived its name. However, as with most technologic advances, it is the combination of all component parts that function to ensure success. Besides the pump and oxygenator, a seamless array of tubing is required to connect the patient to the heart-lung machine. Monitoring lines are necessary not only to ensure patient hemodynamic management but also to assess the proper function of the pump. Manufacturers of tubing and circuit packs can attest to the large number of variations in combinations and configurations of circuit assemblies requested by different institutions, as well as by individual clinicians within the same institution. The following discussion of an "ideal" tubing circuit has been generated

from the experiences of the authors and may differ somewhat among cardiac centers (Fig. 32.23).

The majority of cardiac procedures using CPB through a median sternotomy are performed with venous cannulation of the right atrium (RA) and arterial return into the ascending aorta. Numerous cannulae are available for all types of cardiac surgery, which may reflect the developmental philosophy that if a vessel could conceivably be perfused or drained, then a cannula could be made to facilitate insertion. The key principles of cannulae design include minimizing turbulence, reducing cannulae exit velocity, and avoiding areas of stagnant flow so that blood trauma and thrombus formation are minimal (Fig. 32.24). In the past, cannulae were constructed of stainless steel or tapered polyvinylchloride. Subsequently, thin-walled stainless steel was used to increase effective orifice diameter and reduce cannulae pressure drop across the cannulae. Currently, most cannulae are fabricated from polyvinylchloride with composite polycarbonate thin-walled tips. The ends of the cannulae are formed to permit easy vascular entry while maintaining maximum lumen (caliber) size. According to Poiseuille mechanics, the greatest resistance, measured as pressure drop in a circuit, is found at the smallest opening for fluid flow and has an inverse exponential relation to the fourth power of the radius of the lumen. Therefore to reduce pressure drops across the circuit, cannulae are selected to facilitate the greatest flow with the least injury to the vessel because of mechanical abrasion. Several arterial cannulae designs have incorporated multiple openings and dispersion tips to reduce velocity at the tip of the cannulae and reduce the likelihood of disruption of atheromatous debris from the intimal surface of the aorta.[183,184] Most cannulae have a wire reinforcement body to prevent kinking when the cannula is curved to accommodate placement in the surgical field and to maintain cannula rigidity. Several new designs of venous cannulas have recently emerged that incorporate a malleable, wire-reinforced backbone to allow for bending of the catheter without kinking the lumen. Cannulae could then be positioned out of the surgical field to provide an unobstructed view for the surgeon. Although cannulation of the ascending aorta is preferred for most procedures, femoral arterial cannulation often is selected for reoperations or minimally invasive surgical procedures (Fig. 32.25). The axillary or subclavian artery often is selected for arterial return for patients with severe atherosclerosis of the ascending aorta. This site offers the advantage of providing antegrade flow to the arch vessels, protection of the arm and hand, and avoidance of inadvertent cannulation of the false lumen in cases in which type A aortic dissection has occurred. The axillary artery is accessed through a subclavicular incision.[185] Although the vessel may be cannulated directly with a long thin-walled 7- or 8-mm cannula, the most reported technique is to sew a 10- or 12-mm Dacron graft to the right axillary artery and insert a 20- to 24-Fr cannula directly into the lumen of the graft. Alternatively, the arterial tubing line can be connected directly to the Dacron graft with the aid of a tubing connector. This technique provides uninterrupted flow to the right arm and hand. Transapical aortic cannulation through a 1-cm incision on the anterior wall of the left ventricle also has been described for patients with type A dissection. A 7.0-mm aortic cannula may be placed into the left ventricle and advanced across the aortic valve (Box 32.7).

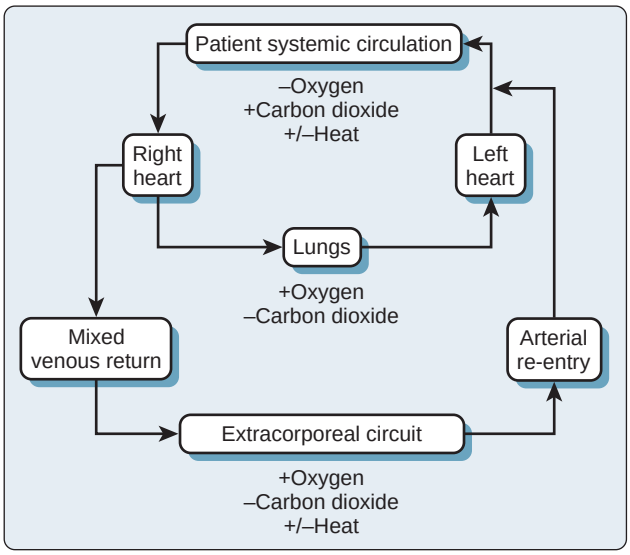

Fig. 32.23 Schematic of an "ideal" tubing circuit used during extracorporeal circulation.

Venous cannulae come in two broad classifications: single or dual stage. Single-stage cannulae are used during most open-heart situations, in which either bicaval cannulation or femoral cannulation will be performed, whereas dual-stage cannulae are used for most closed-heart procedures, in which a single cannula is placed into the RA.

Although both silicone (Silastic) and polyurethane tubing have been used in extracorporeal circuits, plasticized polyvinylchloride is exclusively used in CPB circuits. Plasticizers impart flexibility into tubing and account for as much as 40% of the polymer. The most commonly used plasticizer for medical-grade tubing is DEHP. There is growing concern about the migration (leaching) of DEHP from tubing into the blood because DEHP has been shown to cause inflammation and is potentially a carcinogen and a toxic agent.[186–189] Numerous studies since the 1970s have shown that DEHP and its metabolites are present in blood products[190–193] and tissues,[194,195] as well as intravenous solutions[196] and pharmaceuticals.[197] Recently, the release properties of various plasticized polyvinylchloride tubing exposed to electrolyte solutions for up to 28 days were evaluated. Tubing formulations with one DOA stored in 0.9% sodium chloride solution had significantly

BOX 32.7 ARTERIAL CANNULAE

- The arterial cannulae tip is the point of highest blood flow velocity in the cardiopulmonary bypass circuit.
- Some arterial cannulae have flow-dispersing tips to reduce exit velocity and reduce the risk for atheroma dislodgement from the wall of the aorta.
- Cannula placement should be assessed by a test infusion from the pump and observation of a pulsatile pressure excursion.

less leaching than either DEHP plasticizer or tri(2-ethylhexyl) trimellitate (TOTM). Currently, tubing pack manufacturers are able to offer select sizes and durometer tubing without DEHP additives. However, because removing DEHP reduces the overall durability of the tubing, high-pressure segments of the CPB circuit, such as the roller head raceways, would still require this additive. Several published laboratory studies suggest that the use of covalently bonded heparin coatings significantly reduces the leaching of DEHP from the tubing into the circulation.[198,199]

Blood flows out of the RA cannula and into the venous reservoir when CPB is initiated. The venous line connects the cannula to the venous reservoir. Mixed venous oxygen saturation is measured by optical or chemical fluorescence by flow through cells placed in the venous line. A stopcock is placed in the venous line to facilitate the delivery of medications and for venous sampling. Blood then enters the venous reservoir, which serves as a volume chamber for settling and acts as a safety feature, providing additional response time to the perfusionist. Venous reservoirs come in two broad categories: hard shell (see Fig. 32.16) and soft shell (see Fig. 32.17), terms that refer to the rigidity of the device and its ability to collapse on itself. Hard-shell reservoirs are open to the atmosphere (open systems) through a ventilation port on top of the reservoir and are effective in handling gross quantities of air that may return through the venous or cardiotomy line.[200] Most hard-shell reservoirs include a positive pressure relief valve that prevents overpressurization during patient support. An external vacuum source can also be applied to the ventilation port at the top of the hard-shell reservoir to use VAVD. In VAVD, gravity drainage is improved by connecting a vacuum source to the venous

reservoir.[201] Soft-shell reservoirs are called *closed systems* and will collapse on themselves with the inadvertent emptying of the reservoir. The venous reservoir also has an inlet line that drains blood from a cardiotomy reservoir.

A cardiotomy reservoir is simply a second chamber used for collecting and filtering blood aspirated from the surgical field via suction lines. Vented blood from the left ventricle, pulmonary artery, or aortic root also is returned to the venous reservoir through the cardiotomy device. These are hard-shell devices made of polycarbonate housing material with polyurethane and polyester filters and defoamers to reduce the risk for gas embolism into the venous reservoir. Some venous reservoirs also serve as integral cardiotomy reservoirs, obviating the need for a separate unit.

From the venous reservoir, blood is pumped into the heat exchanger of a membrane oxygenator by the actions of the arterial pump. The heat exchanger is connected to an external water source that maintains the perfusate temperature according to the temperature of the water pumped from the cooler/heater. The heat exchanger housing is typically composed of stainless steel, PPL, or aluminum alloy and uses a counter-current water/blood mechanism for indirect thermal conduction. Blood then passes directly to the oxygenator, where gas exchange occurs in accordance with the operation of a gas blender that controls the FIO_2 by mixing oxygen with medical-grade air, along with a flowmeter that regulates the ventilation rate. The gas blender is attached to the inlet gas port of the oxygenator via a section of 1/4-inch tubing and a bacteriostatic (0.2-μm) filter. Gas exchange across the blood and gas phases of the fiber occurs through the process of simple diffusion. Levels of high gas molecule concentration are permitted to diffuse through tiny slit pores of the oxygenator fiber strands to lower levels of gas concentration. During CPB support, this typically results in the addition of O_2 to the blood phase and the uptake of CO_2 to the gas phase. Many circuits also have a vaporizer for the delivery of volatile, inhaled anesthetic gases placed in-line between the gas blender and the oxygenator.

The oxygenator has two ports on the outflow side by which arterialized blood is accessed: a recirculation port and an arterial outlet port. The recirculation port is used both to provide a safety line for relieving overpressurization and to facilitate easy replacement in the event of device failure. It also is used as an exit port of arterialized blood for sanguineous cardioplegia or in the separate perfusion of a second arterial cannula. In traditional CPB circuits, arterial blood would leave the oxygenator outlet port and flow to the arterial line filter. However, the use of integrated oxygenators has become more common in CPB circuits. An integrated oxygenator incorporates the oxygenator bundle and arterial filter units together in one apparatus (CAPIO FX; Terumo Cardiovascular Group, Ann Arbor, MI [see Fig. 32.13] and Inspire; Sorin Group, Arvada, CO [see Fig. 32.16]). By incorporating both components together, the use of most integrated oxygenators results in a significant decrease in foreign surface area and resultant prime volume. The arterial filter is a screen device constructed of synthetic material, with a specific pore size effectively blocking particles greater in size than the rating of the filter (20 and 40 μm). Microembolic particles originate from many sources in the extracorporeal circuit, including the BGED, tubing, and heat exchanger, and include various substances including polycarbonate, filter material fibers, silicone, and polyvinylchloride particles.[202,203] Although there is considerable variability in terms of where arterial line pressure is monitored, the most common access point is located between the outlet port of the oxygenator and the arterial line filter.[204] An arterial monitoring device can be placed in-line to reflect arterial oxygen saturations and as a trending device for pH, PaO_2, and $PaCO_2$. Just distal to the arterial line filter is a bubble detector that is an essential feature for the conduct of safe perfusion. This device is controlled by a microprocessor and is used to detect microgaseous and macrogaseous emboli. This is the last safety feature in the line before blood returns to the patient through the arterial cannula. When the ascending aorta is the site for arterial perfusion, an aortic cannula is placed through a purse-string suture with positioning of the cannula tip so that flow is directed cephalad toward the brachiocephalic vessels. The location of the aortic cannula and the direction of arterial blood flow emphasize the importance of assuring safe, continuous flow of filtered perfusate devoid of embolic particles.

Cardioplegia Delivery

In the previous section, the main tubing circuit for CPB was described and the devices for bypassing the pulmonary and systemic circulation were identified. Methods of decoupling electromechanical function of the heart have been developed to achieve a safe surgical field during cardiac surgery. During aortic cross-clamping, the heart is rendered globally ischemic by the cessation of coronary blood flow. Some myocardial perfusion undoubtedly occurs through the involvement of noncoronary collateral circulation from mediastinal sources and the bronchial circulation. There are numerous methods of achieving mechanical arrest, and the combination of these techniques is referred to as *myocardial preservation*. Myocardial preservation encompasses both the pharmacologic manipulation of the solutions (cardioplegia) used to protect the heart and methods of mechanical delivery. Potassium-containing solutions arrest the cardiac muscle in a depolarized state by disruption of the myocardial action potential. Other solutions containing lidocaine and magnesium, such as del Nido and custodial cardioplegia solutions, arrest the heart in a polarized state by blocking the calcium channels. This section is devoted to methods of cardioplegia delivery to provide myocardial protection.

Melrose and colleagues[205] were the first to describe chemical arrest of the heart with potassium citrate solution. The arresting solution was delivered with a syringe directly into the aortic root after the application of the aortic cross-clamp.[205] Similarly, others described delivery of various formulations of arresting solutions contained in collapsible intravenous bags using a sterile intravenous tubing set that was passed off the surgical field and attached to an inflatable infusion pump bag. This system was replaced by the use of recirculating circuits where the cardioplegia solution was recirculated in a system that consisted of a polycarbonate-filtered reservoir and cooling of tubing that was placed in a bucket of ice (Fig. 32.26). These recirculating systems provided filtration of the solution and improved control of delivery pressure and temperature. A single-pass system for delivery of blood cardioplegia in a predetermined ratio, which subsequently became the most widely used cardioplegia delivery system, was described in 1978 by Buckberg and colleagues[206,207] (Fig. 32.27). The ratio of blood to cardioplegia could be adjusted by changing the internal diameter of the tubing in the custom delivery set. The blood and crystalloid components were delivered to a miniaturized heat exchanger bubble trap before delivery at the surgical field. With this system, the temperature of the cardioplegia could be regulated from 4°C to 37°C with the use of a cooler/heater device. Menasché[208] described a microplegia system in which arresting additives are added directly to tepid blood from the CPB circuit with a standard infusion pump to arrest the heart. This greatly decreased the volume of crystalloid solutions delivered in a typical CPB procedure and avoided the detrimental consequences of volume overload and subsequent hemodilution. The authors also cited a few particular advantages of minicardioplegia, including improved oxygenation and improved control of blood volume, not to mention reduced cost.

Adjunct means of cooling and protecting the myocardium during aortic cross-clamping include the use of topical application of cold solutions to prevent early transmural myocardial rewarming. A common method for cooling the myocardium is achieved by the surgeon creating a "pericardial well" in the chest by suspending the pericardium with stay sutures to the chest retractor. Cold (4°C) topical saline solution is then applied to the pericardium, bathing the heart in cold solution while a sucker line is placed in the well to evacuate the saline solution. Topical saline has been shown to cool the epicardium and diminish transmural gradients,[209,210] but it also has resulted in phrenic nerve paresis and myocardial damage.[211,212] An alternate technique involves a topical cooling device, which consists of a coolant flow pad in which

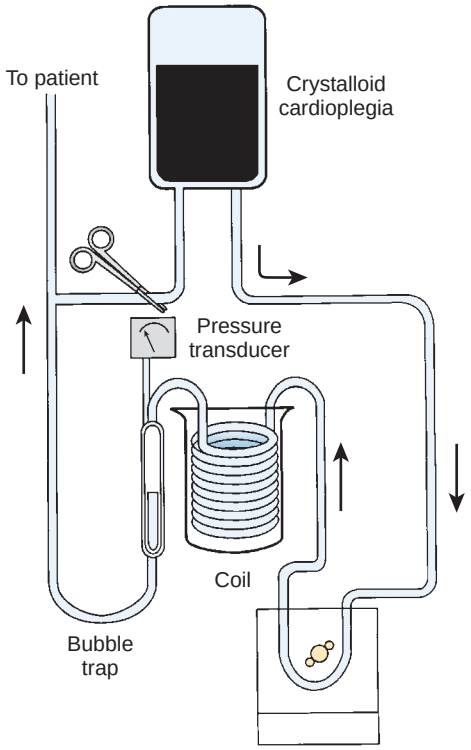

Fig. 32.26 Coil-type cardioplegia delivery system. This can be used for sanguineous or asanguineous cardioplegia solution.

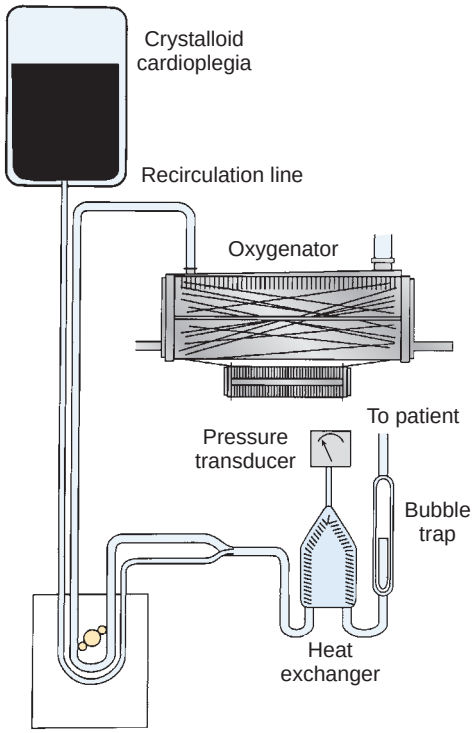

Fig. 32.27 Nonrecirculating cardioplegia delivery system for use in blood to crystalloid mixed solutions of various ratios (1:1, 4:1, or 8:1 crystalloid to blood).

cold (4°C) saline flows, separated from the body by a metal skeleton and polyurethane insulator, which protects the posterior mediastinum and phrenic nerve from hypothermic injury.[213] The benefits of a topical cooling device over topical cold saline include a reduction in total hemodilution, procurement of a drier operative field, reduced blood loss in waste suction, and more uniform distribution of cooling.[213–215] However, these devices are costly, require a separate RP for delivery, and may not be applicable for all procedures in which the heart will be lifted and elevated away from the posterior pericardium.

Disposable Cardioplegia Circuits

All cardioplegia delivery systems consist of two distinct components classified as either disposable or nondisposable devices.[216] Effective myocardial protection is ensured only through the precise interface of both disposable and nondisposable components of the cardioplegia delivery system, which function to ensure safe, precise, and accurate administration of cardioplegic solutions. The disposable items that make up a standard cardioplegic circuit consist of three basic parts: a heat exchanger, a bubble trap with an incorporated filter, and various delivery cannulae. The disposable devices are used on a single-use basis and, because of their consumptive nature, represent the most significant cost associated with mechanical myocardial protection.

Early methods of cardioplegia delivery consisted of infusions of pharmacologic agents directly into the aortic root, or left ventricle, via handheld syringes. Unfortunately, such methods caused a heterogenous distribution of solution and led to the need for more precise delivery techniques. Many clinicians turned to a pressurized bag method in which a bag of crystalloid solution was placed in a pressure bag and cardioplegia was infused at a semicontrolled rate dependent on the degree of pressure and the bore of the cardioplegic needle.[217,218] Although the results were better than those previously obtained, there was a profound lack of safety features such as pressure monitoring and control systems, as well as inadequate air-handling capacity and a lack of temperature control. Vertrees and colleagues[219] described a simple circuit that used a coronary perfusion reservoir, a coil submerged in iced water, and an RP. This system was a significant improvement over previous techniques insomuch because it included a means to trap air and to measure pressure within the circuit.

There are two major disposable circuit configurations for cardioplegia delivery: a recirculating system with a coil (polyvinylchloride or stainless steel heat exchanger) for asanguineous delivery and a sanguineous cardioplegia system for nonrecirculating delivery. In asanguineous systems, crystalloid cardioplegic solution is kept constantly recirculating throughout the cardioplegia circuit and is delivered to the patient by the movement of a clamp, directing flow away from the recirculation line and into the infusion line.[219a,220] These systems generally are the most economic in that they incorporate a coil of polyvinylchloride tubing as the heat-exchanging element, obviating the need for both a metal transfer unit and a separate cooler/heater device to regulate the temperature of the cardioplegic solution. Instead, the coil sits in a container filled with ice. The heat-exchange efficiency of coil systems has been shown to be superior to that of metal units in single-pass trials. These systems also can be used for sanguineous cardioplegia with minor adaptations to the circuit. However, with the increased use of warm sanguineous cardioplegia and the administration of warm reperfusate at the end of aortic cross-clamping, these units are not ideally suitable because of their inability to accurately control delivery temperatures.

Another type of cardioplegia delivery system is termed a *blood cardioplegia system,* which involves the shunting of arterialized blood from the oxygenator into the cardioplegia circuit, where it is mixed with a crystalloid base solution, usually of high potassium concentration, before it is delivered into the coronary circulation. The most frequently used port for obtaining saturated blood from the oxygenator is the recirculation port, although some institutions directly shunt blood from the arterial line filter. Most sanguineous cardioplegia systems are nonrecirculating and only make a single pass through a heat exchanger

before passing to the heart. For this reason, these systems must have a high efficiency rating for caloric exchange between the cardioplegic solution and the cooling, or warming, source. These devices can deliver varying ratios of blood-to-crystalloid base, ranging from a 1:1 to a 1:20 ratio of crystalloid to blood. Most are equipped with temperature monitoring ports and pressure-measuring sites to monitor delivery pressures. Cleveland Clinic has reported on a single-delivery system that can be easily adapted for delivery of 4:1 blood cardioplegia or del Nido 1:4 cardioplegia solution (Figs. 32.28 and 32.29). An important consideration of sanguineous cardioplegia delivery systems is that the main arterial pump can never be turned lower than the flow rate of the cardioplegic solution pump (ie, delivering a higher volume of cardioplegic solution to the circuit than is flowing to the patient). If this were to occur, excessive negative pressures would be created in the recirculation line from the oxygenator, increasing the risk for cavitation (outgassing of solution).

Cardioplegic Delivery Catheters

Antegrade Aortic Root Cardioplegia

The delivery of cardioplegia is made possible through special cannulae that are placed within the ascending aorta or directly into the coronary ostia. These have been specifically designed to minimize pressure drop across the tip of the cannula, which has a relatively small bore (12 to 18 gauge). When cardioplegia is administered into the aorta, it is termed *antegrade cardioplegia*. The most common flow rates achieved in adult cardiac surgery are between 200 and 300 mL/min, with corresponding aortic root pressures usually between 60 and 100 mm Hg. In addition, the cardioplegic needle can be used as a "vent" by which residual air in the aortic root is removed by connecting the needle either to an RP or siphon drain. The final point of attachment is the cardiotomy reservoir.

