11 Cardiovascular Pharmacology

ROGER L. ROYSTER, MD | LEANNE GROBAN, MD | ADAIR Q. LOCKE, MD | BENJAMIN N. MORRIS, MD | THOMAS F. SLAUGHTER, MD

KEY POINTS

1. Ischemia during the perioperative period demands immediate attention by the anesthesiologist. The impact of ischemia may be acute (ie, impending infarction or hemodynamic compromise) and chronic (ie, marker of previously unknown cardiac disease or prognostic indicator of poor outcome).
2. Nitroglycerin is indicated in most cases of perioperative myocardial ischemia. Mechanisms of action include coronary vasodilation and favorable alterations in preload and afterload. Nitroglycerin is contraindicated in cases of hypotension.
3. Perioperative β-blockade may reduce the incidence of perioperative myocardial ischemia by several mechanisms when initiated at an appropriate time in the preoperative period. Favorable hemodynamic changes associated with β-blockade include blunting of the stress response and reduced heart rate, blood pressure, and contractility. All of these conditions improve myocardial oxygen supply-to-demand ratios.
4. Calcium channel blockers reduce myocardial oxygen demand by depression of contractility, reduction of heart rate, and decrease in arterial blood pressure. Calcium channel blockers are often administered in the perioperative period for long-term antianginal symptomatic control.
5. Current guidelines suggest seeking a target blood pressure of less than 150/90 mm Hg in patients 60 years of age or older to minimize the long-term risk of adverse cardiovascular morbidity and mortality.
6. For patients younger than 60 years age or those with diabetes or chronic kidney disease, blood pressures lower than 140/90 mm Hg are recommended.
7. Mild or moderate hypertension does not represent an independent risk factor for perioperative complications, but a diagnosis of hypertension necessitates preoperative assessment for target organ damage.
8. Patients with poorly controlled preoperative hypertension experience more labile blood pressures in the perioperative setting with a greater potential for hypertensive and hypotensive episodes.
9. The signs, symptoms, and treatment of chronic heart failure are related to the neurohormonal response and underlying ventricular dysfunction.
10. Treatments for chronic heart failure are aimed at prolonging survival, along with relief of symptoms.
11. The pathophysiology, treatment, and prognosis of low cardiac output syndrome seen after cardiac surgery are different from those of chronic heart failure, with which it is sometimes compared.
12. Physicians must be cautious in administering antiarrhythmic drugs because their proarrhythmic effects can increase mortality for certain subgroups of patients.
13. Amiodarone has become a popular intravenous antiarrhythmic drug for use in the operating room and critical care areas because it has a broad range of effects for ventricular and supraventricular arrhythmias.
14. β-Receptor antagonists are effective but underused antiarrhythmics in the perioperative period because many arrhythmias are adrenergically mediated due to the stress of surgery and critical illness.
15. Managing electrolyte abnormalities and treating underlying disease processes such as hypervolemia and myocardial ischemia are critical treatment steps before the administration of any antiarrhythmic agent.

Antiischemic Drug Therapy

Perioperative myocardial ischemia is an anesthetic emergency that should be treated promptly with appropriate therapy. The treatment of ischemia during anesthesia is complicated by the ongoing stress of surgery, blood loss, concurrent organ ischemia, and the patient's inability to interact with the anesthesiologist. Nonetheless, the fundamental principles of treatment remain the same as in the unanesthetized state.

All events of myocardial ischemia involve an alteration in the oxygen supply-to-demand balance (Table 11.1). The American College of Cardiology and American Heart Association (ACC/AHA) Guidelines on the Management and Treatment of Patients with Unstable Angina and Non–ST-Segment Elevation Myocardial Infarction provide an excellent framework for the treatment of patients with ongoing myocardial ischemia.[1] The guidelines detail the initial evaluation, management, hospital care, and coronary revascularization strategies for the patient with an acute coronary syndrome. For the anesthetized patient with evidence of myocardial ischemia, initiation of antiischemic drug therapy is the primary intervention until definitive therapy, if needed, can be obtained. This section reviews the common agents used for this purpose (see Chapter 20).

Nitroglycerin

Nitroglycerin (NTG) is clinically indicated as initial therapy for most types of myocardial ischemia.[2] Chronic exertional angina, de novo angina, unstable angina, Prinzmetal angina (ie, vasospasm), and silent

ischemia respond to NTG administration.[2–6] NTG therapy decreases the incidence of anginal attacks and improves exercise tolerance before angina symptoms occur.[7] During therapy with intravenous NTG, if blood pressure (BP) drops and ischemia is not relieved, the addition of phenylephrine allows coronary perfusion pressure to be maintained while allowing higher doses of NTG to be used for ischemia relief.[8] If reflex increases in heart rate and contractility occur, combination therapy with β-adrenergic blockers may be indicated to blunt the undesired increase in heart rate. Combination therapy with nitrates and calcium channel blockers may be an effective antiischemic regimen in selected patients, but excessive hypotension and reflex tachycardia may be a problem, especially when a dihydropyridine (DHP) calcium antagonist is used.[9]

Mechanism of Action

NTG enhances myocardial oxygen delivery and reduces myocardial oxygen demand. NTG is a smooth muscle relaxant that causes vasculature dilation. Nitrate-mediated vasodilation occurs with or without intact vascular endothelium.[10] Nitrites, organic nitrites, nitroso compounds, and other nitrogen oxide–containing substances (eg, nitroprusside) enter the smooth muscle cell and are converted to reactive nitric oxide (NO) or *S*-nitrosothiols, which stimulate guanylate cyclase metabolism to produce cyclic guanosine monophosphate (cGMP)[11–13] (Fig. 11.1). A cGMP-dependent protein kinase is stimulated with resultant protein phosphorylation in the smooth muscle. This leads to a dephosphorylation of the myosin light chain and smooth muscle relaxation.[14,15]

Vasodilation is also associated with a reduction of intracellular calcium.[16] Sulfhydryl (SH) groups are required for formation of NO and the stimulation of guanylate cyclase. When excessive amounts of SH groups are metabolized by prolonged exposure to NTG, vascular tolerance occurs.[17] The addition of *N*-acetylcysteine, an SH donor, reverses NTG tolerance.[18] The mechanism by which NTG compounds are uniquely better venodilators, especially at lower serum concentrations, is unknown but may be related to increased uptake of NTG by veins compared with arteries.[19]

TABLE 11.1 Myocardial Ischemia: Factors Governing Oxygen Supply and Demand

Oxygen Supply	*Oxygen Demand*
Heart rate[a]	Heart rate[a]
O_2 content	Contractility
Hgb, SAT%, PaO_2	Wall tension
Coronary blood flow	Afterload
CPP = DP − LVEDP[a]	Preload (LVEDP)[a]
CVR	

[a]Affects supply and demand.

CPP, Coronary perfusion pressure; *CVR*, coronary vascular resistance; *DP*, diastolic blood pressure; *Hgb*, hemoglobin; *LVEDP*, left ventricular end-diastolic pressure; PaO_2, partial pressure of oxygen; *SAT*, percent oxygen saturation.

Modified from Royster RL. Intraoperative administration of inotropes in cardiac surgery patients. *J Cardiothorac Anesth.* 6(suppl 5):17, 1990.

Physiologic Effects

Two important physiologic effects of NTG are systemic and regional venous dilation (Fig. 11.2). Venodilation can markedly reduce venous pressure, venous return to the heart, and cardiac filling pressures. Prominent venodilation occurs at lower doses and does not increase further as the NTG dose increases.[20] Venodilation results primarily in pooling of blood in the splanchnic capacitance system.[21] Mesenteric blood volume increases as ventricular size, ventricular pressures, and intrapericardial pressure decrease.[21]

NTG increases the distensibility and conductance of large arteries without changing systemic vascular resistance (SVR) at low doses.[22] Improved compliance of the large arteries does not necessarily imply afterload reduction. At higher doses, NTG dilates smaller arterioles and resistance vessels, reducing afterload and BP (see Fig. 11.2).[23] Reductions in cardiac dimension and pressure reduce myocardial oxygen consumption ($M\dot{V}O_2$) and improve myocardial ischemia[24] (Fig. 11.3). NTG may preferentially reduce cardiac preload while maintaining systemic perfusion pressure, an important hemodynamic effect in myocardial ischemia. However, in hypovolemic states, higher doses of NTG may reduce systemic BP to dangerous levels. A reflex increase in heart rate may occur at arterial vasodilating doses.

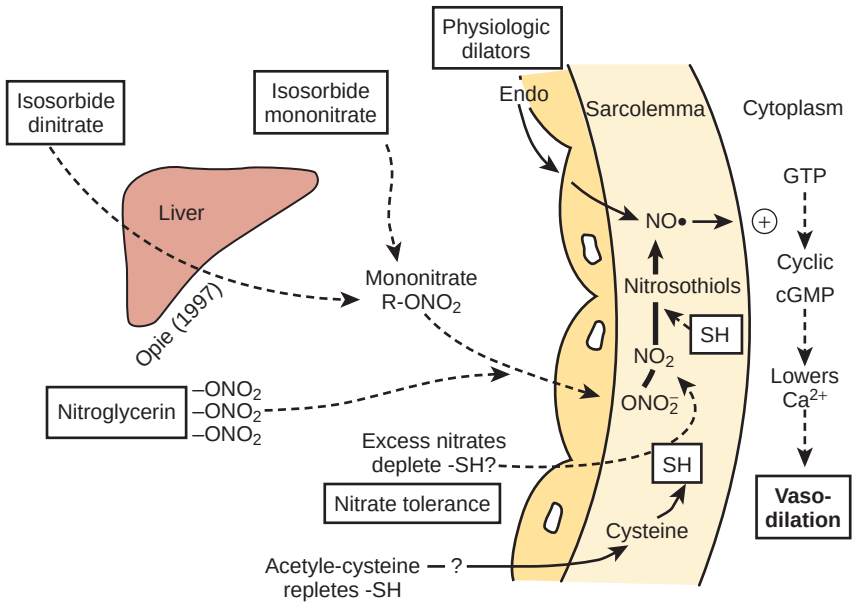

Fig. 11.1 Mechanisms of nitrates *(ONO_2)* in the generation of the free radical nitric oxide (NO•) and stimulation of guanylate cyclase cyclic guanosine monophosphate *(cGMP)*, which mediates vasodilation. Sulfhydryl *(SH)* groups are required for the formation of NO• and stimulation of guanylate cyclase. Isosorbide dinitrate is metabolized by the liver, whereas this route of metabolism is bypassed by the mononitrates. *Endo*, Endothelium; *GTP*, guanosine triphosphate. *(Modified from Opie LH.* Drugs for the Heart. *4th ed. Philadelphia: Saunders; 1995:33.)*

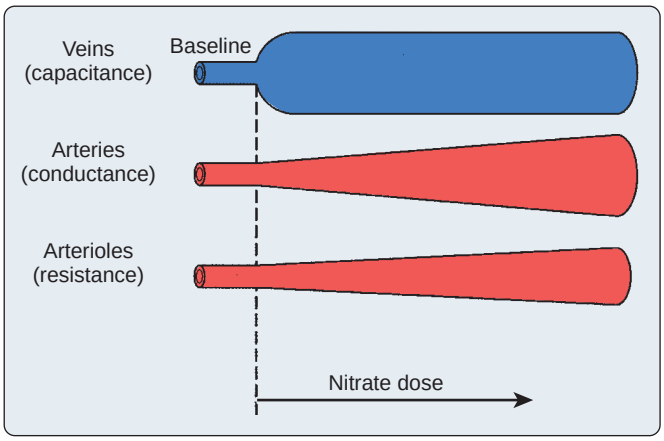

Fig. 11.2 Actions of organic nitrates on the major vascular beds and relation of vasodilation to the size of the administered dose. The venous capacitance system dilates maximally with very low doses of organic nitrates. Increasing the amount of drug does not cause appreciable additional venodilation. Arterial dilation and enhanced arterial conductance begin at low doses of nitrates, with further vasodilation as the dosage is increased. With high plasma concentrations of nitrates, the arteriolar resistance vessels dilate, decreasing systemic and regional vascular resistance. *(Modified from Abrams J. Hemodynamic effects of nitroglycerin and long-acting nitrates.* Am Heart J. *1985;110(pt 2):216; Abrams J. Nitrates. In: Chatterjee K, Cheitlin MD, Karliner J, et al, eds.* Cardiology: An Illustrated Text/Reference. *Vol 1. Philadelphia: Lippincott; 1991:275–290.)*

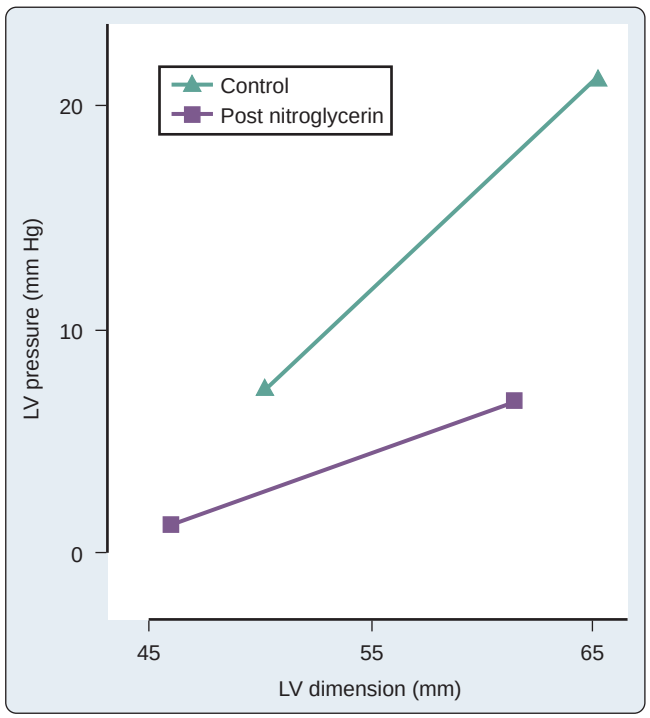

Fig. 11.3 Effect of sublingual nitroglycerin on the left ventricular *(LV)* diastolic pressure-dimension relationship in a patient with chronic aortic regurgitation. Dimensions (from an echocardiogram) and pressure data points were obtained in early diastole (ie, minimal pressure) and at end-diastole (ie, peak of QRS). After the administration of nitroglycerin, the pressure-dimension curve is shifted to the left. *(From Smith ER, Smiseth OA, Kingma I, et al. Mechanism of action of nitrates. Role of changes in venous capacitance and in the left ventricular diastolic pressure-volume relation.* Am J Med. *1984;76:14.)*

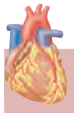

BOX 11.1 EFFECTS OF NITROGLYCERIN AND ORGANIC NITRATES ON THE CORONARY CIRCULATION

- Epicardial coronary artery dilation: small arteries dilate proportionately more than larger arteries
- Increased coronary collateral vessel diameter and enhanced collateral flow
- Improved subendocardial blood flow
- Dilation of coronary atherosclerotic stenoses
- Initial short-lived increase in coronary blood flow; later reduction in coronary blood flow as myocardial oxygen consumption decreases
- Reversal and prevention of coronary vasospasm and vasoconstriction

Modified from Abrams J. Hemodynamic effects of nitroglycerin and long-acting nitrates. *Am Heart J.* 1985;110(pt 2):216.

NTG causes vasodilation of pulmonary arteries and veins and predictably decreases right atrial, pulmonary artery, and pulmonary capillary wedge pressures (PCWP).[23] Pulmonary artery hypertension may be reduced by NTG in various disease states and in congenital heart disease.[25,26] Renal arteries, cerebral arteries, and cutaneous vessels also dilate with NTG.[27] Blood flow to the kidney and brain may decrease if adequate renal and cerebral perfusion pressures are not maintained.

NTG has several important effects on the coronary circulation (Box 11.1). It is a potent epicardial coronary artery vasodilator in normal and diseased vessels. Stenotic lesions dilate with NTG, reducing the resistance to coronary blood flow (CBF) and improving myocardial ischemia.[28,29] Smaller coronary arteries may dilate relatively more than larger coronary vessels, but the degree of dilation may depend on the baseline tone of the vessel.[30] NTG effectively reverses or prevents coronary artery vasospasm.[31]

Total CBF may initially increase but eventually decreases with NTG despite coronary vasodilation[32] (Fig. 11.4). Autoregulatory mechanisms probably decrease total flow as a result of reductions in wall tension and $M\dot{V}O_2$.[23] However, regional myocardial blood flow may improve by vasodilation of intercoronary collateral vessels or reduction of subendocardial compressive forces[33] (Fig. 11.5). Coronary arteriographic studies in humans demonstrate that coronary collateral vessels increase in size after NTG administration.[34] This effect may be especially important when epicardial vessels have subtotal or total occlusive disease.[35] Improvement in collateral flow can also be protective in situations in which coronary artery steal may occur with other potent coronary vasodilator agents. The improvement in blood flow to the subendocardium, the area most vulnerable to development of ischemia, results from improvement in collateral flow and reductions in left ventricular end-diastolic pressure (LVEDP), which reduce subendocardial resistance to blood flow.[36]

With the maintenance of an adequate coronary perfusion pressure (eg, with administration of phenylephrine), NTG can maximize subendocardial blood flow[8] (see Figs. 11.4 and 11.5). The ratio of endocardial to epicardial blood in transmural segments is enhanced with NTG.[36] Inhibition of platelet aggregation also occurs with NTG, but the clinical significance of this action is unknown.[37]

Pharmacology

Organic nitrates are biotransformed by reduction hydrolysis catalyzed by the hepatic enzyme glutathione–organic nitrate reductase.[15] The rate of hepatic denitrification is characteristic of each nitrate and further depends on hepatic blood flow or presence of hepatic disease.[15] Common organic nitrates for clinical use are shown in Table 11.2.