The distribution of cardioplegia to the myocardium with antegrade cardioplegia techniques is hindered in patients with atherosclerotic lesions, where distal perfusion is lost because of vascular obstruction. Furthermore, impaired delivery of cardioplegia may occur because of the retrograde escape of cardioplegia across the aortic valve. This commonly occurs if the patient has aortic insufficiency. However, it may occur in patients with a competent aortic valve that becomes distorted by the placement of the aortic cross-clamp.[220a] Some antegrade cardioplegia cannulae have an integrated pressure monitoring lumen that allows measurement and display of the antegrade cardioplegia infusion pressure. It also is common to measure the cardioplegia delivery system pressure from a site distal to the cardioplegia delivery pump. A high system pressure alerts the team to an obstruction or malplacement

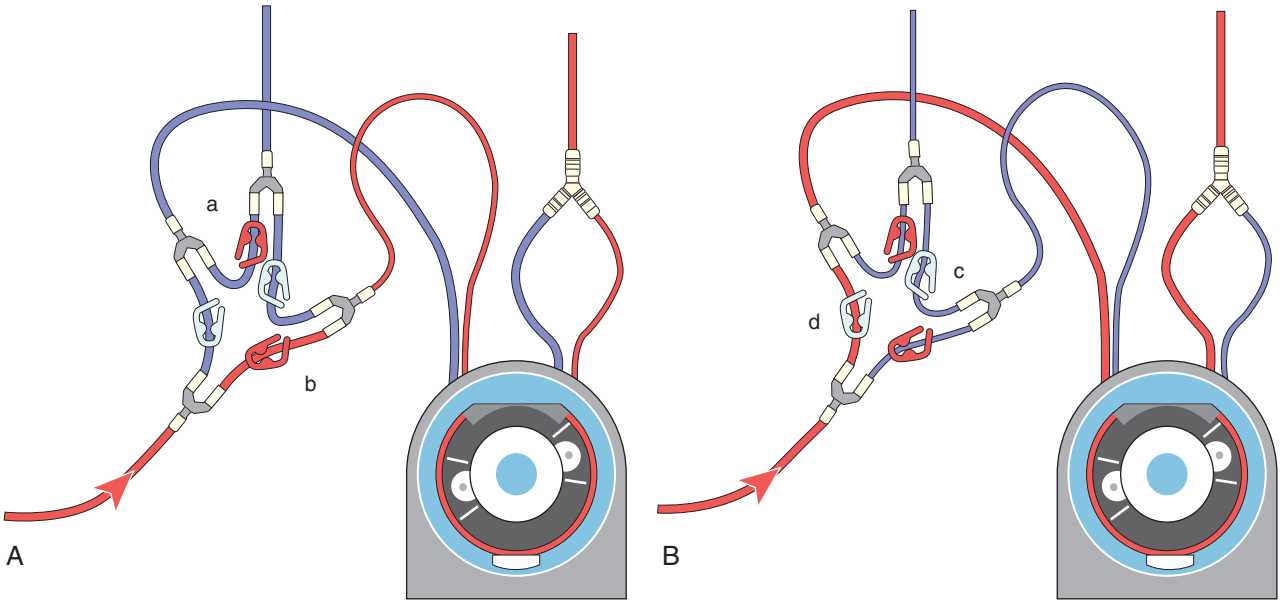

Fig. 32.29 Cleveland Clinic dual cardioplegia circuit changing from Buckberg to del Nido. (A) A set of Robert clamps (*[a]* and *[b]*) is open for del Nido cardioplegia delivery. Clamp *(a)* is open and del Nido cardioplegia is delivered through a 1/4 line. Clamp *(b)* is open and blood is delivered through a 3/16 line (blood : crystalloid ratio is 1 : 4). (B) A set of Robert clamps (*[c]* and *[d]*) is open for the Buckberg cardioplegia delivery. Clamp *(c)* is open and Buckberg cardioplegia is delivered through a 3/16 line. Clamp *(d)* is open and blood is delivered through a 1/4 line (blood : crystalloid ratio is 4 : 1). *(Reprinted with permission Kim K, Ball C, Grady P, Mick, S. Use of del Nido cardioplegia for adult cardiac surgery at the Cleveland Clinic: perfusion implications.* J Extra Corp Tech. *2014;46[4]:317–323.)*

of the cardioplegia delivery cannula. A low system pressure would occur from aortic insufficiency or from some breach of the delivery system. Conditions such as aneurysmal deformation of the ascending aorta and aortic valvular lesions both compromise the delivery of cardioplegia when administered via the antegrade direction. This concern has led to the search for alternative administration techniques for cardioplegic delivery.

Retrograde Coronary Sinus Cardioplegia

Retrograde delivery of blood to the heart via the coronary sinus and venous circulation was first proposed by C. Walton Lillehei. In 1982, Menasche and colleagues[221] revisited the application of retrograde coronary sinus cardioplegia (RCSC), and with this technique they found superior maintenance of left ventricular function when compared with direct coronary artery perfusion in patients with coronary artery disease. Initially, this technique was proposed as a means of delivering cardioplegia as a replacement for direct coronary artery cannulation in procedures involving the aortic valve or root. However, the utility of RCSC quickly expanded as a means of delivering nutritive flow to the distal myocardium in patients with severe coronary artery disease.[222,223] The delivery of RCSC, provided catheter position in the sinus and seal of the sinus by the balloon are optimal, results in a more uniform distribution of cardioplegia than antegrade and causes minimal disturbance of the operative field during administration.

Coronary sinus cardioplegia cannulae come in numerous configurations varying in catheter size, balloon configuration, stylet characteristics, and inflation mode (Fig. 32.30). Various cannula designs are available incorporating geometric design to promote better fit into the sinus. The terminal end of the cannula is fitted with a balloon, which serves the function of seating the cannula in the coronary sinus so that cardioplegia is delivered into the coronary venous system, minimizing the amount of cardioplegia leakage into the RA. Some have textured balloon surfaces to minimize dislodgement of the catheter from the coronary sinus but result in leakage of the cardioplegia solution into the RA. Some designs have balloons that automatically inflate when flow is initiated through the catheter. Others require manual filling

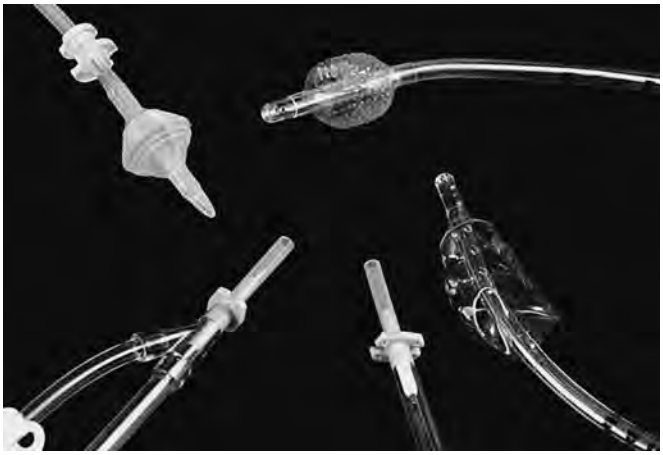

Fig. 32.30 Antegrade and retrograde cardioplegia cannulae.

of the balloon with a syringe. In an animal model, Menasche and colleagues[224] have shown that autoinflated retrograde catheters leak as much as 22% of cardioplegic flow, whereas manually inflated catheters had a leakage rate less than 1%. Several authors have described the efficacy of combining both antegrade and retrograde cardioplegic delivery methods in a single integrated system.[225,226] These authors believe that the delivery of both antegrade and retrograde cardioplegia concomitantly supplies better perfusion to all regions of the myocardium despite the degree of coronary occlusive disease. Drainage is ensured through both thebesian and arteriosinusoidal vessels. Ihnken and colleagues[227] found in a large series of high-risk patients (New York Heart Association class III and IV) that simultaneous delivery of warm cardioplegia directly into the bypass grafts and the coronary sinus was both safe and efficacious in ensuring myocardial protection. A major disadvantage of this multisite simultaneous delivery method is that

most of the flow will be directed down the path of least resistance and not necessarily uniformly to all segments of the heart muscle.

Despite the excellent results achieved with RCSC, complications resulting from cannulation and excessive pressurization of the coronary sinus occasionally are reported. These include rupture of the coronary sinus, poor perfusion of the right ventricle and posterior septum, and nonhomogenous flow patterns.[228,229] In addition, controversy exists concerning the optimal delivery flow rate of RCSC. In one study of 62 patients, retrograde flow rates less than 100 mL/min resulted in reduced coronary venous effluent pH, with the authors recommending that maintenance of a minimum flow rate of 200 mL/min be considered whenever RCSC is used.[230] The optimal delivery pressure also is controversial. Most centers use a guideline of 20 to 40 mm Hg pressure measured in the delivery catheter at a point distal to the balloon. It has been suggested by one researcher that pressures as high as 50 mm Hg are safe.[231]

Cardioplegia Delivery Systems

The currently used nondisposable devices consist of two major components: the mechanical pump and the temperature control unit. The PD twin RP is the most commonly used mechanical pump for cardioplegia. The temperature control module also is termed a *cooler/heater* and serves the function of the caloric transfer of heat by convective means between the circulating water of the cooler/heater and the cardioplegic perfusate.

Historically, commercial delivery systems for blood cardioplegia used a fixed-ratio delivery system of blood-to-crystalloid components. Cardioplegia solution mixing was achieved via a two-line RP system that combined arterialized blood and a crystalloid base solution on the distal side of the occlusive pump in a dual-lumen outlet. The ratio of blood to crystalloid was determined by the lumen size of the tubing within the raceway of the pump. Although these systems are considered as industry standards, they offered little flexibility in altering the ratio of blood or crystalloid components, and the only means of changing ionic or substrate concentration was to make up several base crystalloid bags that contained varying concentrations of solute. Several devices address these shortcomings: the Jostra HL20 Hl30 systems, the Sorin Group S-3 and S-5 Console (Sorin Group, Irvine, CA), Terumo System 1 (Terumo Cardiovascular Group, Tustin, CA), and the Myocardial Protection System (MPS; Quest Medical, Allen, TX).

The Sorin Group S-3 and S-5 heart-lung machines have an integrated cardioplegia delivery system that consists of twin RPs, monitoring and control systems, and an internal cooler/heater for temperature regulation. Two 3-inch RPs are used, containing hybrid direct-drive systems with optical encoders, which permit accurate solution delivery at low-flow delivery rates. The two-RP system was designed to allow the user to select variable ratios of blood-to-crystalloid solutions. Available ratios include 1:1 through 16:1, all blood, and all crystalloid. The system may be stop-linked to a pressure monitor, bubble detector, or to the arterial pump. The system has temperature monitors, automatic dose and ischemic time interval timers, and displays of infused blood, crystalloid, and cardioplegic solution volumes.

The Quest MPS consists of a microprocessor-controlled electromechanical instrument and disposable delivery set that is integral to the device (Fig. 32.31). There is a main pumping mechanism and a pumping subsystem that operates by a set of four pistons, each driven by a stepper motor, that align with several pouches in the disposable cartridge to mechanically displace the pouch contents. The subsystem pouches contain an arresting agent and one additional additive if required. The main pumping mechanism consists of two motor-driven piston pumps and valved pouches that alternately fill and pump extracorporealized blood and crystalloid solutions, providing constant cardioplegia flow. A number of sensors become activated when the cartridge is placed into the console, and the system software completes a series of self-checks before operation. The cardioplegic solution passes through a stainless-steel heat exchanger, which controls the caloric transfer of heat in congruence with the integral cooler/heater. There

Fig. 32.31 Quest Myocardial Protection System (MPS). Cardioplegia is pumped by a system actuated by a stepper motor. Arrest solution and additive solutions are contained in 50-mL pouches and may be precisely added to the delivery solution. The disposable heat exchanger component is attached to the top of the console. The MPS has system and delivery pressure sensors, as well as an air detection and elimination system. Blood-to-crystalloid ratio, temperature, and additive drug concentrations may be adjusted in real time during delivery. *(Courtesy Quest Medical, Allen, TX.)*

are four temperature sensors to provide temperature-controlled cardioplegia delivery, and the inlet water and cardioplegia temperatures are continuously displayed.

The MPS provides the selection of variable blood-to-crystalloid ratios that range from 1:1 to 20:1, as well as the capability to deliver all blood or all crystalloid solutions. However, the MPS allows variable ratio control, which is accomplished without changing the arresting agent concentration. This independent control of cardioplegic additive and total blood delivery is an attractive feature when optimizing oxygen-carrying capacity and enhancing aerobiosis, while ensuring chemical arrest. Likewise, the MPS allows the user to change the arresting agent concentration without altering the ratio of blood to crystalloid solution. The MPS has an auto-flow mode that will vary infusion flow to maintain a set delivery pressure. The MPS is capable of pulsatile cardioplegia delivery, although few studies have demonstrated the efficacy of this delivery feature.

The Heart-Lung Machine Priming Solutions

Before ECC can be attempted, the patient must be connected to the CPB machine, necessitating the creation of a fluid-filled circuit to ensure continuity with the patient. Not only is it important that the circuit be "primed," but it also must be completely devoid of any gaseous bubbles or particulate matter that potentially could embolize. For this reason, perfusionists often perform painstaking maneuvers to rid the circuit of bubbles before bypass. Historically, early priming solutions were formulated to closely match the patient's own rheologic characteristics, which necessitated the use of fresh whole blood.[232] Priming the early oxygenating circuits required vast quantities of blood and balanced electrolyte solutions, and cardiac operations often were scheduled around the availability of blood donors. Eight to 10 units of

heparinized blood were required to prime the average CPB circuit,[233] and the risk for contracting viral hepatitis was substantial. The addition of blood to priming solutions also induced the capillary leak syndrome,[234] which may implicate histamine as a contributing factor in leading to postpump pulmonary dysfunction. As a result of the excellent work on hemodilution by Messmer and colleagues,[235,236] as well as others,[237] it is now the rare adult patient who receives any blood in the circuit before the initiation of CPB. Instead, balanced electrolyte solutions are the first choice in priming bypass circuits. In pediatric circuits, however, where the circuit volume often exceeds the patient's circulating blood volume, allogeneic blood products often are added to the prime to reduce the risk for anemia and hypoproteinemia (see Chapters 31, 34, and 35).

When nonhemic primes are used during CPB, a concomitant reduction in SVR occurs at the onset of ECC as a result of the reduced viscosity of the blood.[238] Although the oxygen-carrying capacity of the pump perfusate is reduced by hemodilution, overall oxygen delivery may not be significantly affected because the reduced viscosity enhances perfusion. Safe levels of hemodilution are dependent on multiple factors that include the patient's metabolic rate, cardiovascular function and reserve, degree of atherosclerotic disease and resultant tissue perfusion, and core temperature. Although an absolute value for the degree of hemodilution tolerated will vary among individual patients, the studies of Kessler and Messmer supported a minimal hematocrit value of 20% to ensure oxygen delivery and tissue extraction.[239,240] More recently, several large retrospective studies have described a trend towards increased morbidity and mortality with nadir hematocrits less than 23%.[241–243] Moreover, postoperative complications from anemia were compounded in patients who were transfused with homologous RBCs.[244] Progress continues to be made in better understanding absolute tolerances of hemodilution through treating patients of certain religious groups who refuse the transfusion of allogeneic blood products.[245–247]

For years controversy has raged over the inclusion of colloids in pump primes, with specific emphasis placed on the value of albumin as a routine prime constituent.[248,249] The nonphysiologic effects of CPB, with both nonpulsatile and pulsatile perfusion, are known to alter various hemodynamic and physiologic forces affecting the extravascularization of plasma water, especially in the lungs, which leads to respiratory dysfunction.[250] Total body water is increased after CPB, leading to tissue edema and altered organ function.[251] Total body fluid shifts may take several days after CPB to correct because of the degree of hypotonicity created during bypass.[252] Although the pathophysiology related to tissue edema is appreciated, the influence of factors such as total bypass time and pressure gradients during CPB remains to be elucidated. Priming of the CPB circuit with crystalloid solutions alone reduces colloid oncotic pressure, and this reduction is directly related to the total volume of prime solution and the overall level of hemodilution. Hypo-oncotic primes promote tissue edema through interstitial expansion with plasma water.[248] A significant decline in plasma albumin occurs after CPB in patients who have been exposed to crystalloid-only primes.[253] Albumin and various high-molecular-weight colloid solutions are added by some groups to the prime to offset these changes, although the benefits associated with each practice remain controversial.[254]

Both high- and low-molecular-weight hydroxyethyl starch (HES), synthetic colloids that are derived from amylopectin, have been previously used as volume-expanding adjuncts to crystalloid primes.[255,256] HES is a colloid oncotic increasing agent that has colloidal properties similar to that of 5% albumin and is relatively inexpensive.[257] However, recent evidence in critical care arenas suggest that these synthetic colloids may be harmful in some patients.[258] In 2012, a metaanalysis conducted by Navickis and colleagues concluded that the use of HES significantly increased postoperative blood loss, reoperation for bleeding, and homologous blood transfusions when compared with albumin fluid replacement therapy.[259] The FDA issued a Safety Communication in 2013 recommending against the use of HES in CPB surgery because of the increased risks of renal injury and excessive bleeding.[260] The use of hypertonic saline solutions (7.2% NaCl) in combination with hetastarch was recently shown to result in better patient hemodynamics with lower fluid requirements during CPB.[261]

The addition of glucose to prime solutions remains an area of controversy because of the relation between high glucose concentrations on CPB and neurologic dysfunction.[262,263] Metz and Keats[264] reported that when glucose was included in prime solutions of 107 patients undergoing CPB, there was a lower fluid balance as evidenced by significant reductions in crystalloid administration and there was no increased neurologic dysfunction. Although there is a paucity of prospective studies on the neurologic outcome of cardiac patients after perioperative glucose administration, evidence exists that glucose administration is associated with greater morbidity after cerebral ischemia.[265,266] The hypothesis for this pathophysiologic phenomenon is related to a shift in glycolysis from aerobic to anaerobic pathways during ischemia, which results in a metabolic end-product accumulation of lactate and decline in intracellular pH.[267] Until further work is done in which tightly controlled preoperative and postoperative neurologic examinations are performed, it may be advantageous to manage glucose conservatively, restricting glucose-containing solutions in cardiac patients.[268] Prolonged periods of perioperative hyperglycemia have also been associated with increases in inflammatory response, renal impairment, infections, and myocardial dysfunction.[269,270] The growing body of evidence advocating for tight glucose management led to the establishment of clinical practice guidelines recommending blood glucose levels to be kept below < 180 g/dL during cardiac surgery.[271]

Marelli and colleagues studied perioperative fluid balance in 100 adult patients divided into two groups who either did or did not receive albumin (50 g) in the bypass prime.[272] They were unable to show any improvement in more than 40 clinical parameters affecting patient outcome when albumin was included in the prime. It is known that, within the first few seconds of CPB, a proteinaceous film is deposited on the surface of all extracorporeal circuit surfaces.[273] Priming the pump circuitry with albumin is thought to decrease the initial adsorption of protein components, which would increase biocompatibility. However, the use of albumin for circuit coating may no longer be efficacious, as commercially available biopassive surface additives can promote CPB biocompatibility. Bonser and colleagues[274] examined complement activation in 36 patients who received priming solutions of either crystalloid, crystalloid plus albumin, or crystalloid plus the plasma expander polygeline. They measured products of both the alternate and common complement pathways and found a significantly greater level of activation in both the crystalloid and crystalloid plus albumin groups when compared with the polygeline patients. A similar study examined both plasma and dextran 70 in priming solutions and their effects on complement activation.[275] When plasma was added to the prime, a significant increase in the plasma concentration of C3 activation products (C3c and C3dg) was observed, which was not present in the dextran 70 group. A study of the effects of postbypass hypoalbuminemia demonstrated that this reduction was well tolerated except in patients with poor left ventricular function.[128]

Further important considerations in choosing a priming solution for CPB circuits include alterations induced by changes in electrolyte activity. Balanced electrolyte solutions are the first-choice base solutions of most prime solution "cocktails" used by perfusionists. Lactated Ringer's solution, Normosol-A, and Plasmalyte are used frequently because of their electrolyte compositions and isotonicity. One potential concern with the latter solutions focuses on the absence of calcium and potential for hypocalcemia. Calcium concentration varies depending on the type of prime constituents, as well as the presence of citrate in allogeneic blood products. Hysing and colleagues[276] reported substantial differences in the calcium concentrations among five different prime solutions throughout the bypass period. They reported an initial decline in ionized calcium with the initiation of CPB followed by a normalization over the first 30 minutes of ECC and emphasized the importance of frequent monitoring of this cation. In pediatric ECC and in certain adult patients who have preoperative deficiencies

in either hemoglobin or coagulation proteins, it may be necessary to prime the heart-lung machine with allogeneic blood products. When calcium-containing prime solutions, such as lactated Ringer's, are used, additional anticoagulation is necessary to prevent circuit thrombus from forming before the initiation of CPB. The most frequently used ratio of heparinization for CPB is 2500 IU of heparin for each liter of prime solution, which would ensure adequate anticoagulation for both sanguineous and asanguineous prime solutions.

Perioperative Methods of Red Blood Cell Conservation

Homologous blood is a precious resource, the transfusion of which confers both benefits and risks. The practice of transfusion began in the 1930s with the Nobel Prize–winning work of Landsteiner.[277] Transfusion medicine expanded through experience gained in battlefield medicine and the development of cardiac surgery, vascular surgery, and oncology. Of the 29 million transfusions administered each year, it is estimated that one-third to one-half are not administered in accordance with evidence-based indications.[278] Cardiac surgery programs are one of the leading consumers of blood and blood products. More than 80% of the blood used in cardiac surgery is transfused in 15% to 20% of the patients undergoing surgery.[279] In the late 1970s and early 1980s, there was concern about transfusion-related hepatitis B and C, HIV, and bacterial infections. With modern blood bank processes and screening, these risks have become extremely low; however, other associated risks, including transfusion-related lung injury, leukocyte-related target organ injury, transfusion errors, and bacterial infections are comparatively common. Furthermore, there is a growing confirmation of the relation between transfusion and reduced short- and long-term survival and increased HF in cardiac surgery patients.[280–286] Transfusion of stored blood and blood products is related to a host of adverse effects, including release of bioactive compounds that cause inflammation, reduced oxygen availability to tissues, and other immunomodulatory effects, all of which contribute to increased morbidity and mortality[287] (see Chapters 34 and 35).

Transfusion practice varies widely, and this variation is based largely on individual physician practice.[288] The administration of allogeneic blood products during cardiac surgery continues to be a major concern for both patients and clinicians. The changing population of patients undergoing cardiac surgery has presented new transfusion-related challenges that are being addressed through both pharmacologic and mechanical means. A combination of increasing age of patients undergoing cardiac surgery and a greater percentage of patients undergoing resternotomy procedures has increased the challenge of bloodless cardiac surgery. Although the safety of receiving allogeneic blood has increased dramatically, risks remain and need to be understood when considering patient transfusion. These risks include both hemolytic and nonhemolytic reactions, disease transmission, graft-versus-host disease, recipient alloimmunization, and hypervolemia.[289] Meticulous attention to bleeding and adherence to restrictive blood transfusion protocols have significantly improved patient care and outcome.[290,291] However, the diversity in surgical practices, anesthesia management, and postoperative care all represent a multifactorial process rendering reproducibility difficult from center to center.[292] An international multidisciplinary consensus panel of experts concluded that over 88% of the published RBC transfusions reviewed in the literature were either harmful or showed no benefit to patients.[293,294] Additionally, one out of three RBC transfusions are administered without a corresponding hemoglobin value.

Isovolumic hemodilution combined with hypotensive anesthesia is an effective strategy for limiting allogeneic transfusions. Intraoperative phlebotomy before ECC is performed easily with volume replacement consisting of either colloid or crystalloid solutions ranging, respectively, from 1 to 3 mL for every milliliter of phlebotomized blood. Relative contraindications to performing intraoperative donation may be left main stenosis, unstable angina, critical aortic stenosis, hemodynamic instability, and a history of cerebrovascular disease.[174] The increased risks associated with allogeneic blood are well known. Although the dangers of receiving contaminated blood vary among geographic regions, it is accepted that the incidence of posttransfusion hepatitis C has decreased markedly,[295] whereas the risk for HIV transmission has been reported to be as high as 1 in 100,000 transfusions. The emphasis on reducing the risks associated with blood exposure has long been evident within hospitals. Standing blood utilization committees are charged with the responsibility of reviewing transfusion practices within hospitals. Some states have enacted laws that protect the rights of patients undergoing elective surgical procedures in regard to blood transfusions. Legislative actions in California have established specific mandates for physician involvement in ensuring that patients at risk for transfusion are informed of the availability of alternate techniques for reducing the risk for allogeneic blood exposure. Professional medical societies have established evidence-based recommendations supporting cardiac surgical blood conservation programs.[296] Clearly, the impetus directing specific blood replacement practices associated with cardiovascular surgery will come under intense scrutiny from both internal and external sources of review.

The term *autotransfusion* has been used generically to represent the process of reinfusing blood collected from a patient at some time before infusion. Autotransfusion can be broken down into three distinct categories delineated by both the time of collection and the methods used to collect the blood. Preoperative donation, intraoperative salvage, and postoperative collection are techniques used in varying degrees at most cardiac centers. Each category is further subdivided according to the techniques used; however, the underlying goal that firmly links all processes together is the reduction in exposure of patients to allogeneic blood.

Preoperative Donation

Predonation before surgery would seem to be a plausible means of obtaining blood and avoiding homologous transfusion, particularly in this era of heightened awareness of the dangers associated with receiving allogeneic blood products. Not only is the use of autologous blood nonimmunogenic, but it also reduces the hospital's dependence on blood banks. However, this technique has had limited success in treating the cardiac surgery patient.[297] From a blood bank perspective, predonation of blood is a logistic nightmare. Furthermore, there are many contraindications to autologous blood collection in cardiac patients, including aortic stenosis, left main coronary artery disease, idiopathic hypertrophic subaortic stenosis, unstable angina, cardiac failure, recent MI, ventricular arrhythmia, symptoms on the day of donation, and the emergency need for surgery. Only 10% of transfusion recipients may be eligible for self-donation[298]; therefore the majority of surgical candidates require alternative measures to reduce exposure to the general blood supply.

Plasmapheresis

Plasmapheresis is the separation of whole blood into plasma (which may be platelet poor or platelet rich), platelets, and RBCs. The first clinical utilization of plasmapheresis in thoracic surgery was reported by Ferrari and colleagues[299] in 1987. The benefits of plasmapheresis in the cardiac surgical patient are derived from the production of autologous blood products that, because of their separation into isolated components, can be administered to treat specific deficiencies related to the patient's hemostatic needs. One of the perceived advantages involves the treatment of patients who would otherwise not be candidates for predonation of blood. The logistic difficulties are overcome when this method is used in the OR with the patient under the direct care of the anesthesiologist.

As with any new treatment, potential disadvantages do exist and are related to exsanguination phenomena. Plasmapheresis reduces circulating albumin and total protein levels before surgery, which when combined with noncolloidal fluid replacement, may lead to extravascularization of plasma water. In addition, there may exist select patients who cannot tolerate the anemia associated with use of this technique before CPB. The expenses associated with plasmapheresis

are minimal because most cardiac centers have purchased cell-washing autotransfusion devices for alternate reasons, and these machines easily can perform intraoperative plasmapheresis. The technique of plasmapheresis uses technology similar to that of cell-washing autotransfusion devices. Both systems use centrifuges, peristaltic pumps, and collection reservoirs. The process for plasmapheresis is unique in several ways, including its processing of whole blood collected using protocols for isovolumic hemodilution, before heparinization. During plasmapheresis the clinician has the ability to alter the collection process to obtain either platelet-poor or platelet-rich plasma (PRP). The platelet-poor plasma is collected at greater centrifuge speeds (5200 to 5600 rpm), resulting in tighter packing of the RBC layer, restricting the separation of platelets into a buffy coat layer. At slower centrifuge speeds (2400 to 3600 rpm), the platelet fraction is sequestered in the buffy coat layer that is then collected, together with a small volume of RBCs, as PRP.

Although it seems reasonable to sequester platelets and plasma from the CPB circulation and the stresses of surgery, an evidence-based review of the literature questions the routine use intraoperative plasmaphersis as a recommended blood conservation strategy. According to both the 2007 and 2011 Society of Thoracic Surgeons Blood Conservation Guidelines, 20 RCTs and one pooled metaanalysis failed to collectively show a clear clinical benefit in transfusion-related rates and outcome.[53,54] Similar studies suggest that the labor intensity and technical mistakes that could occur during sequestration may inadvertently increase the patient's risks of transfusions. Moreover, the patients that would most benefit from this technique are the poorest candidates for the procedure, because of clinical instability during harvest or low platelet concentrations in the systemic circulation.[54] As such, plasma and platelet pheresis may be considered only when large volumes of platelets can be sequestered.

Autologous Priming Techniques

The process of displacing crystalloid prime solution with the patient's own blood to reduce hemodilution during the onset of CPB, known as autologous priming (AP), has become a widely adopted method of reducing the burden of hemodilution that occurs at the initiation of CPB. The process involves slowly removing the clear prime from the pump with the patient's own blood through both the arterial and venous limbs of the perfusion circuit, once the patient has been given heparin and the activated coagulation time is adequately prolonged. It is necessary to position the patient in Trendelenburg position to improve right atrial filling pressure and maintain arterial blood pressure during this process. It often is necessary to also infuse phenylephrine to maintain an acceptable arterial blood pressure during this process.

Rosengart and colleagues'[300] prospective trial led the way for other investigators. Their study, conducted on 60 first-time CABG patients, established that AP limits hemodilution and reduces the number of patients needing RBC transfusions. Since their report, other randomized and observational trials have reported similar benefits.[301–305] A literature review and metaanalysis in 2009 concluded that AP significantly reduced the number of patients receiving RBC transfusions in both the OR theater and the entire length of hospital stay.[306] Trowbridge and colleagues[307] designed a prospective study aimed at identifying optimal characteristics of the AP process and found that when used effectively, defined as removal of at least 1300 mL or when less than 10% of AP volume was returned to the patient, greater hematocrit values were obtained and fewer patients received transfusions. Furthermore, they reported that the amount of removed prime returned to the patient was related to the patient's urinary output and the amount of blood loss during the procedure.[307]

Perioperative Salvage and Autotransfusion

Cardiotomy Suction

Shed blood from the surgical field and blood vented from the LA, left ventricle, pulmonary artery, or the aorta is collected and reinfused into the CPB circuit through the cardiotomy suction system. This system is composed of tubing usually ¼-inch internal diameter directed through an RP into a filtered reservoir. Cardiotomy suction blood contains fat, bone, lipids, and other debris from the surgical field. This blood is also exposed to air, shear forces, and artificial surfaces that cause exacerbation of the systemic inflammatory response and result in microcirculatory dysfunction. These substances may traverse the CPB circuit, enter into the arterial line, and ultimately obstruct the microcapillary circulation of the patient. Brown and colleagues[308] identified thousands of embolic lesions in the brains of patients who died within 3 weeks of cardiac surgery and reported an association between embolic lesions and duration of CPB. For each 1-hour increase in the duration of CPB, the embolic load increased by 90.5%. Cardiotomy suction blood has been identified as a major source of lipid emboli in several studies.[309–311] For this reason, some have advocated eliminating the use of cardiotomy suction, which is returned directly to the ECC. Several clinical studies have examined the effects of eliminating cardiotomy suction. In a randomized trial enrolling CABG patients, use of cardiotomy suction resulted in significant increases in thrombin generation, neutrophil and platelet activation, as well as the release of neuron-specific enolase.[312] Nuttall and colleagues,[313] in a study of patients in whom an open venous reservoir was used, compared the return of cardiotomy suction directly to the ECC, versus sequestration and processing of cardiotomy blood to a cell saver. Numerous blood tests were performed to evaluate platelet function, and no significant difference in any of the tests or in blood transfusion requirements was observed.

Cell Salvaging Through Centrifugation and Washing Techniques

One of the simplest forms of autotransfusion is the use of a cell-salvaging system that uses aspiration and anticoagulation to collect shed blood and return it to the patient. The simplest products to perform this function include collection sets consisting of double-lumen tubes through which an anticoagulant (usually heparin or citrate-phosphate-dextrose) is mixed with shed operative blood, aspirated by negative pressure through a vacuum source, collected in a reservoir, and directly reinfused to the patient through a filter. Inherent problems with this technique include questionable quality of reinfused blood because of contamination with particulate matter aspirated from the field that includes bone fragments, fat particles, and suture materials. In addition, the anticoagulant remains present in the reinfusate. However, this technique is a relatively easy and quick means of returning lost blood in the event of unexpected acute blood loss.

Another form of autotransfusion uses specific machines that salvage and process shed blood and include a cell-washing step. The term *cell saving* has come to denote the process of autotransfusion that involves centrifugation of collected operative blood and processing with a wash solution, 0.9% NaCl, and reinfusing the product back to the patient. The basic operating principles found in autotransfusion include aspiration, anticoagulation, centrifugation, washing, and reinfusion. The ensuing discussion focuses specifically on the processes of cell washing and separation by centrifugation as autotransfusion methods.

The major components of any automated or manual device used for cell processing in autotransfusion are listed in Box 32.8. The process begins with the aspiration of blood from the surgical site together with an anticoagulant via a double-lumen line. The blood, together with other operative contaminants, including bone chips and adipose tissue, is then collected in a cardiotomy reservoir, functioning as the first filtration, with depth and screen filters ranging in size from 40 to 120 μm. A peristaltic pump then transfers the contents from the cardiotomy reservoir into a centrifuge bowl that has been specifically designed to separate blood according to specific particulate density. Centrifugation necessary for this separation process generally is between 4800 and 5600 rpm (Fig. 32.32). The volume of the bowl is an important characteristic of these devices because this capacity has a role in the minimum amount of shed blood required to obtain an acceptable hematocrit in the returned product. Some systems come with 125-mL bowls for use

with small patients or when smaller amounts of shed blood are anticipated. The heavier RBCs are packed farthest from the axis of rotation, whereas the lighter plasma and crystalloid fractions remain closest to the center of the bowl. A wash mode is initiated when the centrifuge bowl has reached its optimal packed RBC level, with sterile physiologic saline pumped through the RBC layer, removing plasma-free hemoglobin, clotting factors, anticoagulant, and nonautogenous particles.

After the wash cycle, the washed product is pumped out of the centrifuge bowl into a collection reservoir and then transferred to a reinfusion bag for administration to the patient. The quality of the finished product is affected by several operating parameters, including the absolute aspiration pressure, the fill speed of the bowl, the wash rate, and the quantity of wash volume used. The percent of hematocrit of the processed blood also is dependent on filling rate and wash rate, and when these are kept within the manufacturer's recommendations, the final product should have a hematocrit between 45% and 60%.

One unique cell-saver design, the Continuous Autotransfusion System (CATS; Terumo Cardiovascular Group, Tustin, CA), does not have a Latham bowl and functions in a continuous manner such that the packed RBC product is harvested during centrifugation (Figs. 32.33 and 32.34). This approach has several advantages: a lower minimum amount of shed blood is required before packed RBCs may be harvested, a greater RBC concentration of resultant product is obtained, and, most important, the separated lipid layer remains suspended

during the process. With the traditional Latham bowl systems in which the centrifugation is stopped between cycles, lipids may remix with the final RBC product and be returned to the patient. Several recent studies have shown that the use of a continuous processing system is superior to the Latham bowl-type systems in terms of lipid removal and neurocognitive outcomes.[314,315] Kincaid and colleagues[316] studied effects of blood processing technique on production of lipid emboli in the brain (small capillary arterial dilations) in a canine model. Two recent randomized trials were designed to determine whether use of a cell saver reduced neurocognitive dysfunction after CPB. In Rubens

and colleagues' study,[317] 266 patients undergoing CABG surgery were randomized to two groups: an unprocessed cardiotomy suction blood group (control) and that processed by centrifugal cell washing (treatment group). Greater blood product administration and blood loss were observed in the treatment group. No differences in microemboli generation, neurocognitive dysfunction, or other adverse events were demonstrated between groups. In another study by Djaiani and colleagues,[314] patients randomized to cell processing with a continuous autotransfusion system had reduced transfusion requirements and improved neurocognitive function. The latter study used a continuous cell processing system that has been shown to reduce blood lipid content. The former study used a Latham bowl intermittent system, which previously has been shown to be ineffective at lipid removal. Further studies are necessary to define the impact of cardiotomy suction on clinical outcomes.

All currently manufactured machines contain microprocessors and operate in either manual or automated modes. In the manual mode, the operator has control over the processing cycle and must be present during each stage of the process. The machines that contain automatic mode capabilities also provide the user with the option of completing several cycles of blood processing without operator dedication. Some models also permit online programming at the user site, which enables the perfusionist to modify the processing program according to the level of aspirated blood contamination, producing an optimal quality product.

The safety features available on autotransfusion machines vary according to the manufacturer. Some of the more prominent features include air-sensing capabilities, level detectors, air and foam detectors, hand-cranking capabilities, two-bag reinfusion systems, and waste bag overfill automatic shutoff. The reinfusion bag from an autotransfusion device should never be directly connected to a patient through an infusion line. The peristaltic pump of the autotransfusion device is connected to the cardiotomy reservoir, which is often emptied during the filling process. The potential, therefore, is that air could be pumped into the reinfusion bag, which could then be passed on to the patient, especially in the situation in which the reinfusion bag is placed under pressure. A second transfer collection bag should be filled from the reinfusion bag and separated from the autotransfusion machine, to reduce the risks for air embolization.

Several large systematic reviews and metaanalyses have demonstrated the efficacy of routine autotransfusion usage in CPB surgery.[318,319] Cost-effectiveness always has been a concern, with the prevailing belief that autotransfusion should be considered only when anticipated blood loss would result in a reinfusion of 1 to 2 units of processed RBCs.[320] However, the active interest in minimizing patient exposure, combined with the use of smaller-volume centrifuge bowls, have prompted increased use of autotransfusion during cardiac surgery. Young and colleagues[321] reported a reduction in allogeneic RBC transfusion from 4.2 to 1.5 units/patient when autotransfusion was used in cardiac patients. The quality of RBCs processed via autotransfusion during cardiac surgery also has been compared with fresh autologous blood, with RBCs collected from the operative field having an in vivo survival comparable with that of phlebotomized blood.[322] Schwieger and colleagues'[323] study examined autotransfusion-collected blood for risk for infection and found that patients who had blood salvaged and processed by cell-washing equipment had no higher rate of infection than patients who had no autotransfusion but received banked blood.

In addition to aspirating shed blood from cardiac patients, the autotransfusion device can be used to concentrate the pump perfusate at the termination of CPB. Although this process is known to reduce the protein concentration of the perfusate when compared with reinfusion of the unprocessed pump contents, this method significantly reduced allogeneic banked blood exposure.[54,324] Many centers will infuse the blood contained in the CPB circuit at the termination of bypass. The blood in the CPB circuit is displaced with a balanced electrolyte solution so that the pump remains primed should it be necessary to return to bypass. Sometimes vasodilators are administered to the patient to increase capacitance and allow this blood to be reinfused. It is common practice in neonate and pediatric cardiac surgery to use a technique referred to as "modified ultrafiltration" (MUF). With this technique, UF is conducted to remove plasma water, while at the same time the blood remaining in the CPB circuit is slowly infused into the patient. Similarly, this technique may be performed using a device called a *Hemobag,* where the contents of the CPB circuit are infused into a collection bag and the contents of the bag are then ultrafiltered and returned to the patient.[325–327] The product returned to the patient has a lower water content and greater concentration of RBCs, platelets, white blood cells, and plasma proteins.

Dilutional coagulopathy is a potential problem with overuse of autotransfusion. When large quantities of blood are processed, the washout of clotting factors may induce bleeding purely from a dilutional effect. However, the use of waste or wall suction would result in a similar reduction in clotting factors, as well as the loss of RBCs. Autotransfusion also is used to treat patients with rare blood types or who are sensitized to donor blood and respond poorly to transfusion. In addition, certain religious beliefs will not allow the acceptance of allogeneic blood but will consider the use of autotransfusion on an individual basis.

The contraindications to the use of autotransfusion are relative and are evaluated on a per-case basis. Therefore the relative contraindications include contaminated wound sites and/or septic procedures, malignancy, aspiration during caesarean sections, and concurrent use when microfibular collagen agents are present. The risks assumed with using cell salvaging and reinfusion techniques in these patients must be weighed against the inherent benefits of autologous versus allogeneic transfusion. Hemoglobinemia resulting from RBC destruction caused by exposure of blood to disposable autotransfusion circuitry and trauma caused by aspiration and mechanical treatment has been reported.[328] The reinfusion of packed RBCs may also lead to pulmonary insufficiency if inadequate filtering of the product results in microaggregate embolization in the pulmonary vasculature. The risk for air embolism also is increased whenever extracorporeal devices are used; therefore proper precautions with operator vigilance are paramount in ensuring patient safety.

Postoperative Shed Mediastinal Blood Collection

The collection and reinfusion of postoperative mediastinal blood after cardiac surgery have been described as postoperative autotransfusion (PAT)[329,330] and have been used in cardiac surgery since 1978.[331] This process consists of connecting either a dedicated collection device or a cardiotomy reservoir from the extracorporeal circuit directly to mediastinal chest tubes and a negative pressure source. Blood flows from the mediastinal tubes into the collection reservoir, where it undergoes gross filtration (40 to 120 μm). The collected product then is reinfused back to the patient via an infusion pump and through an additional 20-μm filter. The volume collected after the operation varies from center to center and according to procedure but may range from 400 to 1200 mL over the first 24 hours. Shed mediastinal blood is defibrinogenated; therefore levels of fibrin(ogen) split products are increased after reinfusion.[332]

Morris and Tan[333] commented on the use of PAT in 155 consecutive cardiac patients. These authors found a substantial and significant reduction of approximately 30% in the use of allogeneic blood products in patients undergoing cardiac surgery with PAT. Other authors have found that when the postoperative blood loss was less than 500 mL, PAT conferred no benefit in reducing banked blood requirements.[334,335] In a prospective, randomized study of cardiac patients undergoing CABG surgery, Bouboulis and colleagues[336] found no benefit to the use of PAT, and patients receiving autotransfusion had greater incidences of febrile reactions. These authors and others have advocated the concurrent use of a cell-washing device to process the PAT product before reinfusion.[337] A portable cell-washing device, the CardioPAT, has been commercially available for processing shed blood from thoracic and pleural drainage. This device functions similarly to the centrifugal

cell-washing systems. The major differences are a smaller footprint and a slower rate of processing than the traditional cell-saver systems. The processing of this blood removes activated white blood cells and fibrinolytic mediators, which may be associated with hemolytic reactions found when unwashed blood is reinfused. Schmidt and colleagues[338] have shown that the reinfusion of PAT blood in CABG patients caused an increase in levels of cardiac enzymes including creatine kinase-MB activity. These increases may result in a compromised assessment of myocardial injury in patients undergoing cardiac surgery with PAT. Current blood conservation clinical practice guidelines indicate that although the reinfusion of washed mediastinal blood is not unreasonable in circumstances of excessive postoperative bleeding, the usefulness and efficacy of this procedure are not well-established[53]

Ultrafiltration

UF is a process in which plasma water is filtered from whole blood via a semipermeable membrane. Although primarily a method of removing plasma water, it is also an effective means of blood conservation in that it indirectly increases the volume of RBCs, platelets, and coagulation factors. The technology used in UF was initially developed as a treatment for dialysis patients who became volume overloaded.[339] UF is used synonymously with hemofiltration and diafiltration and uses similar devices and principles to those seen in continuous arteriovenous hemofiltration and slow continuous UF. Continuous arteriovenous hemodiafiltration uses a dialysate that flows countercurrent to the direction of blood flow around the fibers, removing plasma solutes and electrolytes by diffusion. When UF is used exclusively to remove excessive fluid from CPB circuits, it has been referred to as *hemoconcentration*.

Cardiac patients are particularly susceptible to volume overloading via crystalloid administration for hemodynamic maintenance and prime solution of the heart-lung machine. Priming of the extracorporeal circuit with nonhemic solutions results in hemodilution that ranges from 33% to 200% of the patient's volume. After cardiac surgery, the amount of extravascular fluid load may increase by greater than one-third of the adult patient's prebypass blood volume,[340] whereas in pediatric perfusion, the total volume of hemodilution may far exceed the patient's preoperative blood volume.[341] It is well-known that the body responds to hemodilution by increasing cardiac index as a result of reduced SVR.[342] In sick or compromised hearts, however, there is less myocardial reserve, which may result in inadequate oxygen delivery and hypoperfusion because of decreased output. UF not only reduces the risk for volume overload in these patients, but it can be used to correct electrolyte and acid-base imbalances.

UF is a hemoconcentration technique by which plasma water and certain low-molecular-weight plasma solutes are separated from circulating whole blood by free convective transport. A semipermeable hollow-fiber membrane operates on the principle of a hydrostatic pressure differential generated across the membrane to separate an ultrafiltrate from blood (Fig. 32.35).[343] The composition of the ultrafiltrate is similar to that of glomerular filtrate.[344] Uremic toxins also are selectively removed from the circulating perfusate,[345] which may decrease the incidence of acute tubular necrosis as a result of CPB. Sieving coefficients that are based on the molecular weight of plasma solutes and the porosity of the UF device have been established by the various manufacturers. These are determined by dividing the concentration of the solute in the filtrate by the concentration in the plasma. Generally, solutes greater than 50,000 Daltons do not pass through the membrane pores (albumin has a molecular mass of 65,000 Daltons).