Sublingual Nitroglycerin

Sublingual NTG (0.15- to 0.6-mg tablets) achieves blood levels adequate to cause hemodynamic changes within several minutes; the

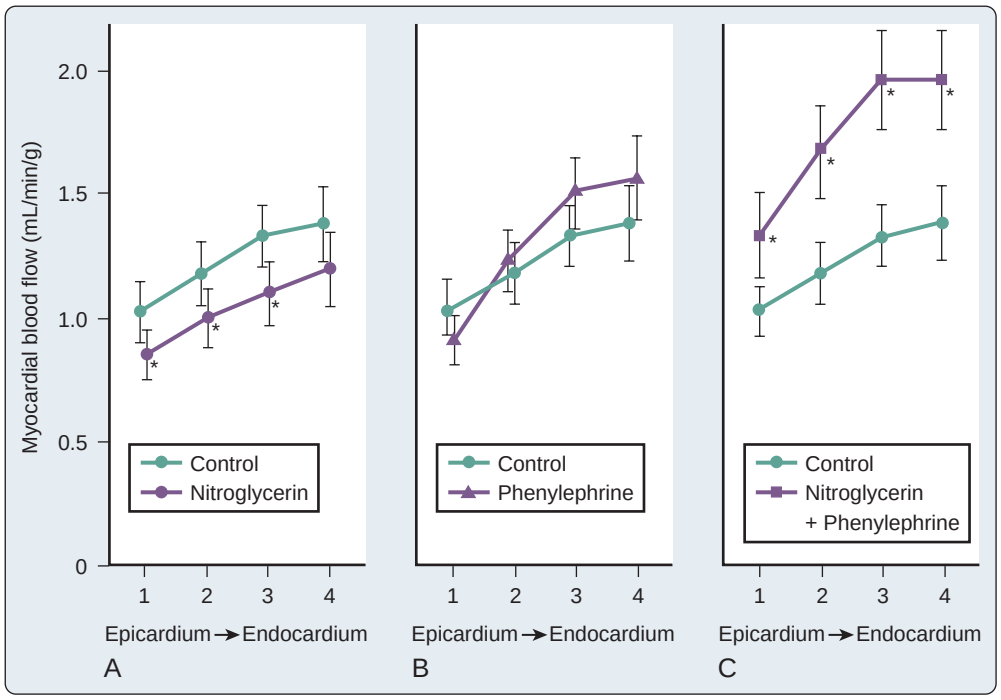

Fig. 11.4 Mean blood flow (mL/min per gram) ± SE to four transmural layers of anterior nonischemic myocardium during occlusion of the circumflex coronary artery in animals. Data are reported during control conditions, during infusion of nitroglycerin (0.015 mg/kg per minute) (A), during administration of phenylephrine to increase mean arterial pressure to 153 ± 6 mm Hg (B), and during simultaneous administration of nitroglycerin and phenylephrine (C). Nitroglycerin decreases blood flow, and phenylephrine usually increases blood flow in normal myocardium. The combination markedly augments flow; *$P < .05$ compared with control measurements. *(A–C, From Bache RJ. Effect of nitroglycerin and arterial hypertension on myocardial blood flow following acute coronary artery occlusion in the dog.* Circulation. *1978;57:557.)*

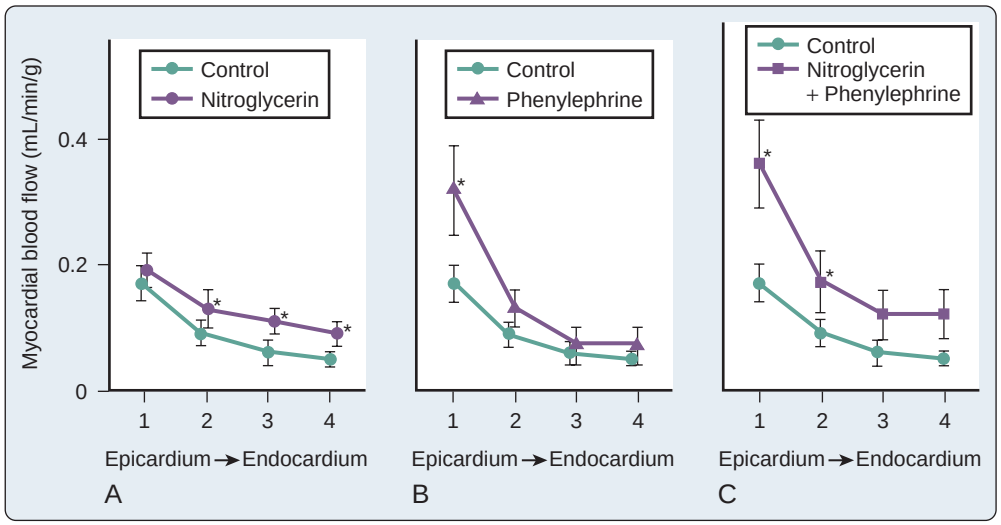

Fig. 11.5 Mean blood flow (mL/min per gram) ± SE to four transmural layers of the central ischemic zone during occlusion of the circumflex coronary artery in animals. Data are reported during control conditions, during infusion of nitroglycerin (0.015 mg/kg per minute) (A), during administration of phenylephrine to increase mean arterial pressure to 153 ± 6 mm Hg (B), and during simultaneous administration of nitroglycerin and phenylephrine (C). Coronary blood flow to all layers of ischemic myocardium is enhanced with the combination; *$P < .05$ compared with control measurements. *(A–C, From Bache RJ. Effect of nitroglycerin and arterial hypertension on myocardial blood flow following acute coronary artery occlusion in the dog.* Circulation. *1978;57:557.)*

TABLE 11.2 Nitroglycerin and Nitrates Used for Angina

Compound	*Route*	*Dosage*	*Duration of Effect*
Nitroglycerin	Sublingual tablets Spray Transdermal Intravenous	0.3–0.6 mg up to 1.5 mg 0.4 mg as needed 0.2–0.8 mg/h every 12 h 5–200 µg/min	1–7 minutes Similar to sublingual tablets 8–12 h during intermittent therapy Tolerance in 7–8 h
Isosorbide dinitrate	Oral Oral, slow release	5–80 mg 2 or 3 times daily 40 mg 1 or 2 times daily	Up to 8 h Up to 8 h
Isosorbide mononitrate	Oral Oral, slow release	20 mg twice daily 60–240 mg once daily	12–24 h
Pentaerythritol tetranitrate	Sublingual	10 mg as needed	Unknown
Erythritol tetranitrate	Sublingual Oral	5–10 mg as needed 10–30 mg 3 times daily	Unknown Unknown

Modified from Gibbons RJ, Chatterjee K, Daley J, Douglas JS. ACC/AHA/ACP-ASIM guidelines for the management of patients with chronic stable angina: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on Management of Patients with Chronic Stable Angina). *J Am Coll Cardiol.* 1999;33:2092–2197.

physiologic effects last 30 to 45 minutes.[38] Sublingual bioavailability is approximately 80% and bypasses the high (90%) first-pass biodegradation in the liver by nitrate reductase to glycerol dinitrate and nitrite, which are renally excreted. Plasma half-life of sublingual NTG is 4 to 7 minutes.

NTG spray has pharmacokinetics and pharmacodynamics equivalent to those of a 0.4-mg sublingual tablet, but it has a longer shelf half-life compared with the tablets, which decompose in air and warm temperatures.[39] A tablet that adheres to the buccal area between the upper lip and teeth has a rapid onset and has the advantage of a longer half-life than sublingual tablets.[40] Although NTG is readily absorbed through the gastric mucosa, the high rate of liver metabolism makes oral administration highly unpredictable.

Nitroglycerin Ointment and Patches

NTG ointment (2%) is readily absorbed through the skin, and this method of administration provides longer-lasting effects.[41] Adequate NTG blood levels are reached within 20 to 30 minutes, and the duration of action is 4 to 6 hours.[41] Ointment (ie, nitro paste) is administered in inches (15 mg/inch), but the surface area of application, not the amount administered, determines the blood level achieved. NTG ointment is messy, requires application four times each day, and is most appropriate for nursing administration in an inpatient setting.[42]

NTG patches contain liquid NTG or NTG bonded to a polymer gel and slowly released to the skin through a semipermeable membrane.[43] The pharmacokinetics approach that of a consistent intravenous infusion.[43] Blood levels are reached within 20 to 30 minutes, and a steady state is reached within 2 hours. Blood levels may be maintained up to 24 hours and are largely determined by patch size. Patches or disks contain an NTG concentration per square centimeter, and doses of 0.2 to 0.8 mg/h are usually required for relief of myocardial ischemia. Although convenient for patients, tolerance may be a problem with sustained-release preparations.[41] Intermittent therapy is recommended to avoid tolerance.[44]

Intravenous Nitroglycerin

NTG has been available since the early 1980s as a parenteral drug with a stable shelf half-life in a 400-µg/mL solution of 5% dextrose in water (D_5W). Blood levels are achieved instantaneously, and arterial dilating doses with resulting hypotension may quickly occur. If the volume status of the patient is unknown, initial doses of 5 to 10 µg/min are recommended. The dose necessary for relieving myocardial ischemia may vary from patient to patient, but relief is usually achieved with 75 to 150 µg/min. In a clinical study of 20 patients with rest angina, a mean dose of 72 µg/min reduced or abolished ischemic episodes in 85% of patients.[45] However, doses as high as 500 to 600 µg/min may be necessary for ischemic relief in some patients. Arterial dilation becomes clinically apparent at doses around 150 µg/min. Drug offset after discontinuation of an infusion is rapid (2–5 minutes). The dosage of NTG available is less when administered in plastic bags and polyvinylchloride tubing because of NTG absorption by the bag and tubing, although this is not a significant clinical problem because the drug is titrated to effect.[46]

Adverse Effects

The metabolism of NTG by liver nitrate reductase produces a nitrite that oxidizes the ferrous iron of hemoglobin to the ferric form of methemoglobin. The ferric iron does not bind or release oxygen.[47] Methemoglobin is formed normally and is reduced by enzyme systems within the red blood cell.[48] Normally, methemoglobin levels do not exceed 1%, but they may increase when direct oxidants (eg, nitrates, sulfonamides, aniline dye derivates) are present in the serum. Methemoglobinemia with levels up to 20% is not a clinical problem. Documented increases in methemoglobin blood levels occur with intravenous NTG, averaging 1.5% in one study of 50 patients receiving NTG for longer than 48 hours.[49] NTG doses of 5 mg/kg per day and higher should be avoided to prevent significant methemoglobinemia.[50] However, rare instances of smaller doses causing clinically significant problems have been reported.[51] Nitrates are effective in producing methemoglobin to bind cyanide in sodium nitroprusside toxicity.

Several mechanisms of nitrate tolerance have been proposed, including a depletion of SH groups, neurohumoral activation, volume expansion, and downregulation of nitrate receptors.[52–57] Tolerance may occur with all forms of nitrate administration that maintain continuous blood levels of the drug.[17,58–61] Discontinuation of the drug after prolonged exposure may result in a rebound phenomenon, possibly resulting in coronary vasospasm and myocardial ischemia or infarction.[62] Tolerance to NTG does not occur in all patients.[63] If tolerance develops after prolonged exposure, physiologic responsiveness may be achieved with higher doses of NTG, an important observation during NTG administration in cardiac surgery.[64] Intermittent dosing with a nitrate-free interval each day or night can maintain NTG responsiveness.[44,65]

NTG interferes with platelet aggregation.[66] The ability of the platelet to adhere to damaged intima is reduced.[67] Primary and secondary wave aggregation of platelets is also attenuated.[68] Previously formed platelet plugs are disaggregated.[69] A clinical study of 10 patients with coronary artery disease (CAD) demonstrated that a mean dose of NTG (1.19 µg/kg per minute) inhibited platelet aggregation by 50%, with a return to baseline platelet aggregation 15 minutes after the infusion was discontinued[70] (Fig. 11.6). NO production increases cGMP, which modulates intracellular platelet calcium and reduces platelet secretion of proaggregatory factors.[71] The clinical significance of these actions remains unclear. As with other potent vasodilators, NTG may increase intrapulmonary shunting of blood and reduce arterial oxygen tension.

NTG may induce resistance to the anticoagulant effects of heparin.[72] During simultaneous infusions of NTG and heparin, an increase in the NTG infusion caused the activated partial thromboplastin time to decrease.[73] Becker and colleagues[74] reported NTG-induced heparin resistance at NTG infusion rates greater than 350 µg/min.

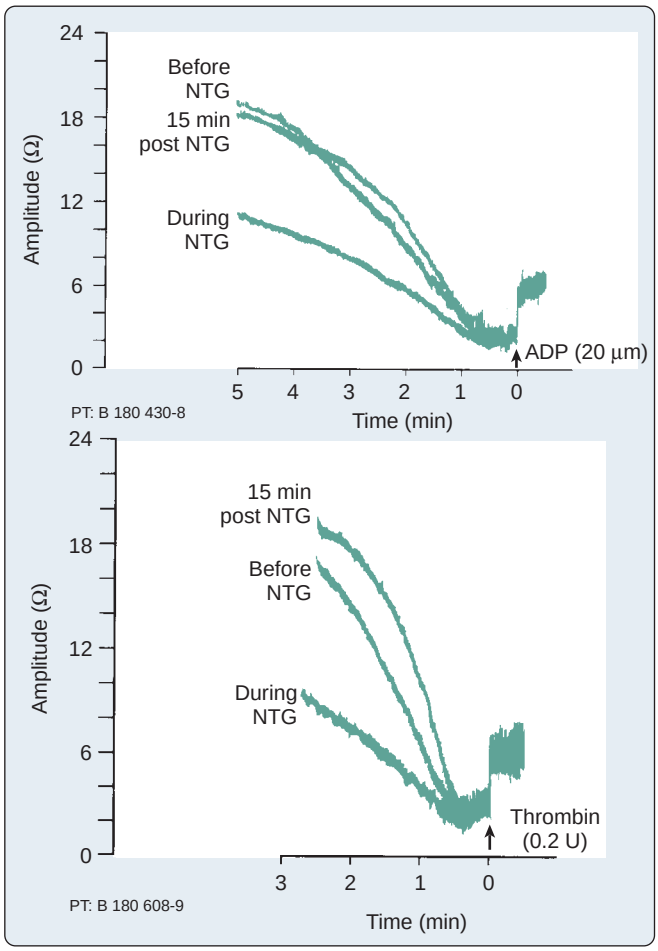

Fig. 11.6 Typical examples of aggregation responses to adenosine diphosphate *(ADP) (top)* and to thrombin *(bottom)* before, during, and after infusion of nitroglycerin *(NTG)* in patients with coronary artery disease. The amplitude of the curve is calibrated in ohms *(Ω)* using a dual-channel impedance aggregometer. NTG inhibits platelet aggregation to both reagents, and the effect is rapidly reversible after discontinuation of the drug. *(Modified from Diodati J, Theroux P, Latour JG, et al. Effects of nitroglycerin at therapeutic doses on platelet aggregation in unstable angina pectoris and acute myocardial infarction.* Am J Cardiol. *1990;66:683.)*

They suggested a qualitative problem with antithrombin III (AT III), because AT III levels did not decrease. Others have suggested that NTG interferes with AT III binding to heparin by *N*-desulfation of the heparin molecule at the AT III binding sites.[75] *N*-Desulfation of heparin reduces its anticoagulant activity.[76]

NTG is contraindicated in patients who have used sildenafil, vardenafil, or tadalafil and in patients who are hypotensive. The drugs for erectile dysfunction inhibit phosphodiesterase type 5 (PDE5), an enzyme that degrades cGMP, which mediates vascular smooth muscle relaxation by NO. NTG-mediated vasodilation is markedly enhanced and prolonged, resulting in cases of profound hypotension, myocardial infarction (MI), and death.[77] Guidelines suggest at least 24 hours between the last dose of sildenafil and vardenafil and nitrate administration and 48 hours for tadalfil.[1,78–80]

Summary

NTG remains a first-line agent for the treatment of myocardial ischemia. Special care must be taken in patients with signs of hypovolemia or hypotension because vasodilating effects of the drug may worsen the clinical condition (Box 11.2). The 2014 ACC/AHA guidelines address the prophylactic intraoperative use of NTG and state there is no benefit in preventing myocardial ischemia and cardiac morbidity in high-risk patients undergoing noncardiac surgery and that NTG use could be harmful.[1]

BOX 11.2 ACC/AHA GUIDELINES FOR EARLY USE OF NITROGLYCERIN AFTER STEMI

Class I

1. Patients with ongoing ischemic discomfort should receive sublingual nitroglycerin (0.4 mg) every 5 minutes for a total of 3 doses, after which an assessment should be made about the need for intravenous nitroglycerin (level of evidence [LOE] C).
2. Intravenous nitroglycerin is indicated for relief of ongoing ischemic discomfort, control of hypertension, or management of pulmonary congestion (LOE C).