The advantages of UF in the cardiac patient are:

1. Hemoconcentration without removing the protein segment of whole blood maintains plasma constituents including albumin and clotting factors.
2. The concentration of the albumin fraction increases colloid oncotic pressure and reduces edema by drawing fluid out of the extravascular area.

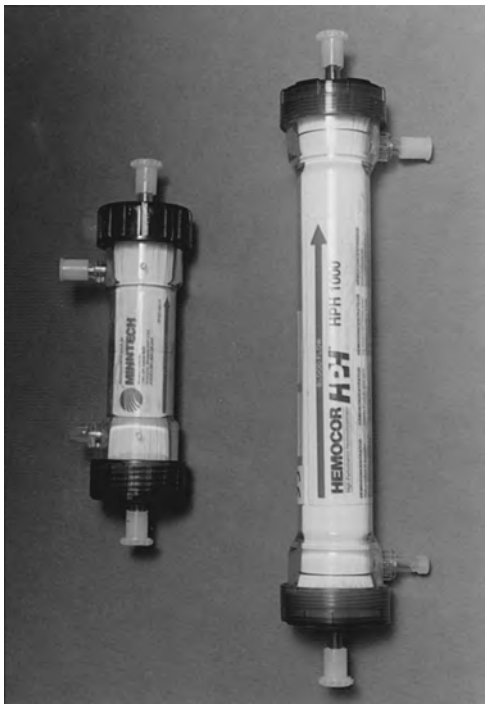

Fig. 32.35 Ultrafiltration device. *(Courtesy Minntech Corp., Minneapolis, MN.)*

3. Pulmonary dysfunction is reduced after CPB by decreasing the amount of extravascular lung fluid.[346]
4. In patients with renal impairment, its concomitant use with dialysis before surgery may prepare the patient for anesthetic induction by optimizing the electrolyte and blood urea nitrogen levels.[347]

UF differs from dialysis in that dialysis is the diffusion of solutes through a semipermeable membrane via a concentration gradient into a dialysate solution. UF uses the hydrostatic pressure gradient in removing plasma water without an osmotic gradient. The principle of operation involves a transmembrane pressure (TMP) gradient, which is the force by which solutes are separated from the solution. The calculation of TMP uses the arterial inlet pressure (P_a), venous outlet pressure (P_v), ultrafiltrate pressure of outlet (P_n), and oncotic pressure at the inlet (P_i) and the outlet (P_o):

$$TMP = P_a/2 + P_v + P_n - P_i/2 + P_o$$

The UF rate is the rate at which plasma volume is removed from the blood passing through the ultrafiltrator and is dependent on TMP and the surface area of the hemoconcentrator.[348]

Ultrafiltrators traditionally have been designed in either parallel-plate or hollow-fiber configuration. The hollow-fiber types are used in hemoconcentration and are manufactured out of cellulose, polyacrylonitrile, or polysulfone materials. Blood passes along the inside of the hollow fiber, with the outside of the hollow fiber open to siphon drainage or negative pressure created by a vacuum suction. The TMP forces created by the movement of blood through the fibers and UF pressure force plasma water and dissolved solutes through the pores in the synthetic material. The pore size of hollow-fiber ultrafiltrators varies among manufacturers but is generally between 30 and 40 angstroms. The wall thickness of the hollow fiber is around 40 μm, and the diameter of the fiber reaches 200 μm. Other factors that influence UF rates include the rate of blood flow through the device, the RBC and protein concentrations, and the temperature of the perfusate passing through the device.

There are few contraindications to hemoconcentration with an ultrafiltrator. As with any nonendothelialized material, biocompatibility becomes an important issue. Leukopenia and complement

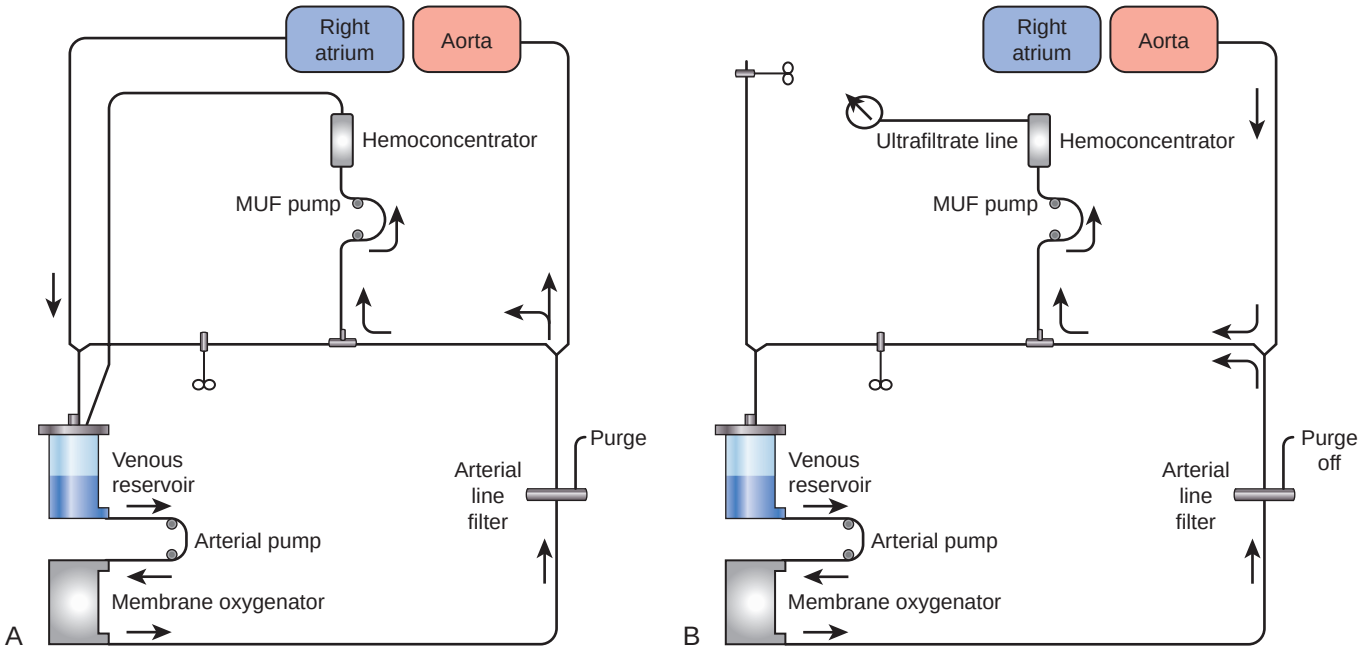

Fig. 32.36 Modified ultrafiltration *(MUF)* circuit used for pediatric cardiac surgery. (A) Conventional ultrafiltration. (B) MUF. *(From Darling EM, Shearer IR, Nanry C, et al. Modified ultrafiltration in pediatric cardiopulmonary bypass.* J Extra Corpor Technol. *1994;26:205.)*

activation have both been reported when blood is exposed to cellulosic membrane material.[349,350] Excessive TMP may lead to increased RBC trauma and release of plasma-free hemoglobin. When concentrating the pump contents, care must be taken during reinfusion because of the retention of heparin in the hemoconcentrated product. The heterogenous molecular size of heparin varies the amount of heparin retained in the hemoconcentrate. Strict cost analysis during routine cardiac surgery is difficult to quantify because patients are known to tolerate positive fluid balances of up to 4 L without adverse pathologic effects.[222] Therefore the benefits of UF in these patients have yet to be established.

Modified Ultrafiltration

In 1991, Naik and colleagues[351] described a modification to the technique of UF that has since been extensively applied to pediatric patients undergoing cardiac surgery. An international survey of pediatric perfusion practices in 2011 indicated that 71% of all respondents employed MUF for neonate, infant, and pediatric cardiac surgery.[352] Pediatric patients are thought to be more susceptible to the injurious effects of fluid overloading and may benefit from this technique because of the greater reoperation rate and use of profound and deep hypothermia seen in pediatric cardiac surgery. The technique is applied after CPB and allows the UF of both the circuit contents and the patient. The timing of MUF is critical and permits a rapid increase in patient hematocrit by the removal of plasma water.[353] The results associated with MUF have been very encouraging and have included reductions in postoperative morbidity,[354] reduced blood loss and blood utilization,[351,355] reduced inflammatory mediators,[356,357] and improvements in myocardial function[358] and cerebral oxygenation.[355] Similar benefits have been observed in adults, as several RCTs and a metaanalysis demonstrate an association with MUF and reduced postoperative bleeding and blood transfusions.[359–361]

MUF generally is performed shortly after termination of CPB and is completed with a typical ultrafiltrator. In pediatric operations, these devices are routinely set up and primed together with the entire ECC. The ultrafiltrator is placed in-line at a point distal to the membrane oxygenator with the inlet of the device connected to the arterial line and the outlet connected to the venous return line (Fig. 32.36). An RP controls the flow rate through the MUF circuit and is located in a parallel circuit between the arterial and venous cannulae. Such a configuration allows conventional UF to take place during the CPB procedure. On separation from CPB, the patient becomes the source for blood for MUF by clamping both the arterial and venous lines proximal to the MUF circuit, draining from the arterial cannula, and reinfusing directly into the venous cannula. The remaining pump contents also are concentrated during MUF and serve as a volume replacement for the removed plasma water. Blood flows during MUF vary with patient size and hemodynamic stability.

During MUF, there is an increase in mean arterial pressure (MAP) that may be related to changes in SVR associated with increasing blood viscosity and via the removal of vasoactive substances.[355,362] The obvious benefit of MUF is the removal of plasma water and the concentration of cellular and acellular elements of blood. However, a number of investigators have shown that UF reduces the production of other potential harmful substances, including cytokines and endogenous pyrogens.[357,363] This reduction in number is independent of the effects of hemoconcentration and is instead related to a reduction in the whole-body inflammatory response associated with CPB.[357] The benefits of MUF are accentuated when aggressive UF is used during the rewarming period of CPB. This is more than likely a result of the removal of the activated complement fragment C3a, which is easily sieved in the ultrafiltrate.[357] Patients treated with MUF have been shown to have a significantly faster rate of pulmonary function recovery than nonultrafiltrated patients, which may be because of a leukocyte stability and a reduced degranulation of polymorphonuclear neutrophils in the pulmonary capillaries.[357,363]

The use of MUF in adults has been well studied. In 2001, a randomized controlled trial by Luciani and colleagues reported significant reduction in early morbidity and lower blood transfusion requirements.[364] Other studies investigated transfusion requirements, blood loss, antithrombin III levels, systolic blood pressure, and cytokine levels.[360] Boodhwani and colleagues conducted a metaanalysis from 132 studies involving 1004 patients to examine the effectiveness of MUF patents on blood transfusions and reported a 0.72 unit reduction in transfusions and a significant reduction in post operative blood

loss.[361] The 2011 Society of Thoracic Surgeons and the Society of Cardiovascular Anesthesiologists Blood Conservation Clinical Practice Guidelines state: *Use of modified UF is indicated for blood conservation and reducing postoperative blood loss in adult and pediatric cardiac operations using CPB. American Heart Association class I level of evidence A.*[53]

Coated Circuits

Bypass-induced coagulopathy represents one of the most prevalent pathophysiologic events associated with the exposure of blood to foreign surfaces.[365] Identifying patients at risk for development of postoperative coagulopathies has long challenged clinicians involved with cardiac surgery. Abnormal postoperative bleeding usually is classified as resulting from a preexisting coagulopathy, acquired hemostatic deficiencies, or inadequate surgical hemostasis (although a single patient can suffer from all of the above maladies). The activation of various humoral and cellular systems is associated with the exposure of blood to negatively charged foreign surfaces, with arguably the primary causative factor related to platelet dysfunction.[366–369] It has long been thought that, during ECC, thrombin formation is initiated through contact activation with factor XII (Hageman factor), with subsequent activation of the intrinsic pathway of coagulation.[370] However, recent research has shown that activation of tissue factor pathway and the extrinsic limb play an important role in the stimulation of thrombin during CPB.[371] The bypass circuit is composed of various synthetic materials, including PPL, polyvinylchloride, stainless steel and/or anodized aluminum, Dacron, and various plasticizers, all of which evoke contact activation of platelets, granulocytes, and proteins associated with the intrinsic pathway. The pathologic events associated with ECC-induced complement activation are poorly understood,[372] although potent mediators such as C3a, C4a, and C5a are thought to play a major role in postbypass whole-body inflammation[373,374] (see Chapter 35).

Surface coatings play a role in the interface between the blood and the circuit components. Attenuation of the inflammatory and coagulation pathways should translate into decreased postoperative morbidity directly related to platelet dysfunction, bleeding complications, and end-organ damage. The desire to avoid anticoagulation of patients undergoing extensive thoracic aortic surgery led to the first reported use of a shunt with a graphite-benzalkonium-heparin coating by Gott and colleagues.[375] Heparin-coating of the CPB circuit was originally intended to supplant systemic anticoagulation with heparin. Subsequently, this concept of eliminating systemic heparin was dismissed, and a strategy combining the use of low-dose systemic heparin with a heparin-coated CPB circuit was introduced.[376–380] In vitro and in vivo studies of these surfaces demonstrated reductions in coagulation and systemic inflammatory processes. Numerous studies have been conducted to evaluate the effectiveness of heparin-treated surfaces compared with circuits without heparin coatings.[381–406] Most studies have shown evidence of reduced platelet activation,[385–388] reductions in inflammation characterized by complement activation,[389–396] and improvements in clinical outcomes including bleeding and transfusions,[397–399] pulmonary function,[400,401] and cognitive function.[402–404] One randomized trial in patients undergoing redo CABG surgery showed no differences in biomarkers of inflammation or differences in blood loss and transfusion.[405] A larger randomized trial from the same center, which included redo valve patients, suggested that heparin-coated circuits imparted benefits including a trend of fewer reoperations for bleeding (0% vs 4.0%; $P = 0.058$) in CABG patients, significantly fewer major bleeding episodes (1.2% vs 5.4%; $P = 0.035$), and significantly lower blood transfusion requirements in the intensive care unit ($P = 0.013$).[406] The authors further commented that the material-independent blood activation (e.g., blood-air interface and cardiotomy suction) may have blunted the total effect of the heparin-coated surface (HCS).

Unfortunately, most of these studies were small and substantially different in anticoagulation management with heparin, the use of a partially or completely coated circuits, the method by which cardiotomy blood was managed, the use of different heparin coatings, and variations in measuring different end points across studies. The heterogeneity of the randomized trials related to heparin coatings precludes the use of metaanalysis as a method of summarizing the effectiveness of these circuits.[53,381] Stammers and colleagues[381] used weighted means in an effort to summarize the effects of 27 RCTs of heparin-coated circuits that included 1515 patients. The authors concluded that heparin-coated circuits have shown statistically better results than similar noncoated circuits by decreasing hospital costs attributable to shorter intensive care unit length of stay and bleeding-related complications; they also concluded that immunologic factors were maintained better with the use of the Carmeda-coated circuits, whereas hematologic factors, excluding platelet count, favored the Duraflo II heparin coating. Two new heparin coatings have been developed: hyaluronan-coated heparin coating (GBSTM Coating; Gish Biomedical, Rancho Santa Margarita, CA) and Bioline (Maquet, Wayne, NJ); however, comparative studies of these surfaces are promising but limited.[407]

Numerous surface modifications rendering the CPB surfaces more thromboresistant and biologically inert are commercially available. These include Xcoating PMEA (poly-2-methoxyethyl acrylate; Terumo Cardiovascular Group, Ann Arbor, MI), SMARxT (Sorin Group, Arvada, CO), *P.h.i.s.i.o.* phosphorylcholine inert surface (Sorin Group), Softline heparin-free synthetic polymer (Maquet, Wayne, NJ), and Safeline synthetic-immobilized albumin (Maquet). Preliminary findings indicate that these surfaces provide some improvements, including reduction of platelet activation, leukocyte activation, bradykinin release, and to some extent, reduction in the release of cytokines compared with noncoated surfaces.[408–412] Gu and colleagues[413] compared circuits with the SMA coating with noncoated circuits and reported improved platelet preservation and function, but no difference in complement activation. Ereth and associates[414] compared hematocrit, leukocyte count, platelet count, terminal complement complex, complement activation, myeloperoxidase, β-thromboglobulin, prothrombin fragment 1.2, plasmin-antiplasmin, heparin concentration, activated coagulation time, fibrinogen, blood loss, and blood-product usage in 36 cardiac surgery patients randomized to a trillium-coated circuit or an uncoated circuit. No significant differences were observed between the trillium-coated and uncoated group. Ferraris and associates[53] concluded that "heparin-coated bypass circuits (oxygenator alone or the entire circuit) are not unreasonable for blood conservation (class IIb, level of evidence B)." Similarly, Shann and colleagues[415] have stated, "Reduction of circuit surface and the use of biocompatible surface-modified circuits might be useful; effective in reducing the systemic inflammatory response (class IIA, level of evidence B)."

Heparin coating, or bonding, of extracorporeal circuit surfaces increases the hemocompatibility of nonendothelialized substances.[367,416,417] The specific benefits of HCS center on a reduction in the activation of humoral protein systems involved in hemostasis and complement systems, together with a benign deposition of platelets and protein on the extracorporeal surface.[418] Bound heparin inhibits the binding of factors Xa, IIa, and XII, inhibiting thrombus formation by restricting the initiation of coagulation.[419,420] Several authors have shown a reduction in granulocyte activation by reduced liberation of primary granule proteins (myeloperoxidase, lactoferrin) during in vitro whole-blood circulation in HCS circuits.[367,421] The amelioration of blood-surface interactions through the use of HCS may reflect similar responses seen in vivo at the endothelial lining of the vasculature.[417] Palatianos and colleagues[422] examined the effect of HCS on platelet preservation in a pig model of ECC, finding no reduction in platelet consumption or platelet count when HCS were used during CPB periods of 3 hours. However, their model did not include functional studies of the residual platelets, nor did they report results of hemostatic differences after ECC. In a similar animal model using calves during CPB with HCS, Tong and associates[423] were able to show superior platelet preservation and function compared with noncoated bypass circuits. Fibrinopeptide levels were reduced in the HCS group, and there was no evidence of thrombus formation in any of the coated circuits.

Once blood comes in contact with HCS, AT III attaches to the bound heparin in an accelerated fashion. Thrombin then combines with AT III, forming an inactivated complex that leaves the HCS, enabling the process to be repeated.[424] HCSs have been evaluated in various clinical settings that have included ECMO,[424] hepatic transplantation,[425] aortic aneurysm repair,[426] pulmonary artery catheters,[427] and during routine cardiac surgery. The efficacy of heparinless bypass may be especially evident when used to treat patients suffering from hypothermic exposure or in trauma patients suffering from head or severe soft-tissue injuries.

The use of HCS may result in the reevaluation of heparin therapy necessary for systemic anticoagulation during certain ECC procedures.[428–430] Reducing heparin levels has the desired effect of limiting the potential for postoperative coagulopathy that is due to heparin-related platelet defects and heparin reappearance after protamine administration (heparin-rebound effect). This may be especially attractive in patients at increased risk for adverse sequelae of heparin exposure (ie, heparin-induced thrombocytopenia, neurosurgical procedures, protamine intolerances). In some studies, the reduced level of heparinization resulted in lower postoperative blood loss.[428,430] Aldea and associates[431] have shown in patients undergoing CABG surgery that when HCSs were used in conjunction with lower heparinization protocols, there was a marked improvement in hemostasis, as well as reduced blood loss and transfusion rates. These benefits were accentuated in patients who were at a greater risk because of the urgent need for care.

Because heparin is the primary means of anticoagulation during CPB, any method that suggests reducing circulating levels must be critically evaluated.[432] Kuitunen and colleagues[433] prospectively evaluated HCS in patients undergoing CPB who received either a reduced heparinization protocol (100 IU/kg) or a full heparinization dose (300 IU/kg). These authors found that thrombin was formed during CPB, and that there was an increased risk for microembolic, intravascular, and circuit clotting with low heparin levels. This was also confirmed in an in vitro model in which whole blood exposed to an extracorporeal heparin-coated circuit with low heparin concentrations demonstrated evidence of contact activation after 120 minutes of simulated bypass.[434] In a retrospective analysis of patients undergoing first-time valve surgery, Shapira and associates[435] compared patients with HCS who had received low (100 IU/kg) heparinization with patients with normal (300 IU/kg) heparinization and non-HCS circuits. The heparin-coated group had significantly better clinical outcomes and lower allogeneic blood transfusions than the conventional group but also had an increased risk for early valve thrombosis. For this reason, the authors recommended using full-dose heparinization protocols in patients undergoing valve surgery with HCS.

One of the major difficulties in developing HCS was the bonding technique used to attach heparin to the various components used during bypass. An early technique for heparin bonding was described by Gott[436] and involved the substance tridodecylmethylammonium chloride. This method of ionic bonding is currently used in the production of shunts for aneurysm surgery and hepatic transplantation (Gott shunts; Sherwood Medical, St. Louis, MO).[425]

The difficulty in bonding heparin to extracorporeal circuits is compounded by both the diversity of synthetic compounds used during bypass and the geometric variations of cardiovascular devices that may produce areas of stagnation and flow stasis. In addition, the benefits associated with HCS are dependent on heparin being minimally eluted from the surface after contact with blood. The quantity of surface-bound heparin necessary to inhibit clot formation generally is greater than 1.0 mg/cm^2 of circuit surface area but is dependent on the distribution of heparin on the surface. It is well known that heparin is not a single unique compound, but rather is a heterogenous class of mucopolysaccharides, which also may influence binding characteristics.

Quaternary ammonium salts have been used to bond heparin ionically to synthetic surfaces, because heparin forms a highly nondissociable complex with quaternary ammonium salt. One manufacturer of HCS (Bentley Duraflow II; Baxter Health Care Corporation, Irvine, CA) uses a water-insoluble complex between heparin (porcine intestinal mucosa) and alkylbenzyldimethylammonium chloride. When ionically bound heparin surfaces are exposed to blood, there is an initial early 5% elution of bound heparin when blood first contacts the surface, but the remaining concentration stays stable for many hours. Synthetic materials that have been used successfully in covalent bonding include silicone and natural rubber, PPL, and polyethylene.

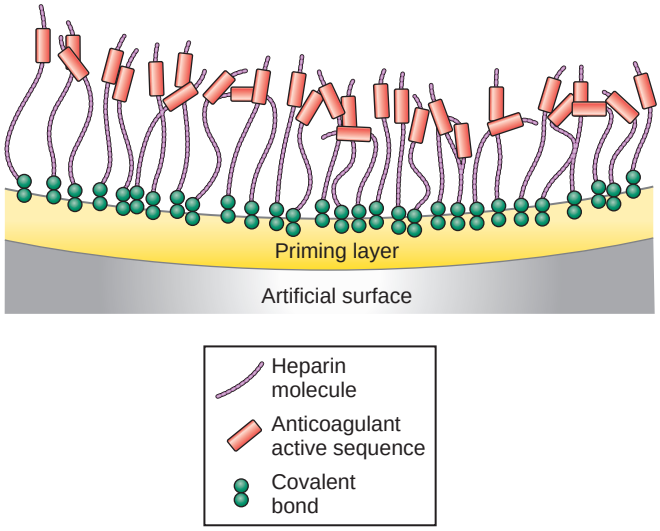

Fig. 32.37 Carmeda Bio-Active Surface. Covalent bonded heparin coating. *(Copyright Medtronic, 2016.)*

Heparin contains a hydroxyl group, carboxylic acid, and an amino group, which are all suited for covalent attachment to artificial surfaces. Covalent bonding of heparin has also been termed *end-point attachment of heparin,* in which an intermediate layer of substrate is first deposited onto the surface to which heparin is affixed by binding to a primary amine.[424] Partially degraded heparin is covalently end-point attached to extracorporeal circuits by a process developed by engineers from the Carmeda Corporation (Carmeda Bio-Active Surface; Carmeda, Stockholm, Sweden; Fig. 32.37).[424,426]

The effectiveness of HCSs is dependent on blood flow dynamics within the circuit, with thrombus inhibition related to the ratio of circuit surface area to blood volume.[437,438] HCSs are effective only when exposed to blood; therefore blood must be kept in constant circulation. Systemic heparinization still would be necessary to decrease clot formation in stagnant or low-flow capillary beds within the body, such as occurs in the pulmonary circulation. Therefore it is not likely that HCS will totally supplant the use of systemic heparinization. However, the use of heparin bonding to these circuits may necessitate the reevaluation of the total concentration of heparin necessary for systemic heparinization and may result in the identification of a more controlled protocol for the administration of heparin.[439]

Perfusion Practices

Minimally Invasive Cardiac Surgery

The changing economics of health care have forced the reevaluation of how techniques and technologies are utilized in the delivery of care. Despite the proven benefits of the heart-lung machine as a resource that enabled cardiac surgery to evolve, the morbidity associated with its use continues to plague clinicians. In a recent survey of cardiac surgeons, the question of which procedure would be preferable to eliminate, median sternotomy or CPB, more than 80% responded with the latter.[440] The development of endoscopic instruments and high-resolution video equipment has shaped the conduct of minimally invasive surgery and changed the conventional wisdom by which surgical practice is directed. The most promising results in applying

these techniques in cardiac surgery have been seen in patients requiring CABG surgery. When the procedure is performed through a left anterior minithoracotomy, it is designated as minimally invasive direct coronary artery bypass grafting. The major benefit to patients who undergo this procedure has been described as being cosmetic, at least when comparing single-vessel disease patients with those undergoing conventional therapy.[441] Although one of the primary goals of minimal invasion is the avoidance of the heart-lung machine, there are situations in which ECC is used to support the patient. This is true in patients with decreased ventricular function or in whom it is necessary to manipulate the heart for posterior access. The degree of involvement will vary from institution to institution, but in general these processes involve specialized cannulae that are most often placed transfemorally, with venous drainage accomplished with a CP kinetically assisted venous drainage (KVAD).[32,33]

When cardiac surgery is performed in patients without the use of a conventional midline sternotomy, it is referred to as *keyhole surgery*. When this technique is combined with CPB, it is referred to as port-access cardiac surgery and has been used for both CABG and valve surgery.[442,443] The success of this operative technique is dependent on a number of factors including surgical expertise and the correct utilization of specialty instruments and cannulae (Heartport EndoCPB; Heartport, Redwood City, CA; Fig. 32.38). The primary cannula, termed an *endoaortic clamp*, has been specifically designed to occlude the aorta, deliver cardioplegia, and vent the ascending aorta. In this way, myocardial protection can be achieved while enabling the surgeon to work in a quiescent, flaccid heart. The endoaortic clamp is positioned under fluoroscopic and echocardiographic guidance. Improper positioning can result in inadequate myocardial protection, left ventricular distention, or occlusion of the arch vessels.[443] A pulmonary artery venting catheter is placed through the jugular vein and used to assist ventricular unloading. The final cannula is a coronary sinus cardioplegia cannula that is used for retrograde cardioplegia administration (see Chapter 31).

The venous return is augmented by the use of KVAD and a CP. Negative pressure is measured at the inlet port to the CP and is regulated by controlling pump inertia.[32] The KVAD pressure is maintained between −50 and −80 mm Hg, which ensures adequate flow rates. The outlet of the CP is connected directly to an integrated cardiotomy/venous reservoir, which in turn, is connected to an arterial pump and the oxygenator (see Fig. 32.38). Patient management during port-access cardiac surgery is performed using similar protocols to those of conventional bypass. Additional monitoring is necessary for the CP and various cannulae that are used to vent the heart and to administer cardioplegia. Once the endoaortic clamp is correctly positioned, the balloon is inflated with a mixture of contrast media and saline, and cardioplegia solution is infused. During antegrade cardioplegia administration, the aortic root pressure will increase to between 60 and 90 mm Hg, and a pressure gradient of 20 to 40 mm Hg will be seen with the MAP. After cardioplegia administration, the aortic root vent is started and a −80 mm Hg pressure relief valve ensures that excessive negative pressure does not occur.

Weaning from CPB is accomplished in a normal fashion with the KVAD siphon gradually reduced, which diverts blood from the heart-lung machine into the patient. The aortic root and endopulmonary vents are removed, the femoral vessels repaired, and the thoracic incision sites are closed in a standard fashion. Although limited data have thus far been collected to assess this technology, it offers the surgeon a unique ability to perform minimally invasive surgery in a controlled environment with high-resolution stereoscopic visualization.

Perfusion during coronary and mitral valve surgery utilizing minimally invasive port-access technology.* J Extra Corpor Technol. *1997;29:66.)*

Monitoring During Cardiopulmonary Bypass

Technologic advancements in physiologic monitoring have made the process of CPB safe, comprehensive, and reliable. Monitoring devices measure both physiologic and mechanical functions of the patient-device interface. From a historic perspective, perfusionists had few devices that functioned as monitors relaying information other than hemodynamic data. Technologic advancement has generated new classes of devices for monitoring that at one time either were cost-prohibitive or viewed by perfusionists as superfluous. However, two developments occurred in the field that have greatly increased the safe conduct of CPB. First, the quantity and quality of information produced during a typical procedure increased and became more specific and sensitive in reflecting patient status. Second, the tremendous resurgence in research on the pathophysiologic events associated with CPB shifted the performance of perfusionists from relying primarily on instinctive reasoning to relying on deduction. This could only be accomplished through stricter methods of monitoring and analyzing both the patient's and machine's response to CPB. This section highlights the major variables monitored in the operation of the heart-lung machine.

After ensuring that an appropriate level of anticoagulation has been achieved, the perfusionist initiates CPB. Undoubtedly, the most important assessment of CPB after initiation of perfusion is the function of the oxygenator. This can be compared with establishing an airway in a patient before initiating basic life support. Without the proper delivery of oxygen to the venous blood and the removal of carbon dioxide, the arterial pump serves no purpose. Traditionally, isolated blood analysis was performed at a distant site from the OR and provided the clinician with a historic marker of oxygenator and patient performance. Unfortunately, this event is only a "snapshot" of one point during CPB and will not reflect ongoing changes or trends in the operation. Routine sampling of blood gases normally occurs every 15 to 30 minutes on bypass, and in the event of oxygenator failure, periods of hypoxemia and/or hypercapnia could result during those intervals. For this reason, the use of in-line blood gas monitoring is imperative and should not be considered a "luxury" because of its added cost.[444] Indeed, in this litigious society, it is questionable not to use readily available technologies that may reduce unnecessary patient risk.

Optical fluorescence technology has made reliable in-line blood gas and electrolyte monitoring a reality, providing minute-to-minute accurate surveillance of these parameters during CPB.[445,446] In-line blood gas monitoring allows for real-time monitoring of the "adequacy of perfusion," and one device currently available for use in CPB is the CDI500 (Terumo Cardiovascular Group, Ann Arbor, MI; Figs. 32.39 and 32.40). The CDI500 provides continuous real-time blood gas and electrolyte measurements for Po_2, Pco_2, pH, HCO_3^-, and K^+. The enhanced safety conferred by the use of this technology has been documented in the literature.[447] A survey of anesthesiologists in the United Kingdom and Ireland in 1994 concerning monitoring device utilization revealed that 98% of the 42 hospitals surveyed intermittently monitored blood gas tensions during cardiac surgery, and 33% used continuous blood gas monitoring.[448] In the United States, it has been estimated that approximately 40% of institutions use continuous blood gas monitoring during CPB.[444,449,450] Practice surveys indicate that the use of inline monitoring is increasingly widespread.[451–453] However, approximately two-thirds of the cardiac surgical centers worldwide do not use this technology. Ottens and colleagues[454] suggested that this may be attributed to the lack of scientific evidence and cost associated with the use of this technology.

Arterial blood oxygen saturation always should be maintained at greater than 99%, with PO_2 tensions between 150 and 250 mm Hg. Arterial PCO_2 levels will vary depending on whether alpha-stat or pH-stat blood gas management is used (see Chapter 31). Currently, there are several devices for measuring oxygenator gas exchange performance, including in-line continuous monitors. These monitors must meet basic criteria before they can be viewed as safe and accurate (Box 32.9). They must possess a rapid response time, be as accurate as standard blood gas analysis methods, be unaffected by hemodilution and temperature, and be easy to use. Alpha-stat blood gas management is achieved by maintaining electrochemical neutrality of blood as temperature declines, by keeping the pH alkalotic during hypothermic perfusion. During alpha-stat management, the rule of thumb for controlling carbon dioxide is to maintain PCO_2 levels equal to the temperature of arterial blood. For pH-stat management, the Pco_2 is kept constant at 40 mm Hg, and the pH at 7.4 at all temperatures. Therefore, when blood gases are temperature-uncorrected, a respiratory acidosis is seen. The venous oxygen saturation (SvO_2) will vary during the operative procedure depending on the metabolic state of the patient but is generally maintained at around 80%.

Clinical decisions for using in-line blood gas monitors ultimately must be determined by the ability of these devices to improve patient outcomes with a value that exceeds that of the total costs associated

BOX 32.9 CHARACTERISTICS OF AN IDEAL POINT-OF-CARE MONITORING SYSTEM FOR CARDIOPULMONARY BYPASS

- High degree of accuracy, precision, and reliability
- Rapid response time
- Minimally affected by hemodynamic conditions
- Wide parameter measurement range
- Easy calibration and alignment processes
- Stable measurement ranges (low drift) over 6 hours
- Self-contained instrumentation with minimal disposable use
- High degree of biocompatibility
- Cost-effective
- Input and output data-handling capabilities

BOX 32.10 REASONS FOR MONITORING DURING CARDIOPULMONARY BYPASS

- Assessment of oxygenator and/or device performance
- Calculation of patient conditions
- Oxygen delivery
- Oxygen extraction
- Oxygen consumption
- Carbon dioxide production
- Analysis of therapeutic interventions
- Quality assurance

BOX 32.11 POINT-OF-CARE MONITORING DEVICES

- Online monitors or analyzers
- In-line monitors
- Intra-arterial monitors
- Exhaust gas monitoring (capnography)
- Transcutaneous monitors (pulse oximetry)

with use. Complications arising from the cardiac surgical procedure remain significant in terms of the expense associated with their management.[455,456] The improvement in patient outcomes by the incorporation of a technology assumes that the intended problem is significant enough to warrant an intervention, a fact not always clear in the manufacturing and marketing of medical devices. For a practice to qualify as a standard of care, there must be some evidence that failure to incorporate the technique potentially could result in patient harm. Some of the reasons for monitoring during CPB are listed in Box 32.10.

Although overall mortality associated with CPB has declined over the past several decades, an increase in death (7.2% to 19.6%) resulting from neurologic injury has been shown.[457] Gill and Murkin[458] reported on post-CPB neuropsychologic dysfunction and have implicated cerebral microemboli generated from the bypass circuit as a major source of morbidity. These authors emphasized that microembolic phenomena are generated secondarily to alterations in bypass temperature, oxygenator type, pH management, and the use of arterial line filtration, and that modifications of these parameters reduce the overall incidence of neurologic dysfunction.

Acid-base alterations during CPB have been studied intensely both in animal and in human models, and the results are equivocal. Neurologic dysfunction has been reported in patients maintained using the pH-stat blood gas regimen, which more than likely resulted from the ensuing cerebral hyperemia consistent with the respiratory acidosis created during this condition.[459] This was confirmed by a clinical study in which 70 CABG patients were randomized either to an alpha-stat or pH-stat protocol and evaluated via neuropsychologic assessment at a mean of 42 days after the procedure.[460] The authors found that patients maintained by the pH-stat strategy had significantly impaired cerebral autoregulation and neuropsychologic impairment, when compared with their alpha-stat counterparts. Nevin and colleagues[461] have shown that hypocapnia during CPB also results in neurologic injury, whereas others have been unable to confirm that either acid-base strategy for hypothermic perfusion resulted in significant differences.[462] Fullerton and associates[463] have shown that respiratory acidemia in patients with pulmonary hypertension from mitral stenosis results in exacerbation of pulmonary hypertension and that a hypocarbic state may benefit these patients.

The effects of CPB-induced hyperoxia have been thought to exacerbate the pathophysiologic events associated with free oxygen radical formation and GME. In vivo animal studies have further confirmed that hyperoxia induces a reduction in functional capillary density caused by perturbations in leukocyte adherence to the vascular endothelium.[464] In a prospective, randomized study of 48 patients, half of whom had oxygen tensions maintained during CPB between 190 and 300 mm Hg, and half between 75 and 112 mm Hg, patient outcomes were significantly affected by the hyperoxic condition.[465] The patients in the hyperoxic group had decreased RBC rheology, increased bleeding diathesis that required greater transfusion rates, longer ventilator times, and a greater post-CPB complication rate when compared with the normoxic group. Hyperoxemia also has been shown to alter microcirculatory response during both normothermic and hypothermic CPB but was most pronounced during normothermia with increased vascular resistance and a decline in oxygen consumption.[466] A recent randomized, controlled trial involving 67 cyanotic infants found that low-to-normal oxygen tension at the onset of CPB is associated with reduced myocardial damage, reduced oxidative stress, and reduced cerebral and hepatic injury compared with hyperoxic CPB.[467]

The benefits of venous blood gas monitoring have been well accepted in cardiovascular medicine, and the information gained from such assessment has been used to guide therapeutic interventions in numerous clinical situations including critical and intensive care, internal medicine, and surgical services. Changes in both venous P_{CO_2} and P_{O_2} levels have been shown to correlate well with changes in global tissue perfusion.[468] During CPB, the importance of mixed venous oxygen saturation monitoring cannot be overemphasized. This parameter has global utility and is the one parameter universally monitored during most extracorporeal procedures. The mixed venous oxygen saturation is used to calculate whole-body oxygen consumption when, according to the Fick equation, perfusion flow and the oxygen content of arterial blood are also known. As a cautionary note, the interpretation of the mixed venous oxygen saturation must be made with a sound knowledge of any patient conditions that could overestimate or underestimate oxygen delivery and uptake, such as in the presence of anatomic or physiologic shunts, or concentrations of abnormal hemoglobin types. It is beyond the scope of this chapter to review all the currently available in-line blood gas monitors. Readers are referred elsewhere for this information (Box 32.11).[469]

The simplest device for measuring oxygen saturation of blood is an optically coupled dual-wavelength (660 and 900 nm) oximeter that reflects oxygen saturation in flowing blood (Bentley Oxysat Meter; Baxter Health Care Corporation, Irvine, CA).[470,471] The device consists of an optical transmission cell that can be placed in both the arterial and venous lines and uses light-emitting diodes and a photosensitive transistor to measure saturations. Limitations of online saturation monitoring are seen when blood flow is less than 100 mL/min, at which the accuracy greatly declines and the oximeter reads falsely high. Also, simultaneous display of arterial and venous values cannot be performed with this device.

A second type of blood gas monitor uses a microprocessor coupled via two fiberoptic cables with disposable flow-through cells and sensors that have both arterial and venous monitoring capabilities (CDI; Cardiovascular Devices Inc., 3M Health Care, Irvine, CA; see Figs. 32.31 and 32.32).[470,471] The sensors contain pads of fluorescent chemicals, which emit light in response to gas and hydrogen ion changes, with intensity of the light correlated to concentration. The microprocessor then uses predetermined algorithms to calculate bicarbonate levels and base deficit on the arterial side and S_{VO_2}. Calibration of the microsensor is achieved before each operation using tonometered gases. This process takes approximately 20 minutes but can be bypassed and a single-point calibration performed in the event of an emergency.

An alternate technology is the use of online systems for blood gas analysis (Gem Systems; Instrumentation Laboratories, Ann Arbor, MI).[472,473] These machines differ from in-line monitors in a number of ways. First, they provide discrete sampling of blood from either an arterial or a venous line. Therefore they can be used independently of the heart-lung machine and do not require blood flow through cells and sensors for operation. They also function by continuously

correcting for sensor drifts through automatic washings and calibrations. In addition to measuring P_{O_2}, P_{CO_2}, and pH, they measure ionized calcium, potassium, sodium, and hematocrit.

As with the use of any device, standards must be set to ensure that performance is accurate and reproducible, incorporating sensitivity and specificity. In the OR, these standards are usually set by blood gas analyzer machines calibrated and maintained by medical technologists or pathologists according to national regulations and guidelines. The accuracy of in-line monitors compared with standard blood gas analyzers recently has come under question.[473–475] Nevertheless, they provide important information on blood gas and acid-base trends, which are subject to rapid change during CPB.

If inadequate oxygenator gas exchange is suspected, several immediate actions should be performed in troubleshooting the problem. The first step is to check that the gas line is properly connected to the gas inlet port of the oxygenator and to ensure that there are no obstructions, kinks, or leaks in the line impeding the delivery of ventilating gas. An important preoperative check would be to ensure that the disposable 0.2-mm gas line filter is set in the proper direction and that gas passes freely through the filter. Second, the air-oxygen mixer (blender) and flowmeter should be examined to ensure that they are functioning properly. A breach in the gas delivery system may be exacerbated by the use of excessive vacuum on the anesthetic gas scavenging system.[476] The integrity of the gas delivery system may be tested by temporarily occluding the gas supply line near the oxygenator and observing the increase in the gas system pressure on a manometer or by observing a decline in the level of the gas flow meter's indicator ball. Use of a suction bulb to test the gas supply system is an alternative method.[477] Algorithms for solving poor gas exchange have been described.[478] The placement of an in-line oxygen monitor in the gas delivery line will reflect the F_{IO_2} of the ventilating gas. If a blender malfunction or gas supply leak is suspected, the problem may be mitigated by attaching a separate supply of 100% oxygen (ie, a regulated E cylinder of oxygen) directly to the oxygenator gas inlet port. This maneuver will exclude any breach in the gas delivery system, including the oxygen and air sources, the gas blender and flowmeter, and anesthetic vaporizer. If inadequate gas exchange continues, additional checks should include the following: the oxygen consumptive rate of the patient (reflecting metabolic activity), whether the oxygenator was correctly sized to the patient, and oxygenator failure (or any combination of the three). An oxygenator may fail because of deposition of clotted blood or platelets on the membrane surface that interfere with gas exchange. This disruption of the gas exchange surface is characterized by increased pressure excursion across the oxygenator. Measurement of the TMP (preoxygenator minus postoxygenator) may be used to confirm this type of malfunction. Separation from CPB and change out of the oxygenator are indicated should poor gas exchange and an increase TMP occur. Groom and associates[479] described a technique for rapid change-out of an oxygenator during CPB that may be conducted in less than 90 seconds without necessarily discontinuing CPB. Early recognition of an oxygenation problem is paramount because prolonged exposure to hypoxic conditions can cause patient injury. Practice drills aimed at detection and correction of an oxygenator failure should be periodically performed to improve detection and correction of a device failure.

Historically, S_{VO_2} or venous P_{O_2} was considered a good indicator of adequacy of tissue perfusion during CPB.[480–482] In the absence of anatomic or synthetic shunts, the relation between oxygen delivery and uptake is reflected in S_{VO_2}. A further indicator of the adequacy of perfusion is the development of acidosis caused by either a loss of blood buffers or an excess of carbon dioxide. Low S_{VO_2} values are treated by either increasing the delivery of oxygen to the tissues or decreasing oxygen demand. This is accomplished by decreasing the metabolic rate (through hypothermia or anesthesia), increasing pump flow, or increasing the hemoglobin level of the pump perfusate. Each patient must be assessed individually for the condition causing the decline in S_{VO_2}, with specific treatment administered that best corrects the deficit.[483]

Ranucci and colleagues set out to investigated the role of the lowest oxygen delivery, lowest hematocrit, and pump flow during CPB as possible risk factors for ARF and renal dysfunction. They found that the best predictor for ARF and peak postoperative SCr levels was the lowest oxygen delivery, with a critical threshold at less than 272 mL/minute/m^2.[484] A similar threshold for oxygen deliver was subsequently reported by de Somer and colleagues.[485] They also reported that nadir D_{O_2}/V_{CO_2} was also somewhat predictive of renal injury. This work is the premise for the Sorin CONNECT Perfusion EMR (Sorin Group), previously mentioned, with GDP monitoring that is capable of calculating and displaying these values in real time (see Fig. 32.12).

In addition to monitoring oxygenator function and maintaining blood gas homeostasis, the perfusionist is charged with controlling hemodynamic indices of adequate perfusion. What value of MAP provides optimal perfusion remains controversial. The majority of research on target MAP during CPB has centered on cerebral blood flow. However, distant organ and tissue function may be altered by setting standards based on single organ characteristics. Many factors influence cerebral blood flow, including autoregulation,[486] pump flow rate, and acid-base balance.[487,488] It generally is accepted that autoregulation is maintained during CPB when MAP is kept between 30 and 110 mm Hg[486,488] (see Chapter 31). This is true in patients who are neither hypertensive nor suffering from cerebrovascular disease. In both these conditions, standards have yet to be established for MAP control that would ensure adequate perfusion, although most would agree that maintenance of greater perfusion pressures is justified. In the presence of atherosclerosis, the changes in viscosity induced through hemodilution will increase flow to the microcirculation by reducing SVR. Pulsatile CPB will result in increased capillary patency when compared with nonpulsatile perfusion, even at the same MAP; this is discussed in the next section.