Class III

1. Nitrates should not be administered to patients with systolic blood pressure less than 90 mm Hg or greater than or equal to 30 mm Hg below baseline, severe bradycardia (<50 beats/min), tachycardia (>100 beats/min), or suspected right ventricular infarction (LOE C).
2. Nitrates should not be administered to patients who have received a phosphodiesterase inhibitor for erectile dysfunction within the last 24 hours (48 hours for tadalafil) (LOE B).

ACC, American College of Cardiology; *AHA*, American Heart Association; *STEMI*, ST-segment elevation myocardial infarction.

BOX 11.3 EFFECTS OF β-ADRENERGIC BLOCKERS ON MYOCARDIAL ISCHEMIA

- Reductions in myocardial oxygen consumption
- Improvements in coronary blood flow
- Prolonged diastolic perfusion period
- Improved collateral flow
- Increased flow to ischemic areas
- Overall improvement in the supply-to-demand ratio
- Stabilization of cellular membranes
- Improved oxygen dissociation from hemoglobin
- Inhibition of platelet aggregation
- Reduced mortality rate after myocardial infarction

β-Adrenergic Blockers

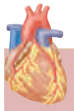
β-Adrenergic blockers have multiple favorable effects in treating the ischemic heart during anesthesia (Box 11.3). β-Adrenergic blockers reduce oxygen consumption by decreasing heart rate, BP, and myocardial contractility. Heart rate reduction increases diastolic CBF. Increased collateral blood flow and redistribution of blood to ischemic areas may occur with β-blockers. Microcirculatory oxygen delivery improves, and oxygen dissociates more easily from hemoglobin after β-adrenergic blockade. Platelet aggregation is inhibited.

β-Blockers should be started early in ischemic patients in the absence of contraindications. If hemodynamics prevent concomitant NTG and β-blockers use, β-blockers should receive precedence.[1] Many patients at high risk for perioperative cardiac morbidity should be started on β-blockers before surgery and continued for up to 30 days after surgery.[81–83] Although the choice of β-blocker for an individual patient is based on clinician familiarity and desired pharmacologic profile, adequate time in initiating β-blocker therapy should be allowed to adjust dosing before surgical procedures. There is no evidence that one specific agent is superior to another, but β-blockers

without intrinsic sympathomimetic activity (ISA) are preferable when treating acute myocardial ischemia.

β-Blockers administered during MI reduce myocardial infarct size.[84] Morbidity has been reduced by acute intravenous metoprolol administration during MI.[84] Similar findings with reductions in mortality extending up to 3 years after MI have been shown in numerous trials with β-adrenergic blockers.[85,86] The mechanisms for mortality reduction are unclear. In the absence of contraindications, β-blockers should be a routine part of care of patients with all forms of CAD, including unstable angina and recent MI.

Data confirm the important role of β-blockade in treating patients after acute MI and in reducing mortality in high-risk populations. Immediate β-blockade after thrombolytic therapy for patients with acute MI significantly decreased recurrent early myocardial ischemia and reinfarction.[87] Early β-blockade is indicated in the treatment of MI[88,89] (Box 11.4). β-Blocker therapy after MI may be greatly underused in patients older than 65 years.[90]



BOX 11.4 ACC/AHA GUIDELINES FOR EARLY THERAPEUTIC USE OF β-ADRENOCEPTOR BLOCKING AGENTS AFTER STEMI

Class I[a]

1. Oral β-blocker therapy should be initiated in the first 24 hours for patients who do not have any of the following: (1) signs of heart failure, (2) evidence of low output state, (3) increased risk[a] of cardiogenic shock, or (4) other relative contraindications to β-blockade (PR interval > 0.24 s), second- or third-degree heart block, active asthma, or reactive airway disease) (level of evidence [LOE] B).
2. Patients with contraindications within the first 24 hours of STEMI should be reevaluated for candidacy for β-blocker therapy as secondary prevention (LOE C).
3. Patients with moderate or severe left ventricular failure should receive β-blocker therapy as secondary prevention with a gradual titration scheme (LOE B).

Class IIa

1. It is reasonable to administer an intravenous β-blocker at the time of presentation to STEMI patients who are hypertensive and who do not have any of the following: (1) signs of heart failure, (2) evidence of a low-output state, (3) increased risk[a] for cardiogenic shock, or (4) other relative contraindications to β-blockade (PR interval >0.24 s, second- or third-degree heart block, active asthma, or reactive airway disease) (LOE B).

Class III

1. Intravenous β-blockers should not be administered to STEMI patients who have any of the following: (1) signs of heart failure, (2) evidence of a low-output state, (3) increased risk[a] of cardiogenic shock, or (4) other relative contraindications to β-blockade (PR interval >0.24 s, second- or third-degree heart block, active asthma, or reactive airway disease) (LOE A).

[a]Risk factors for cardiogenic shock (the greater the number of risk factors, the higher the risk of developing cardiogenic shock) are age older than 70 years, systolic blood pressure less than 120 mm Hg, sinus tachycardia greater than 110 beats/min or heart rate less than 60 beats/min, and increased time since the onset of symptoms of STEMI.

Atenolol can reduce ischemia and adverse outcomes for patients with mildly symptomatic ischemia.[91] Many studies have shown that perioperative administration of β-adrenergic blockers reduces mortality and morbidity when given to patients at high risk for CAD who must undergo noncardiac surgery.[81–83,92,93] These data suggest that intermediate- and high-risk patients undergoing noncardiac surgery should receive perioperative β-adrenergic blockade to reduce postoperative cardiac mortality and morbidity. However, in the POISE trial, the use of higher-dose metoprolol started in patients on the day of noncardiac surgery was associated with an increased risk of severe stroke and a higher total mortality rate.[94] The POISE trial findings have been replicated, and combined with concerns about the validity of the results of the DECREASE trials, they have led to increased scrutiny of perioperative β-blockade usage due to higher rates of stroke, bradycardia, hypotension, and death perioperatively when starting β-blockers in the immediate preoperative period.[92,95]

β-Receptor

The β-receptor was conceptualized by Ahlquist, who divided the various physiologic effects of catecholamine stimulation into α- and β-responses.[96] The β-receptor has been identified biochemically as a polypeptide chain of approximately 50,000 to 60,000 kDa.[97] The receptor's structure is common to most receptor proteins that have been identified: seven transmembrane crossings with two extramembranous terminal ends[98] (Fig. 11.7). All receptors that transduce a signal through G-proteins share this basic structure.[99] Three extracellular and intracellular loops connect the intramembranous portion of the receptor.[98] Agonist-antagonist binding occurs at the intramembranous portion, and the intracellular loops modulate interaction with the G-protein complex.[100,101] The terminal intracellular end contains amino acid residues that undergo phosphorylation, which is related to desensitization and downregulation of the receptor.[102]

Receptor stimulation activates a G-protein, which stimulates adenylyl cyclase. The G-protein complex is composed of stimulatory (G_s) and inhibitory (G_i) intermediary proteins.[99] Adenylyl cyclase converts ATP to cyclic AMP (cAMP) which phosphorylates a protein kinase and produces the appropriate cellular response. A typical cascade of this sequence leading to increases in myocardial contractility from β-receptor stimulation is illustrated in Fig. 11.8.

β-Receptor numbers in any tissue may decrease with chronic stimulation (ie, downregulation) or increase with chronic blockade (ie, upregulation). The process of desensitization of the adrenergic response in chronic stimulation (ie, congestive heart failure [CHF]) may involve downregulation of the receptors and may involve the G-protein complex or adenylyl cyclase. Desensitization may occur very quickly, whereas downregulation with internalization of the receptor within the cell may take days to weeks.[103]

Myocardial ischemia increases β-receptor density, although it remains controversial whether upregulation results in greater adrenergic response.[104] Several studies have demonstrated that high-affinity β-receptors in nonischemic tissue were shifted to a low-affinity state during ischemia.[105,106] The levels and activity of G_s also are reduced during myocardial ischemia.[107] However, stimulation of these receptors with isoproterenol during ischemia does increase cAMP production.[104,108]

β-Receptors have a multitude of responses[109] (Table 11.3). The β_1- and β_2-receptor forms of stimulation primarily involve cardiac function (Fig. 11.9). Responses of isolated human atrial tissue demonstrated greater inotropic response to β_1-receptor stimulation than to β_2-receptor stimulation.[110] Endogenous norepinephrine produces inotropic responses in human atrial appendages and ventricular papillary muscle by β_1-receptor stimulation; epinephrine produces its maximal inotropic effects on the atria by β_2-receptor stimulation and up to 50% of its maximal inotropic response in the ventricle by β_2-receptor stimulation.[111,112] The sinus node, atrioventricular (AV) node, left and right bundle branches, and Purkinje system contain higher densities of β_2-receptors.[113] Both receptor subtypes have cardiac inotropic, chronotropic, and dromotropic properties.

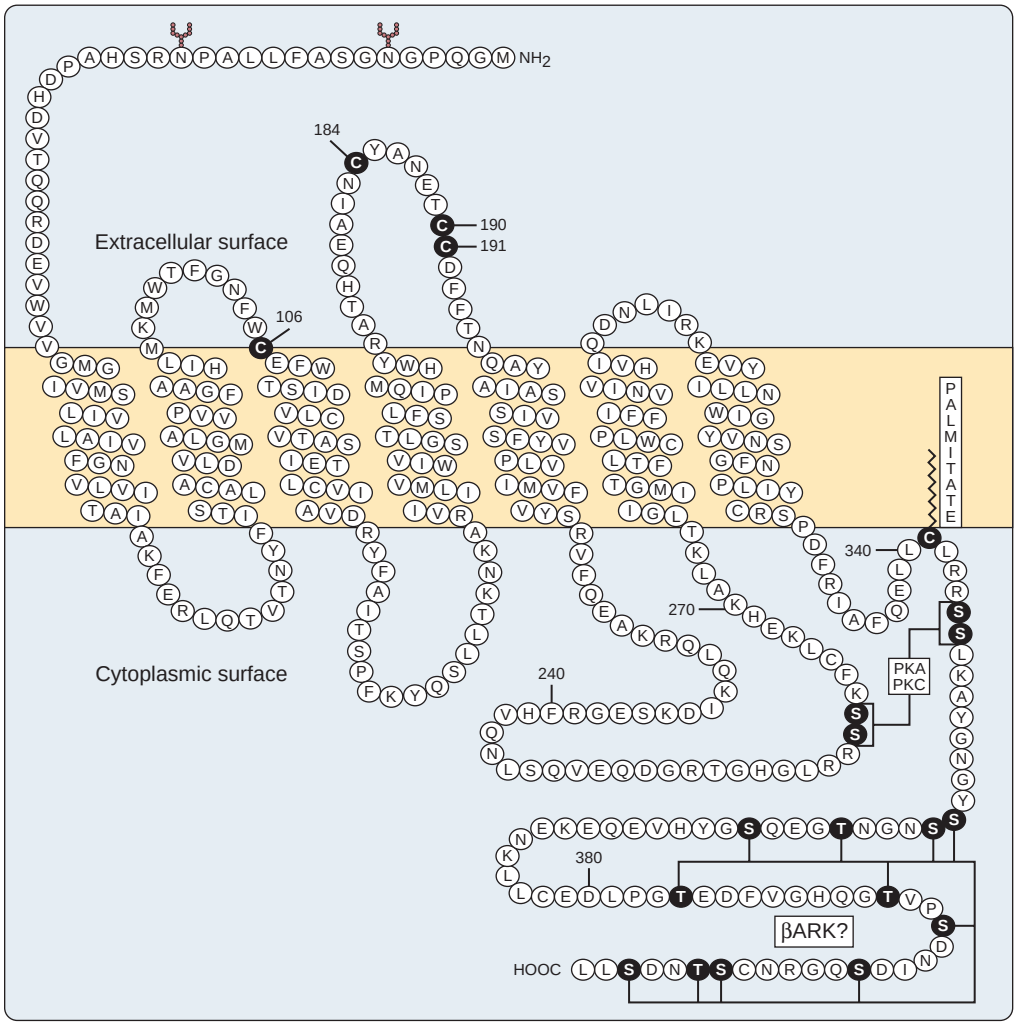

Fig. 11.7 The human β_2-adrenergic receptor (*tan area* represents the cell membrane). Depicted are two sites of extracellular *N*-linked glycosylation (Asn5, 16), four cysteine *(C)* residues that may participate in disulfide bonds (Cys106, 184, 190, 191), an intracellular cysteine residue (Cys341) that may serve as a site of attachment for a palmitate membrane anchor, and multiple threonine *(T)* and serine *(S)* residues located in C-III and the cytoplasmic carboxyl terminus, which are potential sites of phosphorylation by protein kinase A *(PKA)*, protein kinase C *(PKC)*, or β-adrenergic receptor kinase (βARK). *(From Raymond JR, Hnatowich M, Lefkowitz RJ, Caron MG. Adrenergic receptors. Models for regulation of signal transduction processes.* Hypertension. *1990;15:119.)*

β_2-Adrenoceptors comprise 93% of the total population of β-receptors in arterioles and 100% of receptors in the epicardium, vena cava, aorta, and pulmonary artery.[112] β_2-Receptors are found on the intimal surface of human internal mammary artery but not on the saphenous vein,[114] the two vessels most commonly used for coronary artery bypass graft (CABG) surgery β_2-Stimulation results in vascular smooth muscle relaxation and vasodilation.

β_1-Receptor stimulation increases plasma renin production and aqueous humor production. β_2-Receptor stimulation relaxes smooth muscle and produces bronchodilation and uterine relaxation. β_2-Stimulation also increases insulin secretion, glycogenolysis, and lipolysis and shifts extracellular potassium to intracellular sites. β_3-Adrenoreceptors are found on visceral adipocytes, the gallbladder, and colon. Stimulation of β_3-receptors is thought to mediate lipolytic and thermic responses in brown and white adipose tissue.[115]

Physiologic Effects

Antiischemic Effects

β-Blockade on the ischemic heart may result in a favorable shift in the oxygen supply-to-demand ratio (see Table 11.1). Reductions in the force of contraction and heart rate reduce $M\dot{V}O_2$ and result in autoregulatory decreases in myocardial blood flow. Several studies have shown that blood flow to ischemic regions with propranolol is maintained, but this probably results from maintenance of α-vasoconstrictor tone of epicardial vessels and of a pressure gradient to the vasodilated endocardial areas of ischemia.[116,117]

Reductions in blood flow in some patients with vasospastic angina may worsen with the administration of propranolol.[118] Intracoronary infusion of propranolol does not worsen stenotic lesions and increases the luminal size of the stenosis at rest and during exercise.[119]

Antihypertensive Effects

The exact mechanisms involved in BP reduction are not clear. Both β_1- and β_2-receptor blockers inhibit myocardial contractility and reduce heart rate; both effects should reduce BP. No acute decrease in BP occurs during acute administration of propranolol.[120] However, chronic BP reduction has been attributed to a chronic reduction in cardiac output (CO).[121]

Reductions in high levels of plasma renin have been suggested as effective therapy for controlling essential hypertension.[122] However, the

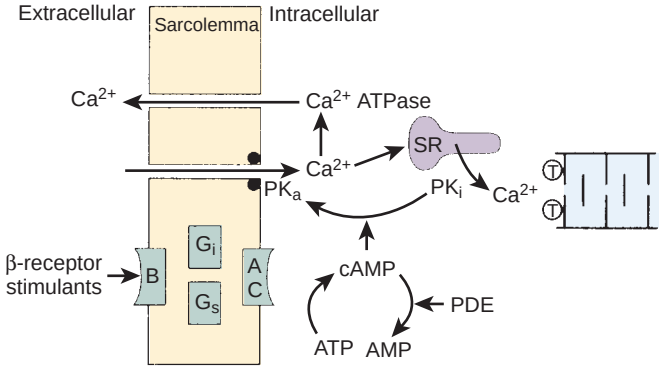

Fig. 11.8 The β-receptor, G-protein, adenylyl cyclase system. With β-receptor stimulation *(B)*, dynamic changes occur in the inhibitory G_i and stimulatory G_s regulatory proteins. Ultimately, G_s stimulates adenylyl cyclase *(AC)* to convert adenosine triphosphate *(ATP)* to cyclic adenosine monophosphate *(cAMP)*, which is metabolized by phosphodiesterase enzyme *(PDE)*. An inactive protein kinase *(PK_i)* is activated *(PK_a)* by cAMP, which opens an energy-dependent receptor-operated calcium channel, allowing calcium entry into the cell. Calcium cycling occurs with calcium actively pumped out of the cell by Ca^{2+} adenosine triphosphatase *(ATPase)*. Calcium cycling causes a release of calcium from the sarcoplasmic reticulum *(SR)*, allowing calcium to bind to troponin C *(T)*, with subsequent activation of the actin-myosin complex. *AMP*, Adenosine monophosphate. *(Modified from Royster RL. Intraoperative administration of inotropes in cardiac surgery patients.* J Cardiothorac Anesth. *1990;4:17.)*

relationship between renin levels and hypertension is not established, and the decrease in BP has no relation to the change in renin levels in patients.[123,124]

Stimulation of prejunctional β-receptors results in norepinephrine release from postganglionic sympathetic fibers and increases in vascular tone to most major organ systems.[125] Prejunctional β-blockade reduces norepinephrine release, sympathetic nerve traffic, and vascular tone.[125]

Electrophysiologic Effects

Several β-blockers have potent local anesthetic effects at higher serum levels because of sodium channel blocking activity and result in depression of phase 0 of the cardiac action potential.[126] However, the membrane-stabilizing or quinidine-like effect is of questionable clinical relevance because it is observed at concentrations far exceeding therapeutic levels.[127] Generalized slowing of cardiac depolarization results from reducing the rate of diastolic depolarization (ie, phase 4). Action potential duration (APD) and the QT interval may shorten with β-adrenergic blockers.[126] The ventricular fibrillation (VF) threshold is increased with β-blockers.[128] These antiarrhythmic actions of β-blockers are enhanced in settings of catecholamine excess as in pheochromocytoma, acute MI, the perioperative period, and hyperthyroidism.

Metabolic Effects

Although β_2-blockers are reported to reduce insulin release, the clinical significance of the reduction is questionable.[129] Catecholamines, however, promote glycogenolysis and mobilization of glucose in response to hypoglycemia. In the diabetic patient, nonselective β-blockade may impede this process, worsening recovery from a hypoglycemic episode. The usual hypoglycemic symptoms of tachycardia and anxiety may be suppressed when taking β-blockers, delaying detection. Bradycardia and hypertension are documented side effects of hypoglycemia in diabetic patients receiving propranolol because of unopposed β-receptor stimulation with catecholamine release.[130]

Stimulation of β_2-receptors increases the movement of potassium into skeletal muscle cells, reduces aldosterone secretion, and increases renal potassium loss, effects that reduce serum potassium levels. β_2-Receptor blockers aid in the maintenance of serum potassium levels by blocking the adrenergic-stimulated movement of potassium intracellularly.[131] β_2-Receptor blockers may cause mild elevations in serum potassium, which may be significant in patients with renal insufficiency.[132]

Inhibition of catecholamine-stimulated lipolysis may occur with β-blockers, which reduces the availability of free fatty acids to activate contracting muscle such as the heart.[133] β-Adrenergic blockers increase serum levels of triglycerides, decrease high-density lipoprotein cholesterol, and cause little change in low-density lipoprotein cholesterol. A proposed mechanism is an increase in the relative ratio of α- to β-receptor activity.[134] Increases in β-receptor activity result in increases in lipoprotein lipase and triglyceride levels.[135] These effects on blood lipids are concerns for patients receiving chronic therapy. However, animal studies have revealed that β-blockers have a retarding effect on the development of atherosclerosis.[136] β-Blockers with ISA produce the smallest changes in the lipid profile.[137]

Intrinsic Sympathomimetic Activity

Several β-blockers (eg, acebutolol, carteolol, penbutolol, pindolol) have agonist and antagonist properties and are characterized as having ISA.[138] These agents are agonists that elicit a submaximal response and block the effects of endogenous catecholamines in a competitive fashion.[138] CO and heart rate are reduced less with ISA drugs.[139] Peripheral blood flow is reduced less, making ISA agents attractive in patients with peripheral vascular disease.[140] ISA drugs also cause less bronchoconstriction and are advantageous in chronic obstructive pulmonary disease. Theoretically, changes in β-receptor density should differ with ISA. The ISA drugs reduce β-receptor density (similar to pure agonists), whereas non-ISA agents increase β-receptor density.[141]

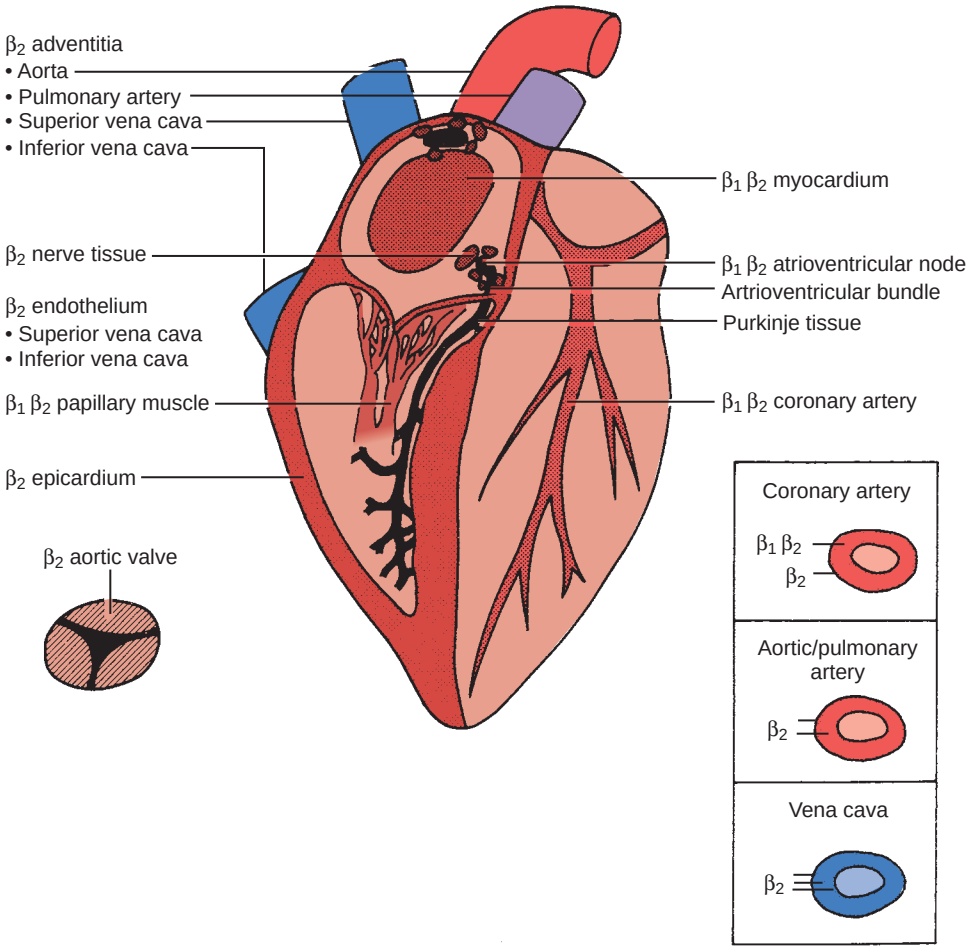

Fig. 11.9 Locations of β_1- and β_2-adrenoceptors in rat, guinea pig, dog, and human hearts determined by autoradiography. The β_1- and β_2-adrenoceptors are located on myocardium and specialized conducting tissue. A greater density of β_2-adrenoceptors is found on the atrioventricular node, bundle of His, and left and right bundle branches compared with surrounding myocardium in guinea pig. The β_2-adrenoceptors are located on blood vessels, nerve tissue, epicardium, and the aortic valve. In large canine coronary arteries (0.5 to 2 mm in diameter), β_1-adrenoceptors account for 85% of the total population of β-adrenoceptors; in small arterioles (16 to 55 μm), β_2-adrenoceptors comprise 93% of the total population. *(Modified from Summers RJ, Molenaar P, Stephenson JA. Autoradiographic localization of receptors in the cardiovascular system.* Trends Pharmacol Sci. *1987;8:272; Jones CR. New views of human cardiac β-adrenoceptors.* J Mol Cell Cardiol. *1989;21:519.)*

Although controversial, ISA drugs appear to have a role in mortality reduction after MI, similar to non-ISA β-blockers.[142]

General Pharmacology

Lipid-soluble β-blockers (eg, propranolol, labetalol, metoprolol) are well absorbed after oral administration and attain high concentrations in the brain.[143] Lipid-soluble agents produce a high incidence of central nervous system (CNS) side effects, such as depression, sleep disturbances, and impotence. The rate of first-pass hepatic metabolism after oral ingestion can be very high but varies from patient to patient and affects daily dosing schedules.[144] Cirrhosis, CHF, and cigarette smoking may reduce hepatic metabolism.[145] Lipophilic agents are highly protein bound. The hepatic metabolism of lipophilic agents is independent of protein binding, which is different from most drugs, for which hepatic metabolism occurs only with the unbound drug.[146]

Lipid-insoluble or water-soluble agents (eg, atenolol, nadolol, acebutolol, sotalol) are less well absorbed orally but are not hepatically metabolized. They are almost entirely eliminated by renal excretion and must be used cautiously in renal insufficiency. The incidence of CNS side effects is low because of lipid insolubility.

Pindolol and timolol have intermediate lipid solubility properties and are metabolized partially by the liver (50%) and excreted through the kidneys (50%). Information on the available oral and intravenous β-adrenergic blockers for treatment of myocardial ischemia is provided in Table 11.4. Some β-blockers with other indications, such as carvedilol (for CHF) and sotalol (for arrhythmias), are covered later in this chapter.

Pharmacology of Intravenous β-Adrenergic Blockers

Propranolol

Propranolol has an equal affinity for β_1- and β_2-receptors, lacks ISA, and has no β-adrenergic receptor activity. It is the most lipid-soluble β-blocker and has the most CNS side effects. Because the rate of first-pass liver metabolism is very high (90%), it requires much higher oral doses than intravenous doses for pharmacodynamic effect.[147] Although propranolol has an active metabolite (ie, 4-hydroxypropranolol), the metabolite's half-life is much shorter and does not add to the clinical effect.[148] Serum half-life of the drug after intravenous dosing is 3 to 4 hours.[149]

TABLE 11.4 Properties of β-Blockers in Clinical Use

Drug	*Selectivity*	*Partial Agonist Activity*	*Usual Dose for Angina*
Propranolol	None	No	20–80 mg bid
Metoprolol	β_1	No	50–200 mg bid
Atenolol	β_1	No	50–200 mg/d
Nadolol	None	No	40–80 mg/d
Timolol	None	No	10 mg bid
Acebutolol	β_1	Yes	200–600 mg bid
Betaxolol	β_1	No	10–20 mg/d
Bisoprolol	β_1	No	10 mg/d
Esmolol (infusion)	β_1	No	50–300 $\mu g \cdot kg^{-1} \cdot min^{-1}$
Labetalol[a]	None	Yes	200–600 mg tid
Pindolol	None	Yes	2.5–7.5 mg tid

[a]Labetalol is a combined α- and β-blocker.

Modified from Gibbons RJ, Chatterjee K, Daley J, Douglas JS. ACC/AHA/ACP-ASIM guidelines for the management of patients with chronic stable angina: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on Management of Patients with Chronic Stable Angina). *J Am Coll Cardiol.* 1999;33:2092–2197.

Because of the high rate of hepatic extraction of propranolol, factors that affect hepatic blood flow markedly affect propranolol plasma levels. Because propranolol reduces hepatic blood flow, it can reduce its own metabolism and the metabolism of other drugs.[150] This must be taken into consideration during anesthetic procedures in patients with liver disease, reduced CO states, and right ventricular heart failure (HF).

Propranolol serum levels of 100 ng/mL produce a maximal β-blocking effect for reducing exercise-induced tachycardia.[144] Propranolol still produces a 50% reduction of exercise-induced tachycardia at serum levels of 12 ng/mL.[151] Reductions in heart rate with propranolol occur at lower serum levels than depression of myocardial contractility.[152] As drug levels decrease after discontinuation of therapy, reductions in the chronotropic response last much longer than reductions in inotropy.[152] This is an important concept in treating tachycardias in patients with significant ventricular dysfunction and CHF.

The usual intravenous dose of propranolol initially is 0.5 to 1.0 mg titrated to effect. A titrated dose resulting in maximal pharmacologic serum levels is 0.1 mg/kg. The use of continuous infusions of propranolol has been reported after noncardiac surgery in patients with cardiac disease.[153] A continuous infusion of 1 to 3 mg/h can prevent tachycardia and hypertension but must be used cautiously because of the potential of cumulative effects.

Metoprolol

Metoprolol was the first clinically used cardioselective β-blocker. Its affinity for β_1-receptors is 30 times higher than its affinity for β_2-receptors as demonstrated by radioligand binding.[154] Metoprolol is lipid soluble, with 50% of the drug metabolized during first-pass hepatic metabolism and with only 3% excreted renally.[155] Protein binding is less than 10%. Metoprolol's serum half-life is 3 to 4 hours. Because of its lipophilic properties, metoprolol has been shown in animal studies to diffuse into ischemic tissue better than atenolol, a hydrophilic β-receptor blocker.[154]

As with any cardioselective β-blocker, higher serum levels may result in greater incidence of β_2-blocking effects. Metoprolol is administered intravenously in 1- to 2-mg doses, titrated to effect. The potency of metoprolol is approximately one-half that of propranolol. Maximal β-blocker effect is achieved with 0.2 mg/kg given intravenously.

Esmolol

Esmolol's chemical structure is similar to that of metoprolol and propranolol, except that it has a methylester group in the *para*-position of the phenyl ring, making it susceptible to rapid hydrolysis by red blood cell esterases (ie, 9-minute half-life).[156] Esmolol is not metabolized by plasma cholinesterase. Hydrolysis results in an acid metabolite and methanol with clinically insignificant levels.[157] Ninety percent of the drug is eliminated in the form of the acid metabolite, normally within 24 hours.[157] A loading dose of 500 μg/kg given intravenously followed by a 50 to 300 μg/kg per minute infusion reaches steady-state concentrations within 5 minutes. Without the loading dose, steady-state concentrations are reached in 30 minutes.[157]

Esmolol is cardioselective, blocking primarily β_1-receptors. It lacks ISA and membrane-stabilizing effects and is mildly lipid soluble. Esmolol produced significant reductions in BP, heart rate, and the cardiac index after a loading dose of 500 μg/kg and an infusion of 300 μg/kg per minute in patients with CAD, and the effects were completely reversed 30 minutes after discontinuation of the infusion.[158] Initial therapy during anesthesia may require significant reductions in the loading and infusion doses.

Hypotension is a common side effect of intravenous esmolol. The incidence of hypotension was higher with esmolol (36%) than with propranolol (6%) at equal therapeutic end points.[159] The cardioselective drugs may cause more hypotension because of β_1-induced myocardial depression and the failure to block β_2 peripheral vasodilation. Esmolol appears safe in patients with bronchospastic disease. In another comparative study with propranolol, esmolol and placebo did not change airway resistance, and 50% of patients treated with propranolol developed clinically significant bronchospasm.[160] Phlebitis may occur at the site of intravenous administration after prolonged infusion.[161]

Esmolol inhibits human plasma cholinesterase during in vitro studies, in which clinically insignificant prolongation of duration of succinylcholine action by esmolol was reported.[162] Digoxin levels may increase slightly with concomitant esmolol administration.[163] Esmolol and landiolol, a short-acting β_1-receptor blocker, suppress the bispectral index during general anesthesia.[164]

Labetalol

Labetalol is an equal mixture of four stereoisomers with various α- and β-blocking properties. Labetalol provides selective α_1-receptor blockade and nonselective β_1- and β_2-blockade. The potency of β-adrenergic blockade is 5- to 10-fold greater than α_1-adrenergic blockade.[15,164] Labetalol has partial β_2-agonist effects that promote vasodilation.[165] It is moderately lipid soluble and is completely absorbed after oral administration.[166] First-pass hepatic metabolism is significant, with production of inactive metabolites.[166] Renal excretion of the unchanged drug is minimal. Elimination half-life is approximately 6 hours.[166]

In contrast to other β-blockers, labetalol should be considered a peripheral vasodilator that does not cause a reflex tachycardia. BP and systolic vascular resistance decrease after an intravenous dose.[167] Stroke volume (SV) and CO remain unchanged, with the heart rate decreasing slightly.[168] The reduction in BP is dose related, and acutely hypertensive patients usually respond within 3 to 5 minutes after a bolus dose of 100 to 250 μg/kg.[169] However, the more critically ill or anesthetized patients should have their BP titrated beginning with 5- to 10-mg intravenous increments. The BP reduction may last as long as 6 hours after intravenous dosing.

Significant Adverse Effects

CHF can be precipitated by β-adrenergic blockers, especially when used with other cardiac drugs with myocardial depressant properties, such as calcium blockers and disopyramide. β-Blockers used with other depressant agents blunt the usual reflex in sympathetic activity.[170] The effects on the conduction system are additive, and heart block can occur. Propranolol reduces the clearance of many drugs that depend on hepatic metabolism by reducing hepatic blood flow (eg, lidocaine).[171]

β_2-Blockers can cause bronchospasm and peripheral vasoconstriction, which can exacerbate symptoms in patients with chronic pulmonary disease and peripheral vascular disease. Impotence is a problem in some patients. The lipophilic agents cause many CNS side effects such as depression, sleep disturbances, and fatigue. Hypoglycemia is a significant problem for diabetics.