Pulsatile Versus Nonpulsatile Flow

When designing early extracorporeal systems, engineers and clinicians attempted to mimic the body's normal hemodynamic state. The earliest pumps, therefore, were designed to deliver a pulse waveform and were complicated devices that required specific engineering skills to operate. In the late 1950s and early 1960s, several events led to the decline of pulsatile flow as a preferred method in the conduct of perfusion. These included the complexity of pumping systems and the realization that patients tolerated periods of nonpulsatile flow without significant morbidity. The physiologic benefits of pulsatile flow are a direct function of the transmission of energy into the blood, from which it is transduced to tissue.[489] It is now realized that earlier comparisons between the two methods of CPB were fraught with methodologic insufficiencies that may have artificially negated the beneficial effects of pulsatile perfusion. The elegant studies of Taylor[490] and others[491–495] have resurrected interest in pulsatile perfusion and resulted in a heightened awareness of its potential benefits. Wright[496] summarized the relationship of the human heart and pulsatile flow in transmitting power to the microcirculatory bed to facilitate fluid movement into the tissues.

The most common operational methods used to generate a pulse wave include alternating the flow rate of the RP or CP or using an intraaortic balloon pump during CPB to generate a pulse wave form. Pulsatility is produced in a RP accelerating during the systolic phase and decelerating in diastole. The pulse wave is defined by setting the cyclic rate (pulses/minute), the cyclic width (the percentage of the time the pump operates at high speed for each cycle), and the percentage of the base flow rate (the percentage of the continuous flow rate). Pulsatile flow produced with CPs has characteristically poorer wave morphology, and there is some evidence that it is less effective.[497] Alternating occlusion systems, such as those used in VADs and artificial hearts, use intermittent occlusive-phase generators to produce a pulse wave. The physiologic benefits of pulsatile perfusion are related to the geometry of the pulse waveform. These include the rate of rise of flow

and/or pressure in the central aorta, as well as the total amplitude of the pulsation.[490,491]

Pulsatile perfusion has been classified by three general theories that attempt to establish quantitative methods of comparison.[490] The theory of energy-equivalent pressure (EEP) states that the benefits of a pulse wave are related to the energy content within the pulsation.[491] The pulsatile arterial wave dissipates energy, used to produce the pulse wave, to the tissues:

$$\text{EEP} = \int \text{P}f\text{d}\text{T} \Big/ \int f\text{d}\text{T}$$

where P = pressure (mm Hg), f = flow (mL/sec), dT = change in time. The increase in energy developed by a pulse waveform is made available to the tissue, which results in maintaining capillary patency, increasing tissue lymph flow, and stimulating cellular metabolism.[494,498] The second theory is that of *capillary critical closing pressure,* which states that peaks of pulsatile systolic pressure will ensure greater flow through the microcirculation by maintaining capillary caliber for greater periods, when compared with nonpulsatile flow. The critical closing pressure at precapillary arterioles, which obliterates tissue perfusion, occurs at higher levels with pulsatile perfusion. Finally, the theory of *neuroendocrine reflex mechanism* is based on the fact that baroreceptors respond to both static and pulsatile aspects of an arterial pressure wave. The baroreceptor mechanism of nonpulsatile perfusion causes a marked increase in discharge frequency of the carotid sinus baroreceptors, inducing reflex vasoconstriction in the systemic circulation.

The concepts of EEP and surplus hemodynamic energy (SHE) have been introduced in studies using pulsatile and nonpulsatile flow. Their main advantage lies in their focus on energy gradients rather than pressure gradients as the driving force of blood flow. These formulas can precisely quantify different levels of pulsatility and nonpulsatility, allowing direct and meaningful comparisons.[499,500]

$$\begin{aligned}\text{SHE (ergs/cm}^3) &= 1{,}332\left[\int_{t1}^{t2} fp\,dt \Big/ \int_{t1}^{t2} f\,dt\right] - 1{,}332\ \text{MP} \\ &= 1{,}332\text{EEP} - 1{,}332\text{MP} \\ &= 1{,}332(\text{EEP} - \text{MP})\end{aligned}$$

The benefits of pulsatile perfusion during CPB include increased blood flow in the microcirculation,[493] reduced fluid overloading and "third spacing,"[494] and decreased release of baroreceptor reflex hormones, which limit reflex vasoconstriction.[494] Pulsatile perfusion has been shown to increase renal, cerebral,[493] and pancreatic[492] flow. In a prospective, double-blind study, Murkin and colleagues[501] recently identified nonpulsatile perfusion as a significant risk factor for postoperative morbidity. In a review of pulsatile perfusion, Hornick and Taylor[502] have identified certain high-risk patients as being particularly susceptible to postoperative morbidity when nonpulsatile perfusion techniques are used. They identified patients as being at risk if they presented with any of the following conditions: occult coronary artery disease, significant preexisting atherosclerosis, chronic arterial hypertension, and chronic organ insufficiency. The authors advocated pulsatile perfusion as a treatment of choice.

More than 150 basic science and clinical investigations that directly compared pulsatile and nonpulsatile perfusion have been published. Although there is an extensive body of literature, there remains uncertainty about the effects of pulsatile perfusion on clinical outcomes.[503] Henze and others[504] compared patients undergoing CABG surgery and found no difference in neurologic outcome in patients treated with either pulsatile or nonpulsatile CPB. In a similar study, Azariades and associates[505] questioned the benefits of pulsatile flow on the stress-related release of cortisol and were unable to show any differences between patients treated with either pulsatile or nonpulsatile flow. Taggart and colleagues[506] studied pulsatile perfusion and its effects on limiting post-CPB endotoxemia in a prospective randomized study of 60 patients. There were no differences in endotoxin levels, complement fragments, or granulocyte elastase between nonpulsatile or pulsatile perfusion groups at any time. Ohri and others[507] evaluated pulsatile and nonpulsatile perfusion on gastric mucosal perfusion and found that pulsatility showed clinical benefit only during normothermic periods and was lost when moderate (28°C) hypothermia was used (see Chapter 31). The sample size and variation in the quality of pulse characteristics in individual studies has lead to inconclusive results.[508,509] Metaanalyses by Nam and colleagues[510] and Sievert and colleagues[511] both showed improvements in renal function. Sievert's further reported that the studies with intraaortic balloon pump (IABP) generated pulsatile flow had the best results and also noted significant reduction in lactate levels in the pulsatile groups.[511] Zangrillo and colleagues carried out a metaanalysis of preoperative use of IABP in 625 high-risk CABG patients and reported a significant reduction in 30-day mortality (risk ratio 0.38 p for effect 0.004).[512] More recently, Lim and colleagues undertook a metaanalysis to look at pulmonary function with pulsatile perfusion and found a significant improvement in pulmonary function and ICU length of stay.[513] Clearly pulsatile flow is an area ripe for future RCTs or observation studies from clinical registries. Growing evidence suggests that it improves end organ function, yet it is not commonly utilized clinically.

Methods of Extracorporeal Circulation

The techniques involved in the practice of ECC have evolved largely from the conduct of CPB during CABG surgery, valvular surgery, congenital cardiac surgery, or a combination of the three. Applications involving alternate means of ECC transcend the conduct of routine CPB and have included various specialties such as neurosurgery, vascular surgery, and general thoracic surgery. The limitations of incorporating ECC in the treatment of disorders once thought not to be amenable to this process now are being reevaluated because of advances in enhancing the biocompatibility of extracorporeal circuits and components.[514,515] This section focuses on the evaluation of new techniques, as well as the reexamination and elucidation of previously accepted practices.

Left-Heart Bypass

Total CPB is attempted in most situations in which the heart will be rendered quiescent to facilitate surgical manipulation and repair, usually involving the administration of cardioplegia. In certain situations, however, the need to arrest the heart is obviated when the surgical repair can be performed without interfering with normal circulatory flow patterns. An alternate situation also arises when the surgery is performed at some point distant from the heart, through incisions not suitable for normal cannulation sites for CPB. *Left-heart bypass* (LHB) and *right-heart bypass* (RHB) are terms used to denote the process whereby univentricular diversion of flow is performed by the creation of a parallel circuit to blood flow. Although this definition also serves as a description for a VAD, in the OR, each term has a specific distinctive meaning, and they are not used interchangeably. LHB is a technique often used in repair of descending thoracic aortic aneurysms (see Chapter 23). Without the use of LHB, cross-clamping of the descending aorta results in a tremendous increase in afterload and a decrease in CO, most likely the result of increased ventricular end-diastolic volumes and reduced ejection fractions.[516] The major purpose of LHB is to ensure adequate perfusion to the distal body, which should reduce the potential for paraplegia caused by hypotension and tissue hypoxia.[517,518] The ensuing discussion primarily focuses on LHB because of its predominant use, although RHB is performed during certain procedures in pediatric cardiac surgery, such as reoperation for right ventricle-to-pulmonary artery conduit replacement.

The term *LHB* is somewhat of a misnomer because it denotes the bypassing of *all* flow through an ECC around the left ventricle. This rarely occurs. Instead, the technique is a form of partial LHB that enables the perfusionist to vary the preload of the left ventricle, thereby controlling the volume of blood ejected into the aorta. This alteration in preload therefore directly affects the patient's hemodynamic status and is influenced by the rate at which volume is shifted from the left

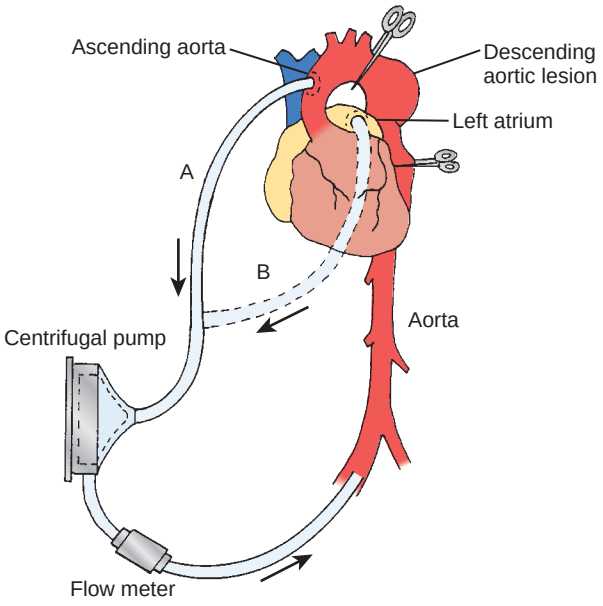

Fig. 32.41 Left-heart bypass with use of a centrifugal pump. *A* is the inflow from ascending aortic cannulation, and *B* is the inflow from left atrial cannulation.

heart. It has been reported that during LHB with seemingly adequate reduction of preload, ventricular dysfunction, as evidenced by TEE, can occur.[519] The most frequently used applications of LHB include repair of thoracic aneurysms or dissections involving the descending aorta, thoracoabdominal aneurysms,[520] and coarctation of the aorta. The bypass circuit used in LHB is an extremely different variation from that used during total CPB, and these differences must be understood by the anesthesiologist to facilitate patient management.

The most prominent difference in the conduct of partial LHB compared with total CPB is the absence of an oxygenator from the circuit. Therefore it is impossible to augment the ventilatory capacity of the patient during LHB. Fig. 32.41 shows the typical LHB circuitry with the use of a CP as the main drive unit.[517] The entire circuit usually consists of two 6- to 8-foot sections of 3/8-inch polyvinylchloride tubing, which have been attached to the inflow and outflow ports of the centrifugal head. Besides not having an oxygenator, the circuit contains neither a cardiotomy reservoir nor a venous reservoir, so that fluids cannot be added to the circuit. The cannulation sites vary, with the most frequent techniques involving drainage from the LA and return to the femoral artery. Purse-string sutures are placed in either the left atrial appendage or superior pulmonary veins for draining blood from the LA. Left atrial cannula size varies, but in most adult patients, the typical single cannula ranges from 32 Fr to 40 Fr. Alternate cannula locations for draining blood from the heart involve the ascending aorta or the left ventricular apex. Blood is returned to the patient via isolation of the femoral artery by cutdown technique, with retrograde flow into the abdominal aorta. The typical cannula sizes used for femoral artery cannulation range from 16 Fr to 22 Fr. Alternate cannulation sites for the return of blood include the descending thoracic aorta.

Management of the patient during LHB can be accomplished only by a combined effort between the anesthesiologist and perfusionist. The risk for perioperative bleeding is high because of the combined use of prosthetic graft materials and large anastomotic sites.[520] For this reason, minimal anticoagulation is used, with a low dose of systemic heparin to increase the activated coagulation time to approximately two times baseline. The use of heparin-bonded circuits in these patients may offer distinct benefits in reducing bleeding associated with systemic heparinization.[514] The regulation of volume is primarily controlled by the rate of blood removal from the LA, which is a function of pump flow. As the pump flow is increased, the rate of emptying of the LA concomitantly increases, reducing the flow into the ascending aorta, which reduced MAP. At the same time, the return of flow to the femoral artery is increased. Likewise, as the pump flow is decreased, the amount of blood ejected into the ascending aorta is increased, with a resultant increase in proximal aortic MAP. With the initiation of LHB, MAPs remain identical in the absence of significant restrictions in the descending aorta. When the upper body circulation is isolated from the lower body circulation by the placement of vascular clamps, the two circulations are separated and pulsatile flow is lost in the lower body. At the time of aortic clamping, the proximal aortic pressure increases precipitously as a result of the dramatic change in afterload. The next several minutes of LHB are usually the most difficult to control, with frequent shifts in pressure and flow most likely a function of baroreceptor response. Radial artery pulsatile pressure is maintained at around 120/80 mm Hg, whereas the femoral artery MAP is maintained between 50 and 70 mm Hg, with a flow rate of 50 mL/kg. Filling pressures, measured with a pulmonary artery catheter or left atrial catheter, usually decline by approximately 50%. Once these flow parameters have stabilized, any alteration in hemodynamics should be adjusted either by pharmacologic control or by fluid replacement. Drugs used most often to treat the initial hypertension are nitroprusside, nitroglycerin, and inhalation agents. Other commonly used drugs are phenylephrine, epinephrine, dobutamine, and dopamine.

Methods of volume replacement during repair of thoracic aortic aneurysms must be considered carefully before the start of the case because the potential for rapid blood loss is high. Rapid-infuser devices capable of large volume transfusions over short periods often are used because the LHB circuit has no capability for replacing volume. The success of LHB is directly dependent on the establishment of excellent communication among the surgeon, anesthesiologist, and perfusionist.

Cerebral Protection During Circulatory Arrest

As mentioned in the previous section, aneurysms of the descending thoracic and abdominal aorta represent a major challenge to the anesthesiologist, surgeon, and perfusionist in developing plans for patient management. Aneurysms involving the ascending and/or transverse aortic arch represent a distinctly different challenge for which the plan of ECC differs greatly. The current options for managing patients with these lesions include deep hypothermic circulatory arrest (DHCA),[521–523] retrograde cerebral perfusion (RCP),[524–526] and selective cerebral perfusion of one or more brachiocephalic vessels[527–529] (see Chapters 23, 26, and 31). The next three sections review some of the specific practices involved in managing a patient with these challenging lesions.

Deep Hypothermic Circulatory Arrest

Use of various methods of DHCA has long been standard practice in treating pediatric patients with congenital heart disease. This technique also has been efficacious in treating various other critical disease processes, including neurologic lesions and renal cell carcinoma.[530–532] More recent adaptations in ECC practices have questioned the need for DHCA in select patients[326,533] and have stressed the benefits of low-flow hypothermic perfusion in preserving neurologic function.[534]

The primary determinant in selecting an extracorporeal technique for treating various lesions is ensuring cerebral protection through the maintenance of either adequate perfusion or sustained protection. Although the morbidity associated with CPB has declined significantly over time, perturbations of the central nervous system remain a significant factor in assessing postoperative neuropsychologic dysfunction[535] (see Chapter 40). Many factors have been shown to affect cerebral blood flow during CPB, including MAP, viscosity of the perfusate, cannula placement, and/or the presence of carotid stenoses. However, in the absence of mechanical limitations, one of the most influential factors affecting cerebral blood flow is acid-base management,[536] specifically, the control of $PaCO_2$.[537,538] Concurrent use of hypothermia with CPB has been shown to be an effective treatment in reducing organ and tissue oxygen demands. However, the use of DHCA results

in metabolic deregulation and changes in membrane integrity, altering cellular maintenance.[539] Hemorrhagic complications induced by DHCA frequently are encountered, necessitating the use of prophylactic transfusion replacement therapy to correct bleeding diathesis.[540,541] Fox and colleagues[542] have shown that, when cerebral temperatures of monkeys were cooled to 20°C, the whole-brain blood flow was decreased concomitantly with the reduction in systemic flow, but the proportion of total flow to the brain was increased. Furthermore, brain oxygen extraction increased as perfusion flow declined, which was unlike other tissue beds in the body. It has been shown that even when nasopharyngeal temperatures are reduced to 15°C, severe cerebral hypoxia quickly develops once DHCA is achieved.[543]

The extracorporeal techniques of DHCA are centered around the regulation and control of circuit and patient temperatures. Core cooling of the patient is achieved through high-flow CPB with cooling temperatures never exceeding 10°C differences between the perfusate temperature (circuit) and the patient core (rectal, bladder) temperature. The perfusate temperature is maintained between 10°C and 15°C during cooling. Other temperatures that can be measured include esophageal, nasopharyngeal, tympanic, and skin temperature. Both tympanic and nasopharyngeal temperatures are remeasured to reflect brain temperatures. The depth of cooling remains controversial, with most clinicians choosing to monitor electroencephalographic activity. Once the electroencephalogram is isoelectric, usually between 15°C and 20°C nasopharyngeal temperature, the patient is cooled for another 5 to 10 minutes before initiating DHCA. Such a technique promotes further global cooling. Some authors advocate monitoring jugular venous bulb oxygen saturation and terminating perfusion only after the saturation is greater than 95%.[544] The period of safe circulatory arrest will vary from patient to patient and depends on a large number of variables, including the degree of preexisting neuropathy, the transmural cooling profile of the brain, and reperfusion-related phenomena. In general, the limit of safe circulatory arrest time in adult patients undergoing profound hypothermia is between 40 and 50 minutes.[544,545] Other authors have successfully monitored brainstem activity with somatosensory-evoked potentials for determining the optimal temperature for circulatory arrest.[546] Surface cooling of the cranium is performed by packing the head with ice at the onset of cooling and throughout the DHCA period.

Warming should be accomplished following the same principle of no greater than a 10°C temperature differential between the core and perfusate temperatures. Patients tend to warm at the same rate at which they were cooled. However, the warming rate should never exceed 1°C core temperature increase per 3 minutes of bypass time. Use of vasodilators to facilitate distal perfusion is warranted and treatment of metabolic acidosis should proceed vigorously. Termination of warming should occur when the nasopharyngeal temperature is between 35°C and 36°C. This mild hypothermia provides additional cerebral protection in the early postoperative period.

The use of barbiturates in providing added cerebral protection has not been clearly defined, and their benefits in cardiac surgery may be related to their early use at the onset of surgery.[547] Barbiturates may possibly provide protection by reducing intracranial blood volume, pressure, and edema, as well as acting as oxygen free radical scavengers.[548–550] The level at which barbiturates provided effective protection was seen at doses that abolished synaptic transmission and electrical activity,[548] which in one study was achieved with a mean thiopental dose of 39.5 mg/kg.[547] However, these patients had depressed myocardial contractility and required longer pulmonary recovery periods. It is not known whether barbiturates and hypothermia have an additive effect on cephaloplegia, but profound cerebral depressant effects are seen during CPB with thiopental doses of 8 to 24 mg/kg at 25°C to 30°C.[550]

The term *cerebroplegia* has appeared in the literature, and it reflects isolated pharmacologic manipulation of the perfusate delivered to the brain.[529,551] The authors in both studies advocated the use of either sanguineous[529] or asanguineous[551] oxygen-rich solutions to protect the brain via carotid perfusion during low-flow hypothermic CPB.