Sudden withdrawal of β-adrenergic blockers can precipitate a state of enhanced adrenergic activity, resulting in tachycardia, hypertension, arrhythmias, myocardial ischemia, and infarction.[172] Most studies indicate that this period of hypersensitivity occurs 2 to 6 days after withdrawal of β-blockade and corresponds to an increase in human lymphocyte β-receptors. Continuing β-receptor blockers before cardiac surgery results in a more stable anesthetic induction, intubation, and sternotomy sequence than performing anesthesia and surgery during a period of withdrawal hypersensitivity.[82,173] Reinstitution of small doses of β-adrenergic blockade after cardiac surgery smoothes the postoperative course and reduces the incidence of tachyarrhythmias.[174]

Summary

β-Adrenergic blockers are first-line agents in the treatment of myocardial ischemia. These agents effectively reduce myocardial work and oxygen demand. Although perioperative β-blockers may decrease perioperative cardiovascular events in noncardiac surgery, the benefit may come at an increased short-term risk for severe complications, including stroke and death if started too close to the time of surgery.[175]

Calcium Channel Blockers

Calcium channel blockers reduce myocardial oxygen demands by depression of contractility, heart rate, and arterial BP.[176] Myocardial oxygen supply may be improved by dilation of coronary and collateral vessels. Calcium channel blockers are used primarily for symptom control in patients with stable angina pectoris. In an acute ischemic situation, calcium channel blockers (ie, verapamil and diltiazem) may be used for rate control when β-blockers cannot be used.

The most important effects of calcium channel blockers may be the treatment of variant angina. These drugs can attenuate ergonovine-induced coronary vasoconstriction in patients with variant angina, suggesting protection by coronary dilation.[177] Most episodes of silent myocardial ischemia, which may account for 70% of all transient ischemic episodes, are not related to increases in myocardial oxygen demands (ie, heart rate and BP); instead, intermittent obstruction of coronary flow is likely caused by coronary vasoconstriction or spasm.[178] All calcium channel blockers are effective at reversing coronary spasm, reducing ischemic episodes, and reducing NTG consumption in patients with variant or Prinzmetal angina.[179]

Combinations of NTG and calcium channel blockers, which also effectively relieve and possibly prevent coronary spasm, are rational therapy for variant angina. β-Blockers may aggravate anginal episodes in some patients with vasospastic angina and should be used with caution.[180] Preservation of CBF with calcium channel blockers is a significant difference from the predominant β-blocker antiischemic effects of reducing $M\dot{V}O_2$.

Calcium channel blockers have proved effective for treating of stable angina in controlled trials.[181–184] However, rapid-acting DHPs such as nifedipine may cause a reflex tachycardia, especially during initial therapy, and exacerbate anginal symptoms. These proischemic effects probably explain why the short-acting DHP nifedipine in high doses produces adverse effects in patients with unstable angina. The introduction of long-acting DHPs, such as extended-release nifedipine, amlodipine, felodipine, isradipine, nicardipine, and nisoldipine, has led to fewer adverse events. These agents should be used in combination with β-blockers. Some patients may have symptomatic relief improved more with calcium channel blockers than with β-blocker therapy; although it is difficult to predict which patients respond better by other than empiric observation.

The causes of unstable angina may involve coronary vasospasm, an accelerated atherosclerotic process, or enhanced platelet aggregation with fibrin clot formation. Calcium channel blockers have favorable effects in all three of the processes and are effective in the relief of symptoms of unstable angina.[185] There are no significant clinical differences in the response of patients with unstable angina to β-adrenergic blockers and calcium channel blockers.[186]

Calcium Channel

Calcium channels are functional pores in membranes through which calcium flows down an electrochemical gradient when the channels are open. Calcium channels exist in cardiac muscle, smooth muscle, and probably many other cellular membranes. These channels are also found in cellular organelle membranes such as the sarcoplasmic reticulum (SR) and mitochondria. Calcium functions as a primary generator of the cardiac action potential and an intracellular second messenger to regulate various intracellular events.[187]

Calcium enters cellular membranes through voltage-dependent channels or receptor-operated channels. The voltage-dependent channels depend on a transmembrane potential for activation (ie, opening). Receptor-operated channels are linked to a voltage-dependent channel after receptor stimulation or directly allow calcium passage through cell or organelle membranes independent of transmembrane potentials.

There are three types of voltage-dependent channels: the transient (T), long-lasting (L), and neuronal (N) channels.[188] The T and L channels are located in cardiac and smooth muscle tissue, whereas the N channels are located only in neural tissue. The T channel is activated at low voltages (−50 mV) in cardiac tissue, plays a major role in cardiac depolarization (ie, phase 0), and is not blocked by calcium antagonists.[189,190] The L channels are the classic slow channels, are activated at higher voltages (−30 mV), and are responsible for phase 2 of the cardiac action potential. These channels are blocked by calcium antagonists.[189,190]

Receptor-operated channels regulate calcium entry through voltage-regulated channels or through channels regulated by the receptor system. The β-adrenergic receptor operates an L-type voltage-dependent channel, which is activated by phosphorylation of a protein kinase by cAMP generated by the β-adrenergic receptor.[190] α_1-Receptor stimulation activates a G-protein, which causes phospholipase C to hydrolyze phosphatidylinositol diphosphate to diacylglycerol (DAG) and inositol 1,4,5-triphosphate (IP3).[191] DAG activates protein kinase C that likely phosphorylates an L-type channel allowing calcium entry, whereas IP3 is a second messenger that interacts with the SR and directly promotes calcium release from the SR through an intracellular calcium channel.[192] A receptor-operated channel may also increase calcium entry stimulated directly by a G-protein. Both α_2-receptor and β-receptor stimulation may activate G-protein–regulated channels, which are not voltage dependent[193,194] (see Chapter 8).

Calcium channel blockers interact with the L-type calcium channel and are composed of drugs from four classes: the 1,4-DHP derivatives (eg, nifedipine, nimodipine, nicardipine, isradipine, amlodipine, felodipine); the phenylalkyl amines, (eg, verapamil); the benzothiazepines (eg, diltiazem); and a diarylaminopropylamine ether (ie, bepridil).[15] The L-type calcium channel has specific receptors that bind to each of the different chemical classes of calcium channel blockers.[195] Binding to calcium blocker receptors by DHP derivatives (eg, nifedipine) is voltage dependent.[196]

Calcium channels transform from a closed resting form that can potentially open, to an activated open form, to an inactive conformation that cannot open, and then back to the closed resting form. Nifedipine binds preferentially to the inactive receptor that has recently undergone activation and cannot open. Nifedipine essentially acts as a plug to block the channel. Verapamil binds to the L-type channel preferentially when it is active or open.[197] The greater the period of activation of the channel, the more effective is the blockade (ie, use dependent). Any repetitive activity, such as cardiac pacemaker activity, is sensitive to use-dependent agents.

Physiologic Effects

Hemodynamic Effects

Systemic hemodynamic effects of calcium channel blockers in vivo represent a complex interaction among myocardial depression, vasodilation, and reflex activation of the autonomic nervous system (Table 11.5).

TABLE 11.5 Calcium Channel Blocker Vasodilator Potency and Inotropic, Chronotropic, and Dromotropic Effects on the Heart

From Ferlinz J, Easthope JL, Aronow WS. Effects of verapamil on myocardial performance in coronary disease. *Circulation.* 1979;59:313.

Nifedipine, like all DHPs is a potent arterial dilator with few venodilating effects.[198] Reflex activation of the sympathetic nervous system (SNS) may increase heart rate. The intrinsic negative inotropic effect of nifedipine is offset by potent arterial dilation, which lowers BP and increases CO in patients.[199] DHPs are excellent antihypertensive agents because of their arterial vasodilatory effects. Antianginal effects result from reduced myocardial oxygen requirements due to the afterload-reducing effect and to coronary vascular dilation resulting in improved myocardial oxygen delivery.

Verapamil is a less potent arterial dilator than the DHPs and results in less reflex sympathetic activation. In vivo, verapamil usually results in moderate vasodilation without significant changes in heart rate, CO, or SV[200] (Table 11.6). Intravenous administration of verapamil in the catheterization laboratory causes increases in right ventricular pressure and LVEDP, decreases in SVR, improvement of the ejection fraction (EF), and little change in pulmonary artery pressure.[201] Verapamil can significantly depress myocardial function in patients with preexisting ventricular dysfunction.[202]

Diltiazem is a less potent vasodilator and has fewer negative inotropic effects compared with verapamil. Clinical studies reveal reductions in SVR and BP, with increases in CO, pulmonary arterial wedge pressure, and EF[203] (Fig. 11.10). Diltiazem attenuates baroreflex increases in heart rate due to NTG and decreases in heart rate due to phenylephrine.[204] Regional blood flow to the brain and kidney increases, whereas skeletal muscle flow does not change.[205] In contrast to verapamil, diltiazem is not as likely to aggravate CHF, although it should be used carefully in these patients.[206]

A comparative study of physiological responses and membrane receptor activity.* Circ Res. *1983;52[suppl I]:29.)*

Coronary Blood Flow

Coronary artery dilation occurs with the calcium channel blockers, along with increases in total CBF (Fig. 11.11). Nifedipine is the most potent coronary vasodilator, especially in epicardial vessels, which are prone to coronary vasospasm. Diltiazem is effective in blocking coronary artery vasoconstriction caused by a variety of agents, including α-agonists, serotonin, prostaglandin, and acetylcholine.[177,207,208]

Calcium channel blockers may dilate the coronary artery at the stenotic site, reducing the pressure gradient across the coronary lesion.[177]

Diltiazem preferentially dilates coronary arteries compared with other peripheral vessels.[209] Animal studies demonstrate that nifedipine, verapamil, and diltiazem increase coronary collateral flow distal to coronary ligation in animals and improve subendocardial flow relative to subepicardial flow[210–213] (Fig. 11.12).

Electrophysiologic Effects

Calcium channel blockers exert their primary electrophysiologic effects on tissue of the conducting system that depends on calcium for generation of the action potential, primarily at the sinoatrial (SA) and AV nodes. They do not alter the effective refractory period (ERP) of atrial, ventricular, or His-Purkinje tissue. Diltiazem and verapamil exert these electrophysiologic effects in vivo and in vitro, whereas the DHPs' (eg, nifedipine) electrophysiologic depression is completely attenuated by reflex sympathetic activation. Nifedipine can enhance SA and AV node conduction, whereas verapamil and diltiazem slow conduction velocity and prolong refractoriness of nodal tissue.[214–216]

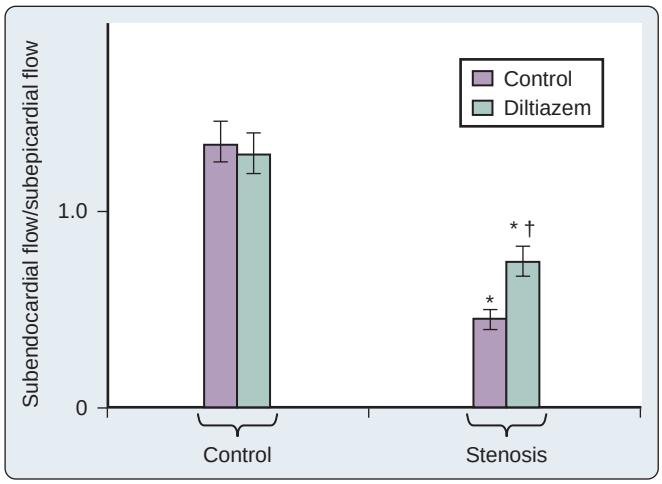

Fig. 11.12 The ratio of subendocardial to subepicardial blood flow during resting control conditions and in the setting of proximal stenosis, which prevented arterial inflow from increasing above the preocclusion control after a 10-second coronary artery occlusion in animals. Diltiazem increased subendocardial to subepicardial blood flow ratio in the ischemic area. Values are mean ± SEM. *$P < .05$ compared with measurements during control conditions with unimpeded arterial inflow. †$P < .05$ compared with the control stenosis. *(From Bache RJ, Dymek DJ. Effect of diltiazem on myocardial blood flow.* Circulation. *1982;65[suppl I]:1.)*

Atherosclerosis

Calcium is involved in the generation of atherosclerotic plaque and in damaged atherosclerotic tissue (ie, calcification).[217] Verapamil and nifedipine have antiatherogenic effects.[217] Nifedipine can retard angiographic progression of CAD in humans.[218] Diltiazem may also reduce atherosclerotic progression after heart transplantation.[219] Diltiazem suppresses aortic atherosclerosis (but not that of coronary arteries), inhibits spontaneous calcinosis in hypertensive rats, and prevents vitamin D–induced calcinosis in arterial elastic tissue.[220–222] Diltiazem also suppresses necrosis of aortic smooth muscle cells by hyperlipidemia serum[223] and intimal thickening in rabbit carotid arteries.[224]

Platelet Aggregation

Calcium antagonists, nitrates, and β-adrenergic blockers inhibit platelet aggregation. This may be the most important effect of all antiischemic drugs, especially in the treatment of chronic disease. Calcium is a mediator involved in the release of platelet aggregatory factors, such as adenosine diphosphate, and verapamil inhibits calcium-induced release of these factors.[225] Diltiazem inhibition of platelet aggregation correlates with changes in intracellular calcium levels.[226] In vivo, diltiazem inhibits platelet aggregation after 24 hours in healthy volunteers.[227] Similar antiaggregatory effects of diltiazem were seen in patients with unstable angina, but no inhibitory effect of platelet aggregation was found with verapamil. Diltiazem metabolites are even more effective in inhibiting platelet aggregation than diltiazem.[228]

Metabolic Effects

Nifedipine may be associated with decreases in serum glucose levels in diabetics, but glucose levels in normal volunteers usually rise slightly with nifedipine and in hypertensive patients with diltiazem.[229,230] Diltiazem reportedly has no effect on insulin, glucagon, growth hormone, or cortisol levels.[231,232] However, nifedipine apparently delays insulin release in diabetic patients.[232]

Pharmacology

Table 11.7 illustrates the pharmacokinetic parameters of the US Food and Drug Administration (FDA)–approved antiischemic calcium channel blockers.

TABLE 11.7 Properties of Calcium Antagonists in Clinical Use

Drug	*Usual Dosage*	*Duration of Action (Half-Life)*	*Side Effects*
Dihydropyridines			
Nifedipine	Immediate release: 30–90 mg qd Slow release: 30–180 mg	Short (0.2–1 h) Long (24 h)	Hypotension, dizziness, flushing, nausea, constipation, edema Hypotension, dizziness, flushing, nausea, constipation, edema
Amlodipine	5–10 mg qd	Very long (30–50 h)	Headache, edema
Felodipine	5–10 mg qd	Long (11–16 h)	Headache, edema
Isradipine	2.5–10 mg qd	Medium (8–12 h)	Headache, fatigue
Nicardipine	Immediate release: 20–40 mg tid Slow release: 30–60 mg bid	Short (6–8 h) Medium (8–12 h)	Headache, dizziness, flushing, edema
Nisoldipine	20–40 mg qd	Short (7–12 h)	Hypotension, dizziness, flushing, nausea, constipation, edema
Nitrendipine	20 mg qd or bid	Long (12–24 h)	Hypotension, dizziness, flushing, nausea, constipation, edema
Miscellaneous			
Bepridil	200–400 mg qd	Very long (3 0–40 h)	Arrhythmias, dizziness, nausea
Benzothiazepines			
Diltiazem	Immediate release: 30–90 mg qd Slow release: 120–480 mg qd	Short (6–8 h) Long (12–24 h)	Hypotension, dizziness, flushing, bradycardia, edema Hypotension, dizziness, flushing, bradycardia, edema
Phenylalkylamines			
Verapamil	Immediate release: 80–160 mg tid Slow release: 120–480 mg qd	Short (6–8 h) Long (12–24 h)	Hypotension, heart failure, myocardial depression, edema, bradycardia Hypotension, heart failure, myocardial depression, edema, bradycardia

From Gibbons RJ, Chatterjee K, Daley J, Douglas JS. ACC/AHA/ACP-ASIM guidelines for the management of patients with chronic stable angina: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on Management of Patients with Chronic Stable Angina). *J Am Coll Cardiol.* 1999;33:2092–2197.

Nifedipine

Nifedipine was the first dihydropyridine derivative to be used clinically. Other dihydropyridines available for clinical use include nicardipine, isradipine, amlodipine, felodipine, and nimodipine.[233] In contrast to the other calcium channel blockers, nimodipine is highly lipid soluble and penetrates the blood-brain barrier. It is indicated for vascular spasm after intracerebral bleeding.

Nifedipine's oral bioavailability is approximately 70%, with peak plasma levels occurring within 30 to 45 minutes. The rate of protein binding is 95%, and the elimination half-life is approximately 5 hours. Nifedipine is available for oral administration in capsular form. The compound degenerates in the presence of light and moisture, preventing commercially available intravenous preparations. Puncture of the capsule and sublingual administration provide an onset of effects in 2 to 3 minutes. Nifedipine GITS (GastroIntestinal Therapeutic System, Procardia XL), a long-acting, controlled-release delivery system, is available for single daily dosing and has become the preferred preparation. It has an onset of action of 20 minutes, with steady-state plasma levels being reached in 48 hours.

Nicardipine

Nicardipine is a dihydropyridine agent with a longer half-life than nifedipine and with vascular selectivity for coronary and cerebrovascular beds. Nicardipine may be the most potent overall relaxant of vascular smooth muscle among the dihydropyridines.[234] Peak plasma levels are reached 1 hour after oral administration, with bioavailability of 35%.[235] Plasma half-life is approximately 8 to 9 hours. Although the drug undergoes extensive hepatic metabolism with less than 1% of the drug excreted renally, greater renal elimination occurs in some patients.[236] Plasma levels may increase in patients with renal failure, and reduction of the dose is recommended in these patients.[235]

Nicardipine is a potent cerebrovascular vasodilator that has prevented ischemia-related neuronal necrosis in animal studies.[237,238] Marked improvements in CBF occur with nicardipine.[239] Although coronary vasodilation is one explanation, positive inotropic effects with phosphodiesterase activity or calcium channel agonist (and antagonist) activity resulting in autoregulatory increases in blood flow may be an additional mechanism.[240]

Verapamil

Verapamil's structure is similar to that of papaverine. Verapamil exhibits significant first-pass hepatic metabolism, with a bioavailability of only 10% to 20%.[241] One hepatic metabolite, norverapamil, is active and has a potency approximately 20% of that of verapamil.[241] Peak plasma levels are reached within 30 minutes. Bioavailability markedly increases in hepatic insufficiency, mandating reduced doses.[241] Intravenous verapamil achieves hemodynamic and dromotropic effects within minutes, peaking at 15 minutes and lasting up to 6 hours. Accumulation of the drug occurs with prolonged half-life during long-term oral administration.[242]

Verapamil's metabolism depends on hepatic blood flow and may decrease in the presence of H_2-receptor blockers. Increased metabolism may occur when hepatic enzyme-inducible agents such as phenobarbital are given concomitantly. Seventy percent of verapamil's metabolites are recovered in the urine and 15% in feces.

Diltiazem

After oral dosing, the bioavailability of diltiazem is greater than verapamil's, varying between 25% to 50%.[243] Peak plasma concentration is achieved between 30 to 60 minutes, and the elimination half-life is 2 to 6 hours.[243] Protein binding is approximately 80%. As with verapamil, hepatic clearance is flow dependent, and major hepatic metabolism occurs, with metabolites having 40% of the clinical activity of diltiazem.[244,245] Hepatic disease may require decreased dosing, whereas renal failure does not affect dosing.[246]

Clevidipine

Clevidipine is a dihydropyridine agent with a unique chemical structure that renders it inactive by cleavage of an ester linkage by nonspecific esterases in the blood and in tissues. This unique property renders it extremely short acting, similar to other drugs (eg, esmolol) that are metabolized through this pathway. Its initial phase half-life is 1 minute, with 90% of the drug eliminated. Its clinical effects are fully reversed in 5 to 15 minutes for most patients after discontinuing the infusion.[247]

Clevidipine is a potent arterial vasodilator whose primary use is as a parenteral antihypertensive agent. A reflexive tachycardia may be seen with its use in healthy volunteers and patients with essential hypertension that combined with possible hypotension would limit its role in treating ongoing myocardial ischemia.[248] In studies looking at perioperative and postoperative cardiac surgical patients, clevidipine was effective in decreasing mean arterial pressure but did not effect heart rate or filling pressures.[249]

Significant Adverse Effects

Most significant adverse hemodynamic effects can be predicted from calcium channel blockers' primary effects of vasodilation and negative inotropy, chronotropy, and dromotropy. Hypotension, HF, bradycardia, asystole, and AV nodal block have occurred with calcium channel blockers.[250] These side effects are more likely to occur with combination therapy with β-blockers or digoxin in the setting of hypokalemia.[250]

Verapamil increases digoxin levels, diltiazem has variable effects, and nifedipine has no effect on digoxin levels.[251–253] Cimetidine and ranitidine increase calcium blockers' serum levels by liver enzyme induction or reductions of hepatic blood flow.[254] The physiologic effects of calcium blockers may be additive to those of anesthetic agents in animal studies, but clinically significant effects vary.[255,256] The cautious use of intravenous verapamil with a β-adrenergic receptor antagonist is necessary because of the increased risk of AV block or severe myocardial depression.

Paradoxical aggravation of myocardial ischemia may be seen with the short-acting dihydropyridines (eg, nifedipine).[257] This may result from decreased coronary perfusion pressure with associated hypotension, selective vasodilation in the nonischemic region (ie, coronary steal), or increased oxygen demand as a result of reflex sympathetic stimulation and tachycardia.

Case reports of a withdrawal syndrome similar to β-blocker withdrawal have been presented. Five of 143 patients had significant ST-segment changes after diltiazem or verapamil withdrawal.[258] MI and coronary spasm have been reported after diltiazem withdrawal.[259,260] One study comparing propranolol with verapamil withdrawal in patients with stable angina found that 2 of 20 patients had severe exacerbation of their angina with propranolol withdrawal, and no patients had hemodynamic or symptomatic evidence of a withdrawal phenomenon with verapamil.[261]

Summary

Calcium antagonists provide excellent symptom control in patients with unstable angina. In the absence of β-adrenergic blockade, the short-acting dihydropyridine nifedipine may increase the risk of MI or recurrent angina. When β-adrenergic blockers cannot be used and heart rate slowing is indicated, verapamil and diltiazem may offer an alternative.

Drug Therapy for Systemic Hypertension

Systemic hypertension, long recognized as a leading cause of cardiovascular morbidity and mortality, accounts for enormous health-related expenditures. Almost one-fourth of the US population has hypertensive vascular disease, but 30% of these individuals are unaware of their condition, and another 30% to 50% are inadequately treated.[262,263] On a worldwide basis, almost 1 billion individuals are hypertensive.[264] Based on data from the Framingham Heart study, normotensive patients at age 55 can expect a 90% lifetime risk for subsequent development of hypertension.[265] Hypertension management comprises the most common reason underlying adult visits to primary care physicians, and antihypertensive drugs are the most prescribed medication class.[262]

Despite the asymptomatic nature of hypertensive disease, with symptom onset delayed 20 to 30 years after development of systemic hypertension, substantial and incontrovertible evidence demonstrates a direct association between systemic hypertension and increased morbidity and mortality. The World Health Organization (WHO) estimates that hypertension underlies one in eight deaths worldwide, making elevated BP the third leading cause of mortality.[261]

Hypertension is the single most treatable risk factor for MI, stroke, peripheral vascular disease, CHF, renal failure, and aortic dissection.[262] In prospective, randomized trials, over the course of adult lifetimes, successful treatment of hypertension has been associated with a 35% to 40% reduction in the incidence of stroke, 50% reduction in CHF, and 25% reduction in MIs.[261,262] Improved treatment of hypertension has been credited with the major reductions in stroke and cardiovascular mortality occurring in the United States during the past 30 years.

Pathophysiologic mechanisms underlying predisposition to hypertension remain unclear. Undoubtedly, genetic and environmental factors play contributory roles.[266] Concordance for hypertension is greater between monozygotic or dizygotic twins and even siblings within a single family than that observed between unrelated individuals, supporting a genetic component. However, by some estimates, genetic predeterminants account for only 30% to 40% of hypertensive disease.[266] A direct association between body mass index and hypertension has been reported, and dietary sodium intake has been associated with a long-term risk of hypertension.[267,268]

In most cases, no single reversible mechanism underlying systemic hypertensive disease can be identified for *primary* or *essential hypertension*. In about 5% of hypertensive patients, a distinct cause promoting systemic hypertension can be identified. The most common cause underlying *secondary hypertension* is renal insufficiency. Less common mechanisms include pheochromocytoma, renal artery stenosis, and hypertension resulting from adrenal cortical abnormalities such as primary aldosteronism or Cushing syndrome. Diagnostic clues for secondary hypertension include hypertensive disease refractory to medical therapy, unusually abrupt onset with severe associated symptoms, or occurrence of hypertension at a particularly young age.

Definitions for hypertension are somewhat arbitrary, although derived from clinical trials suggesting systemic pressures at which the benefits of treatment outweigh the risk for adverse effects related to antihypertensive therapy. BP varies with normal distribution across the population at large, and aging is associated with progressive increases in systolic pressure. After 50 years of age, reductions in diastolic pressure and widening pulse pressure prove common. Published evidence suggests that systolic and pulse pressures are better predictors for morbidity and mortality than diastolic pressure.[262]

The Eighth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC8) provided significant modifications to prior recommendations for the management of high BP. In contrast to prior guidelines, JNC8 recommendations are derived from evidence-based guidelines drawn only from randomized, controlled trials (RCTs). Specific recommendations emanating from the new guidelines include lifestyle interventions and pharmacologic treatment as needed to attain systolic BPs less than 150 mm Hg and diastolic BPs less than 90 mm Hg for adults 60 years of age and older. For younger patients and those with diabetes or chronic kidney disease, treatment goals include systolic BPs less than 140 mm Hg and diastolic BPs less than 90 mm Hg.[262,269]

Although antihypertensive drug therapy is widely regarded as essential for BPs greater than 150/90 mm Hg, evidence suggests benefits to more aggressive BP reduction for certain patient subsets. The association between systemic BP and cardiovascular risk has been described as a J curve, with progressive cardiovascular risk reductions accompanying BP reductions until a critical threshold, after which the potential for myocardial ischemia and other organ injury increases.[270] Risk for cardiovascular disease appears to increase at BPs greater than 115/75 mm Hg, with a doubling in risk associated with each 20/10-mm Hg increment in systemic pressure.[262]

Medical Treatment for Hypertension

Almost 80 distinct medications are marketed for the treatment of hypertension (Table 11.8).[262] Combined therapy with two or more classes of antihypertensive medications is often needed to achieve treatment goals (Table 11.9).[271] Although the specific drug selected for initial therapy is deemed less important than in the past, recognition that specific antihypertensive drug classes alleviate end-organ damage beyond that associated with reductions in systemic BP has led to targeted selection of antihypertensive drug combinations on the basis of coexisting risk factors such as recent MI, chronic renal insufficiency, or diabetes.

Diuretics

Thiazide diuretic therapy comprises the cornerstone of most antihypertensive regimens.[272,273] Three classes of diuretics have proved efficacious in reducing systemic BP: the thiazide and related sulfonamide compounds, loop diuretics, and potassium-sparing agents. All classes of diuretics initially reduce BP by increasing urinary excretion of sodium, with resultant reductions in plasma volume and CO. However, over a period of 6 to 8 weeks, diuretic therapy leads to reductions in SVR, which is hypothesized to activate vascular endothelial potassium channels.

Thiazide diuretics remain the first choice for most patients with hypertension.[274] Although the natriuretic effect achieved by blockade of sodium and chloride transport in the distal convoluted tubule is relatively weak, thiazide diuretics usually produce 10-mm Hg reductions in BP and have proved efficacious in numerous randomized trials to reduce morbidity and mortality related to hypertensive vascular disease.[262,271]

Loop diuretics, the most potent natriuretics of this class, block sodium, potassium, and chloride transport in the thick ascending loop of Henle. Loop diuretics typically are reserved for patients with renal insufficiency (ie, serum creatinine >2 mg/dL or creatinine clearance <25 mL/min) or CHF, conditions for which thiazide diuretics prove relatively ineffective. The short duration of action of loop diuretics (eg, 4 to 6 hours for furosemide) and greater likelihood for adverse effects limit more widespread application.

Potassium-sparing and aldosterone receptor–blocking diuretics are among the weakest natriuretics of this class. These drugs act by a variety of mechanisms to inhibit sodium reabsorption from the distal collecting duct while simultaneously reducing urinary potassium excretion. These drugs most commonly are administered in combination with a thiazide diuretic to reduce the incidence of hypokalemia or for their salutary effects in chronic HF.

Low doses of diuretics are well tolerated, but common adverse effects of this drug class include hypokalemia (due to renal potassium wasting), impaired glucose tolerance and insulin resistance, hyperuricemia, hypercalcemia, hyperlipidemia, and hyponatremia (rare). The potassium-sparing and aldosterone receptor–blocking drugs are relatively contraindicated for patients at risk for hyperkalemia, particularly those with renal insufficiency.

β-Adrenergic Receptor Blockers

β-Adrenergic receptor blockers, which reduce sympathetic stimulation of the heart and vasculature, comprise another common antihypertensive therapy, particularly in settings of CAD or CHF.[275–279] The β-blockers inhibit myocardial and peripheral β_1-adrenergic receptors to reduce CO. β-Blockers reduce renin release from renal juxtaglomerular cells and norepinephrine release by inhibition of prejunctional β_2-adrenergic receptors in the peripheral vasculature.

β-Blockers traditionally are classified on the basis of cardioselectivity, lipid solubility, and intrinsic sympathetic activity. First-generation agents such as propranolol nonselectively block both β_1- and β_2-adrenergic receptors. Second-generation agents (eg, metoprolol, atenolol) exhibit a relatively cardioselective preference for β_1-adrenergic receptor blockade at low doses. Pindolol, a novel β-blocker with ISA, stimulates vasodilation by activation of β_2-adrenergic receptors. Combination agents such as labetalol provide mixed β- and

TABLE 11.8 Oral Antihypertensive Drugs

Drug (Trade Name)	*Usual Dose Range (mg/d)*[a]	*Usual Frequency*
Thiazide Diuretics		
Chlorothiazide (Diuril)	125–500	qd or bid
Chlorthalidone (generic)	12.5–25	qd
Hydrochlorothiazide (Microzide, HydroDIURIL)[b]	12.5–50	qd
Polythiazide (Renese)	2–4	qd
Indapamide (Lozol)[b]	1.25–2.5	qd
Metolazone (Mykrox)	0.5–1.0	qd
Metolazone (Zaroxolyn)	2.5–5	qd
Loop Diuretics		
Bumetanide (Bumex)[b]	0.5–2	bid
Furosemide (Lasix)[b]	20–80	bid
Torsemide (Demadex)[b]	2.5–10	qd
Potassium-Sparing Diuretics		
Amiloride (Midamor)[b]	5–10	qd or bid
Triamterene (Dyrenium)	50–100	qd or bid
Aldosterone Receptor Blockers		
Eplerenone (Inspra)	50–100	qd
Spironolactone (Aldactone)[b]	25–50	qd
β-Blockers		
Atenolol (Tenormin)[b]	25–100	qd
Betaxolol (Kerlone)[b]	5–20	qd
Bisoprolol (Zebeta)[b]	2.5–10	qd
Metoprolol (Lopressor)[b]	50–100	qd or bid
Metoprolol extended release (Toprol XL)	50–100	qd
Nadolol (Corgard)[b]	40–120	qd
Propranolol (Inderal)[b]	40–160	bid
Propranolol long acting (Inderal LA)[b]	60–180	qd
Timolol (Blocadren)[b]	20–40	bid
β-Blockers with Intrinsic Sympathomimetic Activity		
Acebutolol (Sectral)[b]	200–800	bid
Penbutolol (Levatol)	10–40	qd
Pindolol (generic)	10–40	bid
β-Blockers with Vasodilating Nitric Oxide–Mediated Activity		
Nebivol (Bystolic)	5–40	qd
Combined α-Blockers and β-Blockers		
Carvedilol (Coreg)	12.5–50	bid
Labetalol (Normodyne, Trandate)[b]	200–800	bid
Angiotensin-Converting Enzyme Inhibitors		
Benazepril (Lotensin)[b]	10–40	qd
Captopril (Capoten)[b]	25–100	bid
Enalapril (Vasotec)[b]	5–40	qd or bid
Fosinopril (Monopril)	10–40	qd
Lisinopril (Prinivil, Zestril)[b]	10–40	qd
Moexipril (Univasc)	7.5–30	qd
Perindopril (Aceon)	4–8	qd
Quinapril (Accupril)	10–80	qd
Ramipril (Altace)	2.5–20	qd
Trandolapril (Mavik)	1–4	qd
Angiotensin Receptor Blockers		
Azilsartan (Edarbi)	80	qd
Candesartan (Atacand)	8–32	qd
Eprosartan (Teveten)	400–800	qd or bid
Irbesartan (Avapro)	150–300	qd
Losartan (Cozaar)	25–100	qd or bid
Olmesartan (Benicar)	20–40	qd
Telmisartan (Micardis)	20–80	qd
Valsartan (Diovan)	80–320	qd or bid
Direct Renin Inhibitor		
Aliskiren (Tekturna)	150–300	qd
Nondihydropyridine Calcium Channel Blockers		
Diltiazem extended release (Cardizem CD, Dilacor XR, Tiazac)[b]	180–420	qd
Diltiazem extended release (Cardizem LA)	120–540	qd
Verapamil immediate release (Calan, Isoptin)[b]	80–320	bid
Verapamil long acting (Calan SR, Isoptin SR)[b]	120–480	qd or bid
Verapamil (Coer, Covera HS, Verelan PM)	120–360	qd
Dihydropyridine Calcium Channel Blockers		
Amlodipine (Norvasc)	2.5–10	qd
Felodipine (Plendil)	2.5–20	qd
Isradipine (Cynacirc CR)	2.5–10	bid
Nicardipine sustained release (Cardene SR)	60–120	bid
Nifedipine long acting (Adalat CC, Procardia XL)	30–60	qd
Nisoldipine (Sular)	17–34	qd
α_1-Blockers		
Doxazosin (Cardura)	1–16	qd
Prazosin (Minipress)[b]	2–20	bid or tid
Terazosin (Hytrin)	1–20	qd or bid
Central α_2-Agonists and Other Centrally Acting Drugs		
Clonidine (Catapres)[b]	0.1–0.8	bid
Clonidine patch (Catapres-TTS)	0.1–0.3	qwk
Methyldopa (Aldomet)[b]	250–1000	bid
Reserpine (generic)	0.1–0.25	qd
Guanfacine (Tenex)[b]	0.5–2	qd
Direct Vasodilators		
Hydralazine (Apresoline)[b]	25–100	bid
Minoxidil (Loniten)[b]	2.5–80	qd or bid

[a]In some patients treated once daily, the antihypertensive effect may diminish toward the end of the dosing interval (ie, trough effect). Blood pressure should be measured just before dosing to determine whether satisfactory control is obtained, and an increase in dosage or frequency may be needed. Dosages may vary from those listed in the *Physicians' Desk Reference* (PDR), 5th ed.