Retrograde Cerebral Perfusion

Despite the relative safety of DHCA, there is a finite time limit for nutrient decoupling before irreversible central nervous system damage occurs. In 1990, Ueda and colleagues[524] described a technique of RCP and circulatory arrest that provided perfusion of arterialized blood to the cerebral vasculature during the period of circulatory arrest. The use of RCP had been described previously as a treatment for catastrophic air embolism arising during CPB.[552] This technique provides an alternative to selective cerebral perfusion that requires cannulation of one or more of the brachiocephalic vessels and is considered technologically challenging. Although there are similarities in patient management between DHCA and RCP, the major difference has to do with the placement of a cannula into the superior vena cava (SVC) (Fig. 32.42). This can be accomplished with either bicaval cannulation or with an isolated SVC cannula and a dual-stage right atrial cannula.[553] The use of a retrograde cardioplegia cannula placed in the SVC may be desirable because it also contains an end-lumen pressure port for monitoring infusion pressure. During the period of circulatory arrest, blood flow is directed away from the systemic circulation and into the SVC retrograde into the cerebral venous system. The perfusion pressure of RCP as measured in the SVC or jugular vein should be maintained between 20 and 40 mm Hg. Flow rates for RCP range between 250 and 500 mL/min. The temperature of the cerebral perfusate usually ranges between 15°C and 18°C, and despite these cold temperatures, desaturated blood is seen returning from the arch vessels.[544]

Some of the benefits of RCP include the maintenance of cerebral temperature via the delivery of a hypothermic perfusate, a decreased risk for air and atheromatous debris from open brachiocephalic vessels, and a continuous delivery of nutrients to the cerebral tissue. Stroke rates also have been shown to be significantly reduced with the use of RCP.[525] Potential problems with RCP include increased cerebral venous resistance caused by cortical vein collapse, the presence of competent jugular valves, which restrict perfusate delivery, and questionable delivery of nutritive flow to the target tissue.[526]

Selective Cerebral Perfusion

Initial efforts to protect the brain during repair of lesions requiring circulatory arrest included the isolated cannulation of brachiocephalic vessels.[554,555] The primary mandate for ECC is the protection of the central nervous system, and selective cerebral perfusion remains attractive because it supplies a continuous source of nutritive perfusate to metabolically active brain tissue during circulatory arrest. Similar to RCP, by continuously perfusing the brain, the extracorporeal management of the patient can be modified with the lower levels of hypothermia and an extension of the period for surgical repair.[527,528]

The technique of selective cerebral perfusion involves the cannulation of one or more of the brachiocephalic vessels or axillary arteries with small (8 Fr to 14 Fr) cannulae that are connected to a separate circuit with a dedicated heat exchanger (Fig. 32.43). During this technique, the systemic ECC continues to perfuse the patient via femoral cannulation with cold (20°C to 28°C) perfusate at a rate of 60 to 70 mL/kg/min. Arterialized blood is drawn from the oxygenator through a separate pump, either roller or centrifugal, and passed through a cardioplegia heat exchanger (Fig. 32.44) that decreases the temperature to approximately 15°C. The perfusate then passes through a 40-μm filter before perfusing the brachiocephalic vessels. Flow rates to the brain are controlled between 5 and 10 mL/kg/minute, with a perfusion pressure at the circuit kept under 150 mm Hg. As with RCP, acid-base homeostasis is maintained according to alpha-stat principles. Oxygen extraction is assessed through measurement of the venous oxygen saturation returning to the SVC cannula. Because autoregulatory mechanisms in the brain have been shown to be maintained at low blood temperatures (20°C), cerebral blood flow should be adequate under these conditions.[556]

The problems associated with selective cerebral perfusion arise from the use of a secondary circuit and additional cannulation sites. The risk for embolization of atheromatous matter may be of concern because of the additional manipulation of the arch vessels, and the

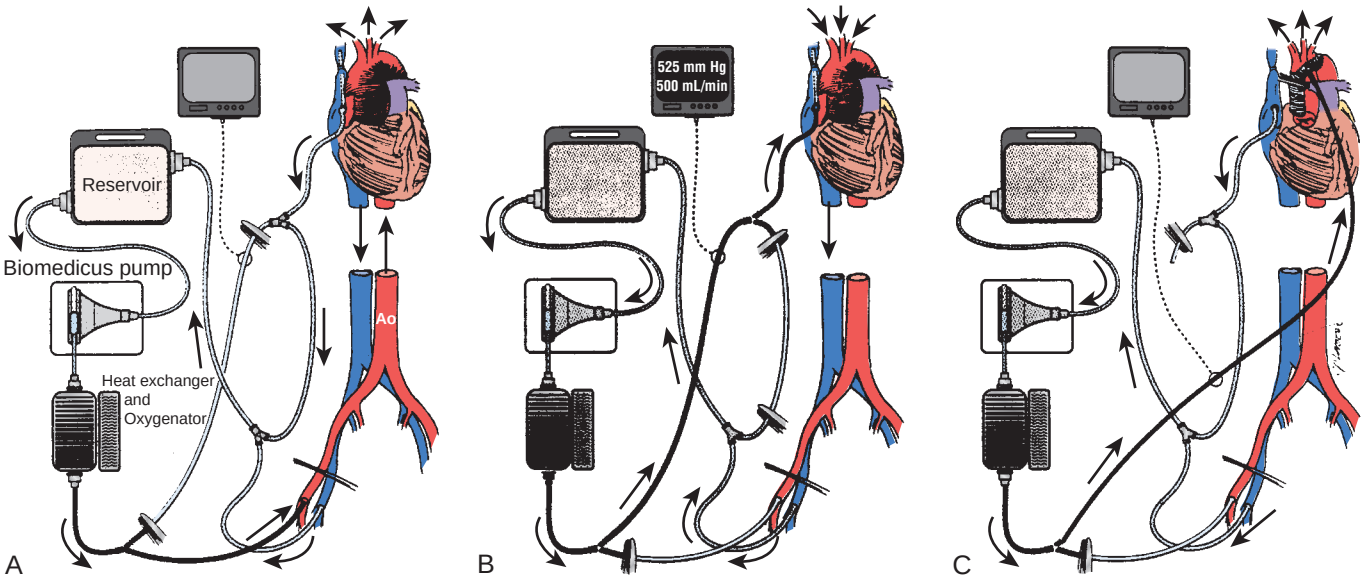

Fig. 32.42 Extracorporeal circuit design for retrograde cerebral perfusion. (A) Cooling period. Venous drainage occurs from superior vena cava and femoral vein cannulae with arterial return to the femoral artery. (B) Retrograde cerebral perfusion with circulatory arrest. Oxygenated blood flows from the arterial line into the superior vena cava, and pressure and flow are monitored. (C) Warming period. presence of additional cannulae also clutters the field.[544] When multiple cannulae are utilized connected to a single RP, the downstream flow cannot be independently determined without individual monitoring devices for each line. This is not of major concern because of the anatomic nature of the circle of Willis and distribution of cerebral blood flow. The improved safety resulting from technologic enhancements to pressure control modules and air detection systems of heart-lung machines makes these arguments moot. Monitoring of jugular bulb oxygen saturations or cerebral oxygenation with near-infrared spectroscopy provides feedback information that is used to adjust flow rates and delivery pressures so that adequate delivery of oxygen is matched with extraction rates.[528,557]

Communication and Teamwork

The American College of Cardiology (ACC) and the American Heart Association (AHA) in a scientific statement on safety in cardiac surgery reported that communication skills have been measured as the worst aspect of team behavior in the cardiac OR and that communication failures are the most common cause of errors and adverse events.[558] Teamwork failures occurred frequently during cardiac surgery (5.4 per case with familiar teams and 15.4 per case with unfamiliar teams).[559] Breakdowns in teamwork that lead to surgical flow or operative disruptions are exceedingly common, having been noted at a rate of 17.4 per hour in one cardiac surgery study[560] and at 11 per case in another.[561] The AHA Scientific Statement on Safety in Cardiac Surgery task force published a list of suggested improvements titled "Opportunities to Facilitate Translation of Current Knowledge Regarding Communication and Teamwork Into Clinical Practice" (Box 32.12).

Most human errors emanate from three specific failures: a failure of perception (things are not as they appear), a failure of assumption (the 10-mL vial in the middle drawer with a blue label is always heparin), and a failure in communication. It is always possible for an individual to fail; however, through teamwork and communication, a system can be designed that is highly reliable in which potential errors are mitigated through situational awareness and communication. Although one team member's perception may be distorted at times, another team

BOX 32.12 OPPORTUNITIES TO FACILITATE TRANSLATION OF CURRENT KNOWLEDGE REGARDING COMMUNICATION AND TEAMWORK INTO CLINICAL PRACTICE

1. Checklists and/or briefings should be implemented in every cardiac surgery case, and postoperative debriefings should be encouraged by leadership in cardiac operating rooms *(ORs; Class I; Level of Evidence B)*.
2. Team training to improve communication, leadership, and situational awareness should be implemented in cardiac ORs and should involve all members of the cardiac operative team *(Class I; Level of Evidence B)*.
3. Formal handoff protocols should be implemented during transfer of the care of cardiac surgical patients to new medical personnel *(Class I; Level of Evidence B)*.
4. It is reasonable to conduct event scenario training for significant and rare nonroutine events (ie, emergency oxygenator change out) on a regular basis that involves the complete cardiac surgery team *(Class IIa; Level of Evidence C)*.
5. It is reasonable to conduct future studies of teamwork and communication that (a) investigate optimal communication models (eg, briefings and structured communication protocols in the cardiac surgical OR); (b) investigate team-training models to determine the "best product" for use in the cardiac OR; (c) investigate impediments to implementation of formal training in teamwork and communication skills; (d) include long-term studies of the sustained impact of such training on provider outcomes (eg, attitudes regarding safety, compliance with best practices, and communication skills); (e) investigate efficacy of formal training in teamwork and communication skills in improving patient outcomes (eg, satisfaction, blood product use, infections, intensive care unit readmissions, mortality, and costs); and (f) include establishment of an anonymous national multidisciplinary event-reporting system to obtain data about events and near-misses *(Class IIa; Level of Evidence C)*.

From Wahr JA, Prager RL, Abernathy JH 3rd, et al. Patient safety in the cardiac operating room: human factors and teamwork: a scientific statement from the American Heart Association. *Circulation*. 2013;128:1139–1169.)

member may detect a problem. Clinicians are prone to assume that aspects of the working environment are reliable. In highly functional teams, the members have an expectation that there will be failure and are constantly observing and questioning. Highly functional teams utilize a shared mental model of expectations that trusts and encourages everyone in the OR to be comfortable speaking up if something of concern is observed. Communication failures are the leading cause of inadvertent patient harm. Analysis of 2455 recent sentinel events reported to the Joint Commission for Hospital Accreditation showed that the primary root cause in more than 70% was communication failure, and approximately 75% of these patients died of their injuries.[562,563] An estimated 234 million patients undergo surgical procedures and more than 1 million succumb to complications related to the surgery, many of which are related to how the surgical team interacts and communicates. Use of a simple checklist could have prevented half of these deaths each year.[564] The World Health Organization has designed a checklist that serves as a tool to enhance communication within a team. The checklist has been tested in eight cities around the world and resulted in a reduction of mortality from 1.5% to 0.8% ($P = 0.003$) and a reduction of inpatient complications from 11.0% to 7.0% ($P > 0.001$). Checklists also should be used to improve reliability of infrequent tasks or unexpected occurrences. For example, a checklist may be used to improve the reliability of completing all of the required interventions before the initiation of DHCA (head packed in ice, cooling blanket on, steroids given, acid-base balance corrected, and timer started). Checklists help clinicians perform simple tasks reliably and allow more cognitive engagement for the things that are complicated and complex.

It is important to see variation as an opportunity to improve and to diminish the likelihood of errors. The perfusion team at Boston Children's Hospital have developed a novel system to record unexpected events and bring about subsequent action to prevent a future occurrence.[565]

Communication and safety training transformed aviation into a highly reliable industry. Gladwell[566] described a pathologic type of communication that he referred to as "mitigated speech." Mitigated speech is a tendency to downplay or sugar-coat the meaning of what is being said. This occurs when an individual experiences a problem but there is a reluctance to speak up about it, when trying to be polite, when ashamed or embarrassed, or when being deferential to authority. The key to breaking this pattern of flawed communication is for leaders to understand that their number-one job is to get the best performance possible out of their team, acknowledge their own fallibility, and let those who work on the team know that they are expected to speak up about anything unusual or anything that is of concern.

More commonly, communication may be difficult because of an abrasive or difficult team member whose behavior exasperates staff. Recipients of this type of behavior can be at a loss for words to respond to this type of abuse. The danger is that communication may be avoided with difficult individuals because it is too painful and frightening to engage such an individual. Frankel[567] has described the "Five Cs," a pattern for responding to individuals who exhibit this type of abusive behavior. The scripted responses to this abuse are designed in a way that one learns to escalate until the pattern is broken. A respondent begins with 1: "I'm *Curious* about why you …" If this is not effective, then escalate to 2, "I'm *Concerned* that …" or 3, "I'm feeling *Challenged* by this problem we are having …" then 4, "We need to *Collaborate* with ____ to get another point of view …" If all else fails, then the fifth "C" is to activate the "*Chain of Command*" and involve leadership in resolving the issue.

Often leaders are not aware of how disruptive their behavior is to the team. They perceive themselves as good communicators and collaborators. Makary and colleagues[568] used a survey to examine the perceptions of collaboration among 3000 team members in the OR. The survey revealed drastic differences in how professional groups in the OR perceived the quality of collaboration of other professionals. For example, 84% of surgeons reported good collaboration with anesthesiologists; however, only 70% of anesthesiologists reported

good collaboration with surgeons. Furthermore, 88% of surgeons thought there was good collaboration between surgeons and nurses, whereas only 48% of nurses considered surgeons good collaborators with nurses. Until recently, relationship issues have been unexplored. There is a growing interest in studying the culture in the OR. The Agency for Healthcare Research and Quality (AHRQ) has responded to requests from hospitals interested in comparing their safety culture survey results with those of other hospitals. AHRQ funded the development of a comparative database on the survey in 2006.[569] The database is composed of voluntarily submitted data from US hospitals that administered the survey. Comparative database reports were produced in 2007 and 2008 and will be produced yearly through at least 2012. Survey elements for the AHRQ survey are shown in Box 32.13.

Overall, survey respondents to the AHRQ survey reported that the level of teamwork is generally quite good. The areas surveyed that appeared to be opportunities for improvement include development of a nonpunitive response to error, handoffs and transitions, and the number of events reported. These surveys are valuable in that they identify areas where there is an opportunity to improve. The survey results can be used as a tool to help leaders to become knowledgeable about the culture within units and professional groups and lead to the development of training and exercises to improve the safety culture.

Perfusion Simulation

Catastrophic perfusion incidents require the delivery of a complex, coordinated response by the perfusionist within a very short timeframe.[570] Human factors research has shown that simulation of clinical events prepares the clinician for an unexpected event by attenuating a clinician's emotional arousal to a level that allows optimal performance.[571] Pioneering work in CPB simulation was reported by Riley and colleagues in 1977[572] and 1984,[573] who built their system on an IBM personal computer platform and predicted that these systems would mature as processing power, storage, and display technology improved. The aim of their work was to develop systems that would simulate important processes that occur during CPB and would reinforce thought processes that would be dangerous and impractical to conduct in the clinical setting. Later, Austin and colleagues[574] emulated the Air Force's flight simulation model by designing a simulation training model for cardiovascular perfusion education. Orpheus, the first commercially available system, is a computer-controlled hydraulic model of human circulation, intended for use in the training of personnel involved in the procedure of CPμ[10] (Fig. 32.45). The system can be used in a number of educational settings (Box 32.14). It may be easily configured to simulate a number of routine and nonroutine scenarios (Box 32.15). Similarly, the Califia simulator has a hydraulic interface that provides a high-fidelity responsive display to changing patient or CPB parameters. In addition to actual changes in flow rate, restriction of venous return, or other pump parameters, the test subject may make changes to oxygenator settings, request blood tests, or display other test results such as cerebral saturation or echocardiography displays (Figs. 32.46–32.48). In the educational setting, a simulator provides a standardized experience and evaluation process for students. The simulation setting allows the student to experience the cognitive challenge, stress, and physical demands in a setting far removed from an OR. Students or experienced perfusionists may be subjected to a particularly challenging clinical problem over and over again, and their response to the clinical problem can be accurately evaluated.[575] Ninomiya and colleagues have developed a simulator for adult and infant perfusion crisis management.[576] The system reports the relative percent of the time the adult's or infant's hemodynamic parameters are maintained within range. The authors believe that these systems will supplant recertification requirements based on completing an actual number of clinical cases with periodic required simulation examinations (see Chapter 17).

"Orpheus" cardiopulmonary bypass simulation system.* J Extra Corpor Technol. *2007;39:228–233.)*

Periodic performances of drills that simulate various CPB crises may be conducted in any OR setting using a mock setup and scripted scenarios. A survey of 314 perfusionists from centers in the Northeastern region of the United States in 2002 revealed that 97% of the perfusionists surveyed believed that such practice drills would be beneficial; however, only 17% reported that such drills are conducted at their centers.[577] A wide range of reasons was reported for not doing so: left up to the individuals to maintain proficiency (19 [39%]), not motivated (11 [22%]), confident of proficiency (9 [19%]), no time (8 [17%]), dubious value (1 [2%]), and cost prohibitive (1 [2%]).

BOX 32.15 ROUTINE AND NONROUTINE PERFUSION SIMULATION SCENARIOS

- Routine bypass
- Initiation of bypass
- Weaning from bypass
- Cooling and rewarming
- Use of centrifugal pumps
- Variations in patient resistance
- Variations in patient coagulability

Summary

Substantial innovations and improvements have been made in CPB devices and techniques over the past six decades, and the use of CPB has increased from a few hundred procedures per year at a handful of centers around the world in 1955 to the current rate of more than a million procedures performed per year at a few thousand centers worldwide. Great strides have been made in conserving blood and reducing transfusions, attenuation of the systemic inflammatory response, and organ protection. Despite the many advances and widespread use of CPB, there remain substantial opportunities to improve devices, techniques, and safety. Certain techniques have demonstrated

sound evidence for efficacy—for example, miniaturized CPB systems, modified UF for adults, and pulsatile flow during CPB—but have not been adopted into clinical practice. Perfusion devices will continue to improve with the introduction of improved design and the introduction of improved gas exchange surfaces and biocompatible surface coatings. The use of computer technology, human factors, science, and simulation training will improve the operator-machine interface and the nontechnical skills of teams, further enhancing safety and improving patient outcomes.

Extracorporeal Membrane Oxygenation

JACOB T. GUTSCHE, MD | HARISH RAMAKRISHNA, MD, FASE, FACC

KEY POINTS

1. Extracorporeal membrane oxygenation (ECMO) has had a profound resurgence as therapy for acute cardiopulmonary failure.
2. Advancements in equipment and improvements in techniques and management have led to better outcomes for patients undergoing ECMO.
3. Venoarterial (VA) ECMO should be considered for patients with acute cardiac or combined cardiac and respiratory failure.
4. Venovenous (VV) ECMO is indicated for patients with adequate cardiac function in the setting of severe acute respiratory failure refractory to standard management.
5. Cerebral hypoxia can complicate the management of patients on VA ECMO who have pulmonary failure and recovery of cardiac function.
6. Complete cardiac rest for patients on VA ECMO may require placement of ventricular drains or assist devices to prevent ventricular distention.
7. Bleeding and thrombosis remain the two most common complications associated with ECMO.
8. Careful titration of anticoagulation may require multiple laboratory modalities, including a heparin assay to guide anticoagulation management.
9. ECMO can produce changes in drug pharmacokinetics that may affect systemic concentrations of lipophilic or highly protein-bound medications.
10. ECMO is increasingly used for newer indications such as acute pulmonary hypertension and accidental hypothermia and to facilitate surgery in patients with compromised pulmonary or cardiac function.
11. Walking ECMO (ie, awake ECMO) can provide a bridge to transplantation for patients with end-stage lung disease.

The development of modern extracorporeal membrane oxygenation (ECMO), also called extracorporeal life support (ECLS), for cardiopulmonary support can be traced to the original heart-lung machine, which was designed by Gibbon and first successfully used for cardiac surgery in 1953.[1] The original cardiopulmonary bypass (CPB) machine was insufficient for prolonged extracorporeal support because it damaged cells and proteins circulating in blood due to direct exposure to gas during exchange. In the 1960s, the creation of silicon membranes to separate gas from blood during oxygen and carbon dioxide (CO_2) exchange facilitated the construction of membrane oxygenators that could be used clinically for prolonged periods with less harm to blood components.[2,3] Further advancements in technology and design of the oxygenator, pump, and circuit technology have facilitated the expansion of ECMO use (see Chapters 31 and 32).

There are two basic types of ECMO: venoarterial (VA) ECMO, which supports the heart and lungs, and venovenous (VV) ECMO, which supports the lungs only. ECMO can temporarily support cardiopulmonary function as the patient recovers or serve as a bridge to a permanent solution such as a ventricular support device or transplantation.[4] Although ECMO is challenging to manage and is associated with relatively high morbidity and mortality rates, increased experience and the durability of ECMO circuits have allowed care teams to support patients for several weeks. In this chapter, the history of ECMO, basics of the circuitry and cannulation, and care of the patient on ECMO are reviewed.

History, Evolution, and Current Status of ECMO

Interest in ECMO for respiratory support has dramatically increased in the past decade and been aided by advancements in extracorporeal technology, publication of key randomized trials, and the resurgence of viral infections causing respiratory failure (particularly the H1N1 influenza pandemic in 2009).[5] The first published report of its use for long-term support of adult patients was by Hill and associates in 1972; they used the Bramson Membrane Lung for support of patients in acute posttraumatic respiratory failure.[6] The first use of ECMO in infants was published in 1976 by Bartlett and colleagues.[7]

The early years of ECMO were marked by relatively basic circuit technology and significant complications from bleeding and anticoagulation. This was exemplified by the first randomized, prospective trial, which was published in 1979.[8] This landmark trial compared VA ECMO with conventional mechanical respiratory support of patients with acute, severe respiratory failure. It was terminated after randomization of only 90 patients because of unacceptably high mortality rates (>90%) for both groups.[8] Key problems in the trial included the choice of VA ECMO, the use of high-pressure mechanical ventilation in patients with acute respiratory distress syndrome (ARDS), and severe bleeding.[8]

After the negative study, Gattinoni and coworkers, in a series of papers in the 1980s, described the concept of extracorporeal removal of CO_2 in patients with severe respiratory failure in conjunction with low-frequency, positive-pressure ventilation that allowed the lungs to rest.[9,10] The next decade saw further growth in the United States, with Bartlett and colleagues at the University of Michigan publishing data on the use of extracorporeal support (along with standard mechanical ventilation) for patients with respiratory failure who had better outcomes.[11,12]

In the neonatal population, ECMO has become the standard of care for cardiopulmonary support, and it was recommended in 2013

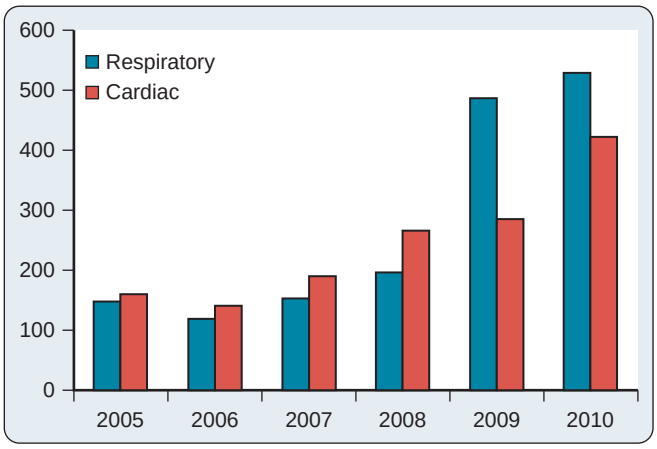

Fig. 33.1 Extracorporeal Life Support Organization (ELSO) registry data for venoarterial (VA) and venovenous (VV) extracorporeal membranous oxygenation (ECMO). VA ECMO is indicated for patients with acute cardiac or cardiopulmonary failure. VV ECMO is indicated for those with adequate cardiac function but acute respiratory failure refractory to standard management. *(Data from Extracorporeal Life Support Organization.* ECLS registry report: international summary. *July 2015. http:*www.elso.org.*)*

by the Pediatric Cardiac Intensive Care Society and the Extracorporeal Life Support Organization (ELSO) in a statement on mechanical circulatory support in children.[13] Extracorporeal circulatory support in the adult population has become common in the setting of refractory cardiogenic shock; VA ECMO is recommended by the American Heart Association to bridge patients to recovery or a ventricular assist device (VAD).[14] However, the widespread use of ECMO for adult respiratory support, particularly in the setting of the 2009 H1N1 pandemic, has been controversial in North America despite being recommended in Europe.[15]

The dramatic increase in the use of ECMO worldwide in the past 5 years (Fig. 33.1) can be attributed to two important events. The first was publication of the results of the Conventional Ventilatory Support Versus Extracorporeal Membrane Oxygenation for Severe Adult Respiratory Failure (CESAR) trial in 2009, which randomized patients with severe respiratory failure to conventional medical therapy in general hospitals or ECMO support in specialized medical centers (ie, 70 centers in the United Kingdom, 180 patients, and a 6-month monitoring period).[16] Key inclusion criteria included severe, potentially reversible respiratory failure with a Murray lung injury score of 3.0 or greater in conjunction with uncompensated hypercapnia (pH <7.2). Key exclusion criteria were prolonged high-pressure ventilation with a fraction of inspired oxygen (FIO_2) greater than 0.8 for longer than 7 days and any contraindication to ECMO. The investigators found significantly lower rates of death and disability for the ECMO group 6 months after randomization (37%, vs 53% in the mechanical ventilation group, $P = .03$), although the study was criticized for lack of standardization of lung-protective ventilation in the control group.[16]

The second event that promoted ECMO was the 2009 influenza A (H1N1) pandemic, which dramatically increased VV ECMO use worldwide as emergent salvage therapy for patients with severe viral pneumonia or ARDS unresponsive to mechanical ventilation. The first report attesting to the success of ECMO in this group came from Australia and New Zealand[17] and was quickly followed by data from Europe,[18,19] South America,[20] Canada,[21] Taiwan,[22] and Hong Kong.[23]

Gattinoni and coworkers reviewed the upsurge in ECMO use and found that more than 1000 papers on ECMO were reported on Medline between early 2009 and May 2011. Most ECMO use was related not to H1N1 but to other causes of respiratory failure and cardiac failure.[24]

The trend has continued, as demonstrated in a 2014 study that reported a significant (433%) increase in ECMO use in adults in the United States from 2006 to 2011.[25] Using data from the Nationwide Inpatient Sample (NIS), which is part of the Healthcare Cost and Utilization Project (HCUP) and sponsored by the Agency for Healthcare Research and Quality (AHRQ), and summary data sets from the ECMO registry maintained by ELSO, Sauer and colleagues calculated ECMO use rates, survival rates, and overall costs for patients 18 years or older.[25] In terms of ECMO use, there was no significant difference from 1999 to 2007, but the rate increased by 433% between 2006 and 2011, from 375 to 2004 patients.