[b]Available now or soon to become available in generic preparations.

Modified from Chobanian AV, Bakris GL, Black HR, et al. Seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. *Hypertension.* 2003;42:1206.)

α_1-adrenergic blocking properties, resulting in inhibition of sympathetic activity and direct vasodilatory effects.

As with the diuretics, β-blockers typically are well tolerated at low doses, but nonselective blockade of β-adrenergic receptors may result in bronchospasm, Raynaud phenomenon, depression, and HF or heart block. β-Blockers are relatively contraindicated for patients with asthma or reactive airways disease, heart block, or depression. Rapid withdrawal of β-blockers may be associated with rebound adrenergic stimulation and potential for exacerbating myocardial and peripheral vascular ischemia; β-blocker discontinuation must occur by gradual, stepped dose reductions.

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme (ACE) inhibitors reduce peripheral vascular resistance by inhibiting conversion of angiotensin I (Ang I) to the highly vasoconstrictive angiotensin II (Ang II).[280] Evidence suggests that much of the long-term antihypertensive effect of ACE inhibitors is derived from protective effects on bradykinin degradation. Bradykinin, a potent vasodilator under normal conditions, undergoes degradation by the action of ACE. ACE inhibition results in increased plasma and tissue concentrations of bradykinin.

Persistent, dry cough accounts for the most common adverse effect associated with ACE inhibitor administration. Attributed to

TABLE 11.9 Combination Drugs for Hypertension

Fixed-Dose Combinations[a] *(mg)*	*Trade Names*
Angiotensin-Converting Enzyme Inhibitor/Calcium Channel Blocker	
Amlodipine/benazepril hydrochloride (2.5/10, 5/10, 5/20, 10/20)	Lotrel
Enalapril/felodipine (5/5)	Lexxel
Trandolapril/verapamil (2/180, 1/240, 2/240, 4/240)	Tarka
Angiotensin-Converting Enzyme Inhibitor/Diuretic	
Benazepril/hydrochlorothiazide (5/6.25, 10/12.5, 20/12.5, 20/25)	Lotensin HCT
Captopril/hydrochlorothiazide (25/15, 25/25, 50/15, 50/25)	Capozide
Enalapril/hydrochlorothiazide (5/12.5, 10/25)	Vaseretic
Fosinopril/hydrochlorothiazide (10/12.5, 20/12.5)	Monopril HCT
Lisinopril/hydrochlorothiazide (10/12.5, 20/12.5, 20/25)	Prinzide, Zestoretic
Moexipril/hydrochlorothiazide (7.5/12.5, 15/25)	Uniretic
Quinapril/hydrochlorothiazide (10/12.5, 20/12.5, 20/25)	Accuretic
Angiotensin II Receptor Blocker/Diuretics	
Candesartan/hydrochlorothiazide (16/12.5, 32/12.5)	Atacand HCT
Eprosartan/hydrochlorothiazide (600/12.5, 600/25)	Teveten HCT
Irbesartan/hydrochlorothiazide (150/12.5, 300/12.5)	Avalide
Losartan/hydrochlorothiazide (50/12.5, 100/25)	Hyzaar
Olmesartan medoxomil/hydrochlorothiazide (20/12.5, 40/12.5, 40/25)	Benicar HCT
Telmisartan/hydrochlorothiazide (40/12.5, 80/12.5)	Micardis HCT
Valsartan/hydrochlorothiazide (80/12.5, 160/12.5, 160/25)	Diovan HCT
β-Blocker/Diuretic	
Atenolol/chlorthalidone (50/25, 100/25)	Tenoretic
Bisoprolol/hydrochlorothiazide (2.5/6.25, 5/6.25, 10/6.25)	Ziac
Metoprolol/hydrochlorothiazide (50/25, 100/25)	Lopressor HCT
Nadolol/bendroflumethiazide (40/5, 80/5)	Corzide
Propranolol LA/hydrochlorothiazide (40/25, 80/25)	Inderide LA
Timolol/hydrochlorothiazide (10/25)	Timolide
Centrally Acting Drug/Diuretic	
Methyldopa/hydrochlorothiazide (250/15, 250/25, 500/30, 500/50)	Aldoril
Reserpine/chlorthalidone (0.125/25, 0.25/50)	Demi-Regroton, Regroton
Reserpine/chlorothiazide (0.125/250, 0.25/500)	Diupres
Reserpine/hydrochlorothiazide (0.125/25, 0.125/50)	Hydropres
Diuretic/Diuretic	
Amiloride/hydrochlorothiazide (5/50)	Moduretic
Spironolactone/hydrochlorothiazide (25/25, 50/50)	Aldactazide
Triamterene/hydrochlorothiazide (37.5/25, 75/50)	Dyazide, Maxzide
Triple Drug Combinations	
Aliskiren/amlodipine/hydrochlorothiazide	Amturnide
Valsartan/amlodipine/hydrochlorothiazide	Exforge HCT
Olmesartan/amlodipine/hydrochlorothiazide	Tribenzor

[a]Some drug combinations are available in multiple fixed doses, which are reported in milligrams. Modified from Chobanian AV, Bakris GL, Black HR, et al. Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. *Hypertension.* 2003;42:1206.

elevated concentrations of bradykinin, this side effect frequently leads to discontinuation of therapy. Angioedema, also attributable to elevated bradykinin concentrations, occurs less commonly. Angioedema may occur at any time during therapy, occurs most frequently in African Americans, and may prove fatal due to airway compromise. Increased potential for hyperkalemia occurs in patients with renal insufficiency and those receiving potassium supplements or potassium-sparing diuretics. ACE inhibitors can induce renal failure in patients with bilateral renal artery stenosis and may potentiate severe, intractable hypotension in patients with particularly elevated renin activity (eg, decompensated HF, intravascular volume depletion). ACE inhibitors pose a teratogenic risk and are therefore contraindicated in pregnancy.

Angiotensin II Antagonists

Ang II antagonists (ie, angiotensin receptor blockers) may be the best tolerated of all current antihypertensive therapies and are increasingly a favored drug therapy for management of hypertensive vascular disease.[280] Ang II antagonists bind and competitively inhibit Ang II AT_1 receptors, directly inhibiting the vasoconstrictive effects of Ang II.[281]

Similar concerns to those for ACE inhibitors exist with regard to administration of Ang II antagonists in the settings of bilateral renal artery stenosis or hypovolemia, but Ang II antagonists typically are not associated with cough and are rarely implicated in angioedema. Ang II antagonists are contraindicated in pregnancy.

Calcium Channel Blockers

Calcium channel blockers, commonly classified as dihydropyridines or nondihydropyridines, share a common mechanism of action in binding various sites on the α_1 subunit of the L-type voltage-dependent calcium channel to partially inhibit calcium entry into cells. Although all calcium channel blockers induce arterial vasodilation, the dihydropyridines more frequently induce reflex tachycardia, whereas the nondihydropyridines (eg, diltiazem, verapamil) more commonly impair cardiac conduction and contractility.[282]

Common side effects reported with calcium channel blockers and relating to arterial vasodilation include ankle edema, flushing, and headaches. Nondihydropyridines are relatively contraindicated in patients with preexisting HF or cardiac conduction defects due to the potential for precipitating HF and heart block. Controversy surrounding the safety of calcium channel blockers has been somewhat negated by prospective, randomized trials demonstrating the safety and efficacy of long-acting calcium channel blockers for the treatment of hypertensive cardiovascular disease.[283–285] Administration of short-acting dihydropyridines (eg, nifedipine) for rapid control of hypertension has been associated with an increased incidence of acute coronary events and is contraindicated in the acute treatment of severe hypertension.

α_1-Adrenergic Receptor Blockers

α_1-Adrenergic blockers competitively inhibit binding of norepinephrine to α_1-adrenergic receptors in the peripheral vasculature to produce vasodilation and BP reductions. Prazosin and its congeners selectively block postsynaptic α_1-adrenergic receptors. Continued activity of the presynaptic α_1-receptors allows for downregulation of norepinephrine release, limits development of tolerance, and reduces the incidence of compensatory tachycardia. In contrast, phenoxybenzamine, commonly used in the preoperative management of pheochromocytoma, blocks both presynaptic and postsynaptic α_1-adrenergic receptors.

Adverse effects associated with α_1-blockers include orthostatic hypotension, fluid retention, and reflex tachycardia.[286] Although rarely administered as monotherapy, α_1-blockers continue to prove useful in combination with other antihypertensives due to their lack of metabolic side effects and propensity to dilate urethral smooth muscle to alleviate symptoms of prostatism.[262]

Central α_2-Adrenergic Receptor Agonists and Other Centrally Acting Drugs

Centrally acting antihypertensive agents (eg, clonidine, methyldopa) stimulate α_2-adrenergic and imidazoline receptors within the CNS to reduce sympathetic outflow and SVR. In the case of clonidine, activation of presynaptic α-adrenergic receptors inhibits norepinephrine release and subsequent catecholamine generation.[287] Reserpine differs from the α_2-agonists in that it inhibits reuptake of norepinephrine by storage vesicles in the postganglionic adrenergic neurons, depleting norepinephrine. As opposed to the α_2-agonists, reserpine's peripheral effects predominate over central activity.

More widespread use of centrally acting antihypertensives has been limited by CNS-mediated adverse effects, including sedation, depression, and dry mouth. Autoimmune hemolytic anemia has been reported with methyldopa. Abrupt discontinuation of clonidine frequently results in rebound hypertension, but this effect may be

alleviated with transdermal clonidine patches or the longer-acting oral agent guanfacine. All centrally acting antihypertensives are contraindicated in the setting of depression.

Direct Vasodilators

Hydralazine and minoxidil produce potent direct arterial vasodilation mediated by activation of ATP-sensitive potassium channels within the arterial vasculature. The relative lack of effect by direct vasodilators on venous capacitance vessels reduces the potential for orthostatic hypotension. The potency and propensity for adverse effects limit applications to hypertensive disease resistant to standard pharmacologic approaches, most often in the setting of severe hypertension associated with chronic renal failure.

Hydralazine and minoxidil promote peripheral edema formation and profound reflex sympathetic activation manifested as tachycardia, headaches, and flushing. Minoxidil, a more potent antihypertensive than hydralazine, frequently is associated with hirsutism. Reflex sympathetic responses to direct vasodilators necessitate concomitant administration of diuretics and β-adrenergic blockers to alleviate potential for fluid retention and myocardial ischemia.

Novel Approaches to Antihypertensive Therapy

Despite the array of antihypertensive medications available, the heterogeneity of treatment effect and adverse effects of current drugs on quality of life measures suggest the need for alternative approaches to antihypertensive therapy.[288] Promising approaches include aldosterone receptor blockers and renin inhibitors. With the exception of the potential for hyperkalemia, aldosterone receptor inhibitors have been well tolerated, and renin inhibitors administered in concert with Ang II inhibitors have alleviated the compensatory rise in plasma renin activity. Third-generation β-blockers incorporating vasodilatory activity offer particular promise for treating hypertension in the setting of concomitant HF. Further modifications to endothelin receptor antagonists and dual vasopeptidase inhibitors may offer novel antihypertensive approaches for the future. Several interventional approaches for control of pharmacologically resistant hypertension have been reported, including renal sympathetic denervation, targeted baroreflex stimulation, and percutaneous device placement to create a central iliac arteriovenous fistula—thereby mitigating arterial stiffness.[289–291] Lack of appropriate control groups limit conclusions about the efficacy of these treatments. The interventional nature of the procedures poses novel risks for morbidity and mortality.

Ultimately, gene therapy may prove the definitive solution to essential hypertension. It appears likely that environmental factors interacting with multiple genetic polymorphisms contribute to overall risk for hypertension. Gene therapy offers a viable approach to long-term management of hypertension but requires further identification of target genes, improvements in gene transfer efficiency, and development of safer transfer vectors. Advances in personalized medicine offer the potential for testing DNA polymorphisms to identify antihypertensive drugs most likely to benefit specific patients.[292]

Management of Severe Hypertension

Severe hypertension may be characterized as a *hypertensive emergency,* with target organ injury (eg, myocardial ischemia, stroke, pulmonary edema), or as *hypertensive urgency,* with severe elevations in BP not yet associated with target organ damage. Specific BPs associated with these conditions prove somewhat arbitrary, but BPs exceeding 220/125 mm Hg pose an immediate risk for life-threatening end organ damage. Chronic elevations in BP, even when severe, do not necessarily require urgent intervention and often may be managed with oral antihypertensive therapy on an outpatient basis. In contrast, a hypertensive emergency necessitates immediate therapeutic intervention, most often with intravenous antihypertensive therapy and invasive arterial BP monitoring. In the most extreme cases of *malignant hypertension*, severe elevations in BP may be associated with retinal hemorrhages, papilledema, and evidence of encephalopathy, which may include headache, vomiting, seizure, and coma. Progressive renal failure and cardiac decompensation may characterize the most severe hypertensive urgencies.

A common therapeutic approach to hypertensive urgency includes a limited reduction in BP (about 10%) over the initial 1 to 2 hours of therapy, followed by further modest reductions in diastolic BP during the next 12 hours. Further reductions in BP to acceptable target levels should proceed over a period of days to minimize potential for ischemic injury in the setting of altered autoregulatory flow to target organ vascular beds.[262,293]

Sodium nitroprusside, long favored as a parenteral treatment for hypertensive urgencies in intraoperative settings[262] (Table 11.10), acts as an NO donor to induce arterial and venous dilation. A rapid physiologic response and relatively predictable titratable effect prove useful for intraoperative settings. However, the potency of sodium nitroprusside and the potential for prolonged administration to be associated with cyanide or thiocyanate toxicity have provided an opportunity for newer parenteral antihypertensive drugs.

Nicardipine and clevidipine, parenteral dihydropyridine calcium channel blockers, have proved particularly applicable for hypertensive urgencies in perioperative settings (see Table 11.10). Although less potent and predictable than sodium nitroprusside, NTG, another NO donor, may be preferable in the setting of myocardial ischemia or after CABG surgery. NTG preferentially dilates venous capacitance beds rather than arterioles. However, rapid onset of tolerance limits the efficacy of sustained infusions to maintain BP control. Fenoldopam, a selective dopamine D_1-receptor antagonist, has been promoted for hypertensive control in the setting of chronic kidney disease.

Several drugs remain available for intermittent parenteral administration in hypertensive emergencies or urgencies. Enalaprilat, an intravenous ACE inhibitor, has been administered in settings of severe hypertension complicated by HF. Hydralazine, labetalol, and esmolol provide additional therapeutic options for intermittent parenteral injection for hypertensive control. In most cases of emergent or severe hypertension, a diuretic is required to maintain prolonged natriuresis to sustain an antihypertensive response. In settings of renal insufficiency or failure, minoxidil and acute dialysis may be necessary for BP control.

Indications for Specific Antihypertensive Drug Selection

Despite compelling evidence supporting the preferential administration of thiazide diuretics as agents of choice for treatment of hypertension, most patients require addition of a second nondiuretic antihypertensive drug to achieve desired target BPs.[262] Selection of a complementary antihypertensive agent necessitates a thorough understanding of the mechanisms of action to optimize the additive effect of combined therapy. For example, β-blockers, ACE inhibitors, and Ang II antagonists inhibit renin release. Combinations of these agents are unlikely to achieve a maximal additive antihypertensive response. Similarly, diuretics and dihydropyridine calcium channel blockers produce peripheral vasodilation, and combination with other antihypertensive drug classes may prove more efficacious.