Survival rates from 2006 to 2011 showed a trend toward improvement that was not statistically significant. Patients in 2011 were twice as likely to be categorized as critically ill as those in 2006. Analysis of the ELSO registry showed survival rates of 41%, with no significant change between 2006 and 2011. There were also no significant changes in costs incurred due to ECMO over the same period.[25]

Survival rates have dramatically improved since the original study by Zapol and colleagues[8] for both types of ECMO (Table 33.1), with respiratory ECMO survivors having a clear survival advantage over cardiac ECMO patients. Fig. 33.2 illustrates the growth in ECMO centers reported by the ELSO registry. In a 2009 metaanalysis, Cardarelli and associates[26] reported that survival rates for ECMO-treated adults after cardiac arrest increased from 30% in 1990 to 59% in 2007.

ECMO Physiology and Gas Exchange

A basic ECMO circuit consists of inflow and outflow cannulas, tubing, a pump, and a membrane oxygenator with heat exchanger (Fig. 33.3). The oxygen and CO_2 levels in the blood pumped through the ECMO circuit are controlled by altering the oxygen content and the flow rate (ie, sweep) of gas through the membrane oxygenator.

The success of ECMO reflects the advancements made in oxygenator, pump, and circuit technology. The film and bubble oxygenators used in the early days of ECMO were associated with significant hemolysis, platelet destruction, systemic inflammation, and microemboli formation, but most current ECMO circuits employ hollow-fiber polymethylpentene (PMP) oxygenators (Fig. 33.4) that are designed to function as complete nonmicroporous membranes with a well-defined blood-gas interface.[27–29] They confer the significant advantages of lower resistance to blood flow and smaller priming volumes (<300 mL) in addition to lower platelet consumption, less plasma leakage, a relatively large gas exchange surface area (1.5–2 m^2), and better gas exchange at blood flow rates that can vary from 1 to 7 L/min. Modern membrane oxygenators are coated with biocompatible thrombus-resistant polymers that limit inflammation and thrombus formation.[30–34] When PMP oxygenators do fail, it is from deposition of a fibrinous network

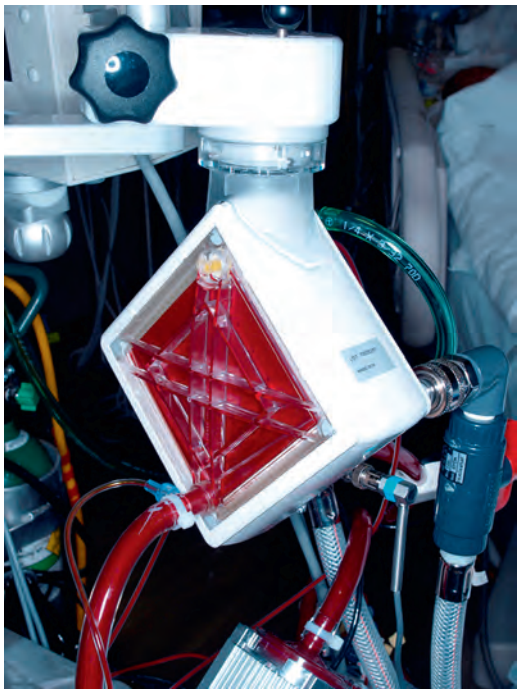

Fig. 33.4 Polymethylpentene membrane oxygenator.

of red cells and platelets on the membrane that eventually creates resistance to blood flow and gas diffusion.

The modern centrifugal pump is integral to ECMO, and it is usually preload and afterload dependent. The older generations of pumps were prone to excessive heat production, stagnation, and thrombosis.[5] In the mid-1990s, Mendler and colleauges[35] created a new generation of more efficient and safer pumps, referred to as Mendler-designed pumps, with significantly smaller priming volumes (<40 mL). The pumps do not need circuit bridges, venous reservoirs, or gravity drainage, and they can operate for longer periods than the older generation of pumps because of their unique design with a central opening in the rotor. The newer-generation pumps are impeller driven at 2000 to 5000 rpm, creating a negative upstream pressure and positive downstream pressure

Fig. 33.5 Rotaflow centrifugal pump. *(Courtesy Maquet Holding Company, Rastatt, Germany.)*

BOX 33.1 INDICATIONS FOR VENOARTERIAL ECMO

- Pulmonary embolism
- Myocardial infarction
- Myocarditis
- Postcardiotomy cardiac failure
- Heart transplantation
- Acute-on-chronic heart failure
- Cardiac arrest
- Acute respiratory distress syndrome with severe cardiac dysfunction
- Refractory ventricular arrhythmia
- Cardiac trauma
- Acute anaphylaxis
- Cardiac support for percutaneous cardiac procedures

(Fig. 33.5). Components are magnetically suspended to reduce friction, and small contact bearings are used. Hemolysis, a significant concern with ECMO, is less of an issue with the new generation of pumps (eg, CentriMag, Thoratec Corporation, Pleasanton, CA; Rotaflow, Maquet Cardiovascular, Wayne, NJ; Revolution, Sorin Cardiovascular, Milan, Italy) compared with the older-generation centrifugal pumps (eg, BioMedicus, Medtronic, Eden Prairie, MN) and roller pumps.[29,36,37]

Management of Venoarterial ECMO

ECMO for Hemodynamic Support

VA ECMO may be used to provide circulatory support or a combination of pulmonary and circulatory support.[38] The VA ECMO circuit consists of venous drainage to a centrifugal pump in series with a membrane oxygenator and return of oxygenated blood to the arterial circulation to maintain end-organ perfusion.

There are numerous acute and subacute indications for VA ECMO (Box 33.1), but most can be classified as severe cardiac insufficiency causing end-organ ischemia.[39] Practitioners determining the need for VA ECMO or VV ECMO in cases of pulmonary insufficiency must evaluate right and left ventricular function. Although no established standards exist for the minimal ventricular function that should trigger the use of VA ECMO, patients with severe ventricular dysfunction do not benefit from VV ECMO. VA ECMO may be used as a means of support during recovery of native cardiac function or in patients with little hope of cardiac recovery as a bridge to a mechanical VAD or heart transplantation.

Contraindications to VA ECMO include disseminated malignancy, advanced age, severe brain injury, and unwitnessed arrest. VA ECMO may be technically difficult to implement or manage in patients with significant aortic regurgitation, aortic dissection, or contraindications to anticoagulation.

Cannulation for Venoarterial ECMO

Cannulation for VA ECMO can be broadly divided into central and peripheral types. Central cannulation is used in patients failing to wean from CPB after cardiotomy. Access is obtained by direct cannulation of the right atrium (RA) and aorta (Fig. 33.6). The benefits of central cannulation include the ability to place large-diameter cannulas and direct insertion of a left ventricular drainage catheter (ie, vent), but cannula placement may preclude closure of the chest unless the cannula is placed through the chest wall. Central aortic cannulation eliminates the risk of limb ischemia associated with peripheral arterial cannulation.

Peripheral cannulation includes one or more venous drainage catheters and an outflow cannula inserted into the arterial system (Fig. 33.7). Any large peripheral artery may be used, but the usual method is placement of a cannula in the femoral artery with the percutaneous Seldinger technique. Leg ischemia may result from femoral artery cannulation, and a distal small cannula should be placed and connected to the outflow circuit. We typically insert a 6- or 8-Fr catheter before insertion of the proximal cannula because the proximal cannula reduces distal blood flow, making it difficult to isolate the vessel. In emergent cases, such as during cardiopulmonary resuscitation, it may be necessary to place the proximal arterial cannula before placement of the distal catheter. In this circumstance, we perform a surgical cutdown and confirm distal catheter position and flow with fluoroscopic guidance. Alternative methods for distal leg perfusion include placement of an 8-Fr cannula in the posterior tibial artery of the foot.[40] Many venous cannulation combinations can be used to gain full venous drainage. In almost all cases, at least one femoral venous catheter is advanced to the RA.

During VA ECMO, blood returns to the left ventricle (LV) through the sinus venosus, thebesian vessels, and bronchial circulation despite adequate venous cannula access. This blood must be ejected through the aortic valve or be adequately drained (vented). Without treatment, distention of the LV results in elevated left ventricular pressures, pulmonary edema, ventricular clot formation, pulmonary venous hypertension, and impeded ventricular recovery. Serial echocardiographic examinations are recommended to screen for left ventricular distention in all patients on VA ECMO. Patients with no left ventricular contractility or significant aortic insufficiency should have venting strategies implemented early.[41]

Methods to facilitate left ventricular ejection during percutaneous ECMO include use of inotropes, insertion of an Impella VAD (Abiomed, Danvers, MA),[42] and placement of an intraaortic balloon pump. Methods to vent blood from the LV include insertion of a TandemHeart percutaneous VAD (Cardiac Assist, Pittsburgh, PA) with an oxygenator,[43] balloon atrial septostomy,[44] percutaneous drainage through the pulmonary artery,[45] and surgical or percutaneous placement of venting cannulas in the left atrium and LV. No randomized, controlled trials have favored any venting strategy over another.[46] The most important consideration is the ability of the lungs to oxygenate blood. If the patient is unable to oxygenate, venting strategies that drain the blood to the ECMO circuit should be used to prevent proximal-distal syndrome.

Proximal-distal syndrome exists in patients on VA ECMO when poorly oxygenated blood is ejected from the heart. In patients with poor pulmonary oxygenation, the watershed within the aorta (ie, the point at which oxygenated blood from the ECMO circuit meets the poorly oxygenated blood ejected from the heart) may be located distal to the aortic valve, and poorly oxygenated blood may be delivered to the heart or arch vessels.[47] Strategies to treat proximal-distal syndrome include using maneuvers to improve oxygenation of blood shunting through the pulmonary circulation, increasing right heart venous drainage, placing a vent in the left heart, and placing an arterial outflow cannula in the ascending aorta or other aortic arch branch vessel.

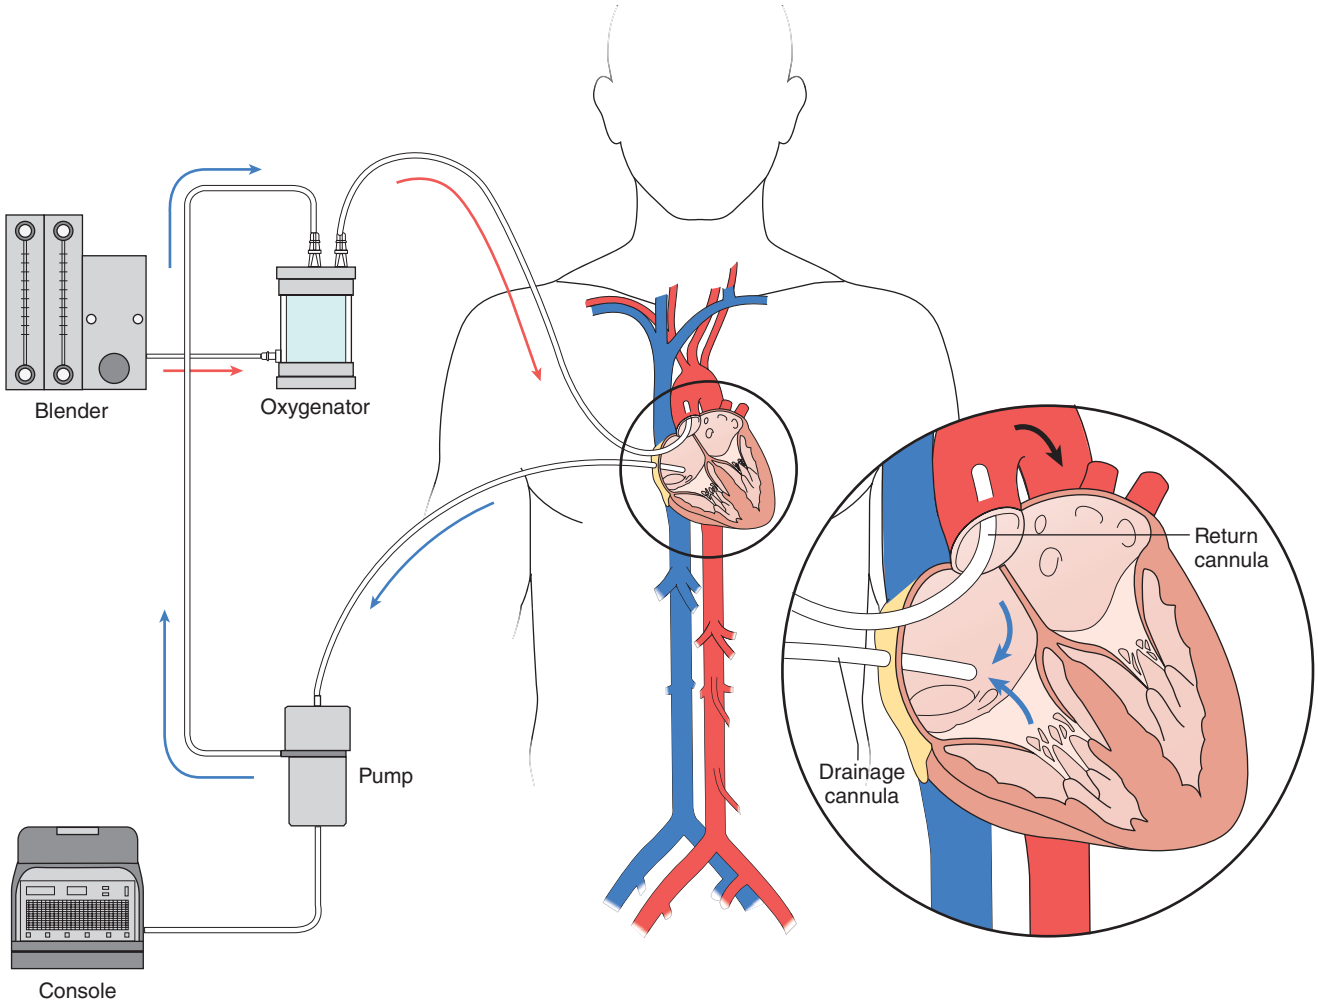

Fig. 33.6 Central venoarterial ECMO cannulation and circuit.

Initiation of Venoarterial ECMO

After cannulation, the ECMO circuit flows are increased to the target range, which should be based on clinical parameters, including arterial blood pressure, oxygen saturation of the venous return to the circuit, and measures of global ischemia such as serum lactate (Box 33.2). Initial settings should be standardized based on patient size (estimated at 50–60 mL/kg per minute).[48] Additional determinants of arterial blood pressure include arterial blood flow and arterial vascular tone.

The volume of arterial blood flow is supplied by the combination of native heart function and the ECMO circuit.[49] Patients with an adequate volume of blood flow who have persistent hypotension need vasopressors to maintain sufficient vascular resistance and preserve adequate blood pressure. In some cases, increases in pump speed may not increase flow, and drainage line "chatter" may indicate insufficient venous return volume or catheter malposition. If flows are still insufficient after cannula repositioning and augmentation of central venous volume, additional venous drainage cannulas should be placed. Sweep flows should initially be set to match arterial flow and then adjusted based on system arterial partial pressure of carbon dioxide ($PaCO_2$) and pH. Regardless of the indication for ECMO, the ventilator should be managed with lung-protective strategies.

BOX 33.2 INITIAL SETTINGS AND GOALS AFTER IMPLEMENTATION OF VENOARTERIAL ECMO

Circuit flow	≥2 L/min per 1 m^2
Sweep gas flow	Equal to blood flow
Fractional of inspired oxygen (sweep gas)	100%
Inlet pressure (centrifugal pump)	≥100 mm Hg
Oxygen saturation (outflow cannula)	100%
Oxygen saturation (inflow cannula)	>65%
Arterial oxygen saturation	>95%
Mixed venous oxygen saturation	>65%
Arterial carbon dioxide tension	35–45 mm Hg
pH	7.35–7.45
Mean arterial pressure	60–90 mm Hg
Hematocrit	30–40%
Activated partial thromboplastin time (aPTT)	1.5–2.0 times normal
Platelet count	>100,000/mm^3

Adapted from Sidebotham D, McGeorge A, McGuinness S, et al. Extracorporeal membrane oxygenation for treating severe cardiac and respiratory failure in adults. Part 2: technical considerations. *J Cardiothorac Vasc Anesth*. 2010;24:164–172.

Weaning From Venoarterial ECMO

Daily clinical, hemodynamic, and echocardiographic evaluation of cardiac function should guide the strategy and timing of weaning

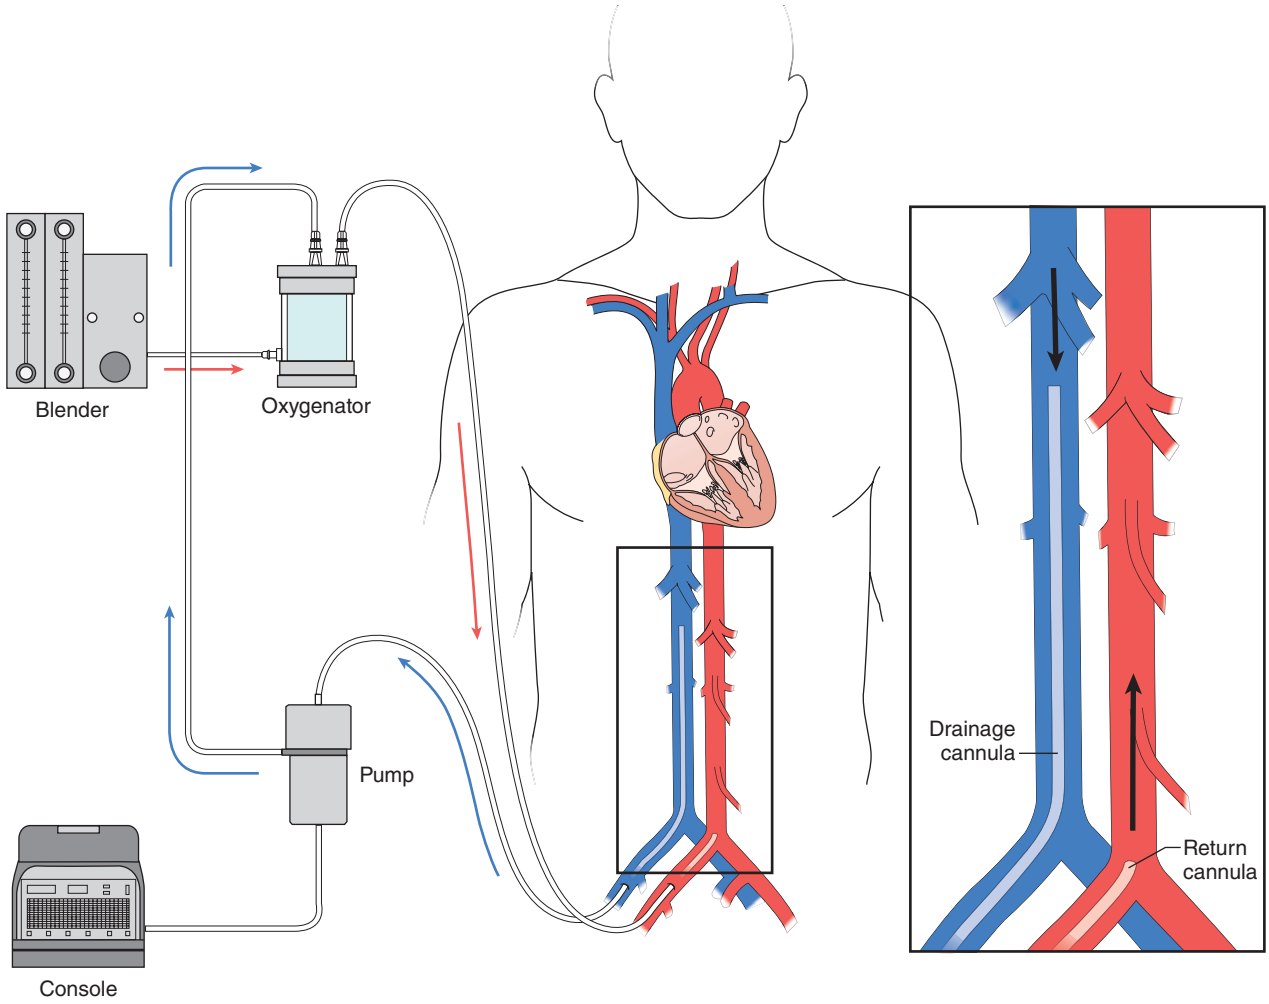

Fig. 33.7 Peripheral venoarterial ECMO standard cannulation and circuit.