Data derived from ongoing outcomes-based trials of antihypertensive therapy for patients with coexisting diseases suggest that specific antihypertensive drugs reduce morbidity beyond that expected for BP reduction alone (Table 11.11).[262] For example, in patients with ischemic heart disease and especially a recent MI, β-blockers have reduced mortality and morbidity related to subsequent cardiac events.[277,279,294,295] Although precise mechanisms remain unclear, reductions in overall sympathetic stimulation and antiarrhythmic effects presumably play contributory roles. In the setting of renal insufficiency, ACE inhibitors and Ang II antagonists delay progression of diabetes- and nondiabetes-associated renal disease.[295–298] Calcium channel blockers have proved efficacious in the setting of peripheral vascular

TABLE 11.10 Parenteral Drugs for Treating Hypertensive Emergencies[a]

Drug	*Dose*	*Onset of Action*	*Duration of Action*	*Adverse Effects*[b]	*Special Indications*
Nicardipine hydrochloride	5–15 mg/h IV	5–10 min	15–30 min, may exceed 4 h	Tachycardia, headache, flushing, local phlebitis	Most hypertensive emergencies except acute heart failure; caution with coronary ischemia
Clevidipine	1–2 mg/h IV	2–4 min	5–15 min	Headache, nausea, vomiting, soy and egg allergy cross-reactivities	Most hypertensive emergencies except severe aortic stenosis
Sodium nitroprusside	0.25–10 µg/kg per minute as IV infusion[c]	Immediate	1–2 min	Nausea, vomiting, muscle twitching, sweating, thiocyanate and cyanide intoxication	Most hypertensive emergencies; caution with high intracranial pressure or azotemia
Fenoldopam mesylate	0.1–0.3 µg/kg per min IV infusion	<5 min	30 min	Tachycardia, headache, nausea, flushing	Most hypertensive emergencies; caution with glaucoma
Nitroglycerin	5–100 µg/min as IV infusion	2–5 min	5–10 min	Headache, vomiting, methemoglobinemia, tolerance with prolonged use	Coronary ischemia
Enalaprilat	1.25–5 mg every 6 h IV	15–30 min	6–12 h	Precipitous fall in pressure in high-renin states; variable response	Acute left ventricular failure; avoid in acute myocardial infarction
Hydralazine hydrochloride	10–20 mg IV 10–40 mg IM	10–20 min IV 20–30 min IM	1–4 h IV 4–6 h IM	Tachycardia, flushing, headache, vomiting, aggravation of angina	Eclampsia
Adrenergic Inhibitors					
Labetalol hydrochloride	20–80 mg IV bolus every 10 min 0.5–2.0 mg/min IV infusion	5–10 min	3–6 h	Vomiting, scalp tingling, dizziness, nausea, heart block, orthostatic hypotension, bronchoconstriction	Most hypertensive emergencies except acute heart failure
Esmolol hydrochloride	250–500 µg/kg per minute IV bolus, then 50–100 µg/kg per minute by infusion; may repeat bolus after 5 min or increase infusion to 300 µg/min	1–2 min	10–30 min	Hypotension, nausea, asthma, first-degree heart block, heart failure	Aortic dissection, perioperative
Phentolamine	5–15 mg IV bolus	1–2 min	10–30 min	Tachycardia, flushing, headache	Catecholamine excess

[a]Doses may vary from those in the *Physicians Desk Reference* (PDR).
[b]Hypotension may occur with all agents.
[c]Requires special delivery system.

diseases (eg, Raynaud syndrome), and α_1-blockers favorably influence symptoms of prostatism.

Hypertension in the setting of pregnancy continues to pose challenges given concerns about drug effects on the fetus. Historically, methyldopa and hydralazine were mainstay approaches for the management of hypertension complicating pregnancy.[262]

Perioperative Implications of Hypertension

There is little evidence to suggest that mild or moderate degrees of hypertension significantly impact perioperative morbidity and mortality. The ACC/AHA guidelines state that mild or moderate hypertension does not represent an independent risk factor for perioperative cardiovascular complications.[299] However, given the strong association between hypertension and vascular or kidney diseases, a preoperative diagnosis of hypertension necessitates assessment for evidence of target organ damage such as cardiovascular disease, chronic kidney disease (ie, nephrosclerosis), cerebrovascular disease and dementia, and atherosclerotic vascular disease.[300] In contrast to isolated mild hypertension, secondary cardiovascular diseases in many cases do pose an increased risk of perioperative morbidity and mortality. In patients with a preoperative diagnosis of hypertension, an electrocardiogram

is performed to assess for evidence of ischemia, prior MI, or left ventricular (LV) hypertrophy, and serum electrolyte and glucose levels may be used to assess for concomitant kidney disease or diabetes. Specific antihypertensive therapies may necessitate additional evaluations, such as assessment of plasma potassium and sodium levels in patients taking diuretics.

In cases of mild to moderate hypertension, few controlled trials assessing the association between preoperative hypertension and perioperative morbidity and mortality are available. Most investigations are observational and fail to account adequately for confounding variables. In many cases, the number of study participants proves inadequate to ensure statistical power to assess for relevant associations between outcomes and a preoperative diagnosis of hypertension. Howell and colleagues[293] published a metaanalysis summarizing 30 studies that included more than 12,995 patients for whom an association between hypertension and perioperative complications could be assessed. The investigators calculated an odds ratio of 1.31, suggesting a slightly increased risk for perioperative cardiovascular complications in patients with preexisting hypertension. However, given the limitations of the dataset, they further concluded that such a small odds ratio in the setting of a "low perioperative event rate" likely represented a clinically insignificant association between preexisting hypertension and cardiac risk. Other investigators have reported similar small associations between isolated systolic hypertension preoperatively and subsequent perioperative morbidity.

In contrast, cases of severe hypertension (ie, diastolic BP >110 mm Hg) frequently lead to questions about whether elective surgery should be postponed to allow for titration of antihypertensive therapy to acceptable systemic BPs. There are no data to support conclusive recommendations regarding acceptable preoperative BPs or the time period needed to attain a new steady-state systemic pressure. Patients with poorly controlled BP experience more labile BP responses in the perioperative setting, with a greater potential for hypertensive or hypotensive episodes.[300–302] Guidelines published by the ACC/AHA suggest that systemic BPs exceeding 180 mm Hg systolic or 110 mm Hg diastolic should be controlled before surgery.[299] In a review, Howell and colleagues[301] concluded that surgery need not be cancelled in the setting of severe hypertension. However, careful preoperative assessment for target organ damage (ie, cardiovascular, renal, and cerebrovascular disease) should be performed preoperatively, and intraoperative arterial pressures should be maintained within 20% of preoperative BPs.[288] At a minimum, invasive monitoring of arterial pressure with strict control of perioperative BPs continuing into the postoperative setting, appears justified for patients with severe hypertension, Given the predilection for CAD in these patients, perioperative therapy with β-blockers may be indicated.[93,303]

Pharmacotherapy for Acute and Chronic Heart Failure

Chronic HF is a major cardiovascular disorder that continues to increase in incidence and prevalence in the United States and worldwide. It affects almost 5.7 million persons in the United States, with 870,000 new cases annually among those 55 years of age or older.[304,305] Currently, 1% to 2% of those between 40 and 59 years of age and 11% to 14% of individuals older than 80 years have HF.[304] Because HF is primarily a disease of the elderly, its prevalence is projected to increase 46% from 2012 to 2030, resulting in more than 8 million people with HF, paralleling the substantial increase in growth of this population sector.[306] The disease also affects the black population disproportionately compared with whites.[307,308]

The increasingly prolonged survival of patients with various cardiovascular disorders that culminate in ventricular dysfunction (eg, patients with CAD are living longer rather than dying acutely with MI), and the greater diagnostic awareness further compound the HF epidemic. By age 40, the lifetime risk of developing HF for men and women is one in five, and this risk remains constant into the 80s, even in the face of a much shorter life expectancy.[305] Despite improvements in the understanding of the neurohormonal mechanisms underlying its pathophysiology and remarkable advances made in pharmacologic therapy, HF continues to cost the United States an estimated $31 billion annually in medical expenditures,[305] and it is projected to increase 127% (almost $70 million) by 2030.[306]

More importantly, functional capacity is impaired in HF, causing a significant decline in the individual's quality of life.[309] Given the public health impact of the disease and the rapid pace of therapeutic advances, it is essential that the perioperative physician remain aware of contemporary clinical practice for the benefit of patients with chronic HF presenting to the operating room or intensive care unit.

The pharmacologic management of HF was revised in the 2013 guidelines published by the American College of Cardiology Foundation and the American Heart Association (ACCF/AHA).[304] The focus is primarily on chronic HF with a reduced ejection fraction (HFrEF) and HF with a preserved ejection fraction (HFpEF), although acute HF is also discussed. For each drug commonly used in clinical practice, the general format includes whether it alters the progression of myocardial damage (for agents administered chronically), its mechanisms of action, clinical data on trials of its use for HF, and its current place in the treatment of HF. New pharmacologic options in HF management are also reviewed.

Level of Evidence

To gain the best understanding of the guidelines for the management of HF, it is important to review definitions of terms, class of recommendation (COR), and level of evidence (LOE). The COR is a statement of the strength of the recommendation. The COR ranges from class I, in which case treatments or procedures should be administered or performed, to class III, in which case treatments or procedures have no benefit (ie, a treatment strategy is no better than with the control) or may be harmful to the person (ie, outcomes were worse with the intervention than with the control).

Class I is the strongest recommendation; the benefit is substantially better than the risk. Class II is based on whether the treatment or procedure's benefit outweighs the risk to the individual. Class II is divided into IIa (ie, it is reasonable to perform the treatment or procedure, with intermediate strength that the benefit is somewhat greater than risk) and class IIb (ie, performing the treatment or procedure may be considered, or marginal benefit-risk ratios exist).

The LOE describes the certainty or precision of the information supporting the recommendation and is based on the type and quality of the evidence. Level A evidence is derived from multiple RCTs or a metaanalysis based on high-quality RCTs. Level B evidence is derived from single randomized or nonrandomized trials, and level C evidence is based on expert opinions, case studies, or standards of care.

The term *guideline-directed medical therapy* (GDMT) has been designated in the revised guidelines to represent optimal medical therapy, which is primarily a class I, LOE A recommendation (Fig. 11.13). Adherence to GDMT for HF improves outcomes through reductions in morbidity, hospitalizations, and mortality (Fig. 11.14).

Heart Failure Terms

EF is important in classifying patients with HF because of different patient demographics, comorbid conditions, prognoses, and therapies and because most clinical trials select patients according to EF. Although EF measurement has been used to differentiate between systolic and diastolic dysfunction, the 2013 guidelines use the terms HFrEF and HFpEF to differentiate systolic from diastolic HF. HFrEF is based on a clinical diagnosis of HF combined with an EF of 40% or less. HFpEF classification includes the following: those with an EF of 50% or greater; those with an EF between 41% and 49% (ie, HFpEF, borderline); and those who had improved HFpEF of greater than 40%.

Several criteria have been proposed to define the syndrome of HFpEF, including clinical signs or symptoms of HF, evidence of preserved or normal left ventricular ejection fraction (LVEF), and

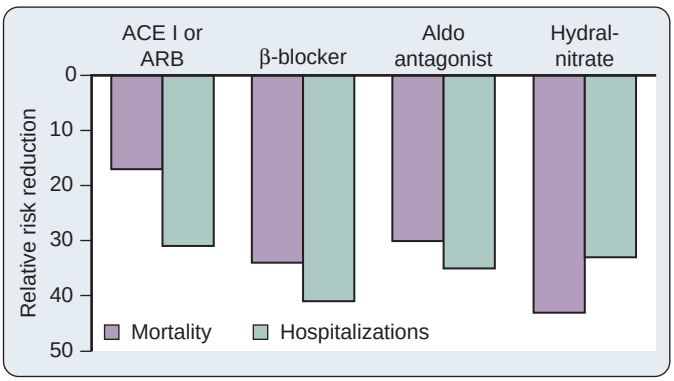

Fig. 11.14 Guideline-directed medical therapy improves outcomes. Class I, level of evidence A recommendations for the treatment of heart failure with reduced ejection fraction has been shown to reduce mortality and hospitalizations for heart failure in various trials, including SOLVD-Treatment, CHARM-Alternative, COPERNICUS, MERIT-HF, CIBIS-II, and EMPHASIS-HF. *ACE I*, angiotensin-converting enzyme inhibitor; *aldo*, aldosterone; *ARB*, angiotensin-receptor blocker; *hydral-nitrate*, hydralazine and isosorbide dinitrate.

evidence of abnormal LV diastolic dysfunction that can be determined by Doppler echocardiography or cardiac catheterization. Patients who previously had a reduced EF but had improvement or recovery in the EF are categorized as *HFpEF improved*. The diagnosis of HFpEF is more challenging than the diagnosis of HFrEF because it is largely one of excluding other noncardiac causes of symptoms that suggest HF.

Heart Failure Classification

The ACCF/AHA guidelines for evaluating and managing HF include the four-stage classification system, which emphasizes the evolution and progression of the disease (Fig. 11.15), and the New York Heart Association (NYHA) classification (Table 11.12), which focuses on exercise capacity and symptomatic severity of the disease.[304] The four-stage classification system calls attention to patients with preclinical stages of HF to focus on halting disease progression. By recognizing its progressive course and identifying those who are at risk (ie, the first two stages, A and B, are clearly not HF), it reinforces the importance of determining the optimal strategy for neurohormonal antagonism in an attempt to improve the natural history of the syndrome.

The NYHA classification focuses on exercise capacity and symptomatic status of the disease, which correlate with quality of life and survival.[304] It is subjective and can change frequently over short

periods, whereas the stages of HF are progressive and inviolate; after a patient moves to a higher stage, regression to an earlier stage of HF is not observed. In comparing the NYHA classification with HF staging (see Table 11.12), notice that there is no classification for stage A and that stage B correlates with NYHA class I (ie, no limitation of physical activity). For stage C HF, the classification ranges from no limitation to class IV (ie, unable to carry on any physical activity without symptoms of HF or symptoms of HF at rest). Stage D HF correlates with NYHA class IV symptoms even at rest. The two classifications are complementary in nature.

TABLE 11.13 Neurohormonal Effects of Impaired Cardiac Performance on the Circulation

Response	*Short-Term Effects*	*Long-Term Effects*
Salt and water retention	Augments preload	Pulmonary congestion, anasarca
Vasoconstriction	Maintains blood pressure for perfusion of vital organs (eg, brain, heart)	Exacerbates pump dysfunction (ie, excessive afterload), increases cardiac energy expenditure
Sympathetic stimulation	Increases heart rate and ejection	Increases energy expenditure

Overview of Heart Failure Pathophysiology

Although the pathophysiology of HF has been addressed elsewhere, it is important to mention key concepts as the basis of current pharmacologic therapy. HF is a complex clinical syndrome resulting from any structural and functional abnormalities in ventricular filling or ejection of blood that causes cardinal symptoms of dyspnea and fatigue, which may limit exercise tolerance and cause fluid retention, leading to congestion and edema. HF remains the final common pathway for CAD, hypertension, valvular heart disease, and cardiomyopathy, in which the natural history results in symptomatic or asymptomatic LV dysfunction (specifically, LV systolic dysfunction for the purposes of this discussion).

The neurohormonal responses to impaired cardiac performance (eg, salt and water retention, vasoconstriction, sympathetic stimulation) are initially adaptive, but if sustained, they become maladaptive, resulting in pulmonary congestion and excessive afterload. This leads to a vicious cycle of increases in cardiac energy expenditure and worsening of pump function and tissue perfusion (Table 11.13). Although the cardiorenal and cardiocirculatory branches of this neurohormonal hypothesis of HF were the original foundation for the use of diuretics, vasodilators, and inotropes, seminal information in the early 1990s emerged from large, randomized clinical trials that showed ACE inhibitors[310,311] and angiotensin receptor blockers,[312,313] but not most other vasodilators,[314] prolonged survival of patients with HF. In a similar fashion, the use of β-blockers, despite their negative inotropic effects, improved morbidity and mortality in RCTs.[315–317]

The finding that low-dose aldosterone antagonists added to conventional therapy for HF reduce mortality in patients with severe HF suggests that there is more to the neurohormonal hypothesis of drug efficacy than cardiorenal and hemodynamic effects alone.[318,319] Taken together with evidence from basic investigations showing that Ang II is a growth factor and a vasoconstrictor,[320] the clinical data promoted a shift in focus from cardiorenal and cardiocirculatory processes toward cardiac remodeling as the central component in the progression of the neurohormone-mediated cardiac syndrome.[321] The renin-angiotensin-aldosterone system (RAAS), excess sympathetic activity, endothelin, and various cytokines have been implicated as stimuli of proliferative signaling that contribute to maladaptive cardiac growth. Ventricular remodeling, or the structural alterations of the heart in the form of dilation and hypertrophy (Box 11.5), in addition to the counterregulatory hemodynamic responses, lead to progressive ventricular dysfunction and represent the target of current therapeutic interventions (Fig. 11.16).

BOX 11.5 MECHANICAL DISADVANTAGES CREATED BY LEFT VENTRICULAR REMODELING

- Increased wall stress (ie, afterload)
- Afterload mismatch
- Episodic subendocardial hypoperfusion
- Increased oxygen consumption
- Sustained hemodynamic overloading
- Worsening activation of compensatory mechanisms

Pathophysiologic Role of the Renin-Angiotensin System in Heart Failure

The renin-angiotensin system (RAS) is one of several neuroendocrine systems that are activated in patients with HF. The RAS is also an important mediator in the progression of HF. In the short term, the juxtaglomerular cells of the kidney release the proteolytic enzyme renin in response to a decrease in BP or renal perfusion (eg, hemorrhage), generating Ang I from circulating angiotensinogen. ACE cleavage of Ang II from Ang I in the lung produces circulating Ang II. Acutely, Ang II acts as a potent arteriolar and venous vasoconstrictor to return BP and filling pressure to baseline, respectively. Ang II also stimulates the release of aldosterone from the adrenal cortex and antidiuretic hormone from the posterior pituitary. Both contribute to increases in blood volume through their effects on the kidney to promote salt and water reabsorption, respectively. In the long term, elevations in Ang II lead to sodium and fluid retention and increases in SVR, which contribute to symptoms of HF, pulmonary congestion, and hemodynamic decompensation (Fig. 11.17).

In addition to the cardiorenal and cardiocirculatory effects, most of the hormones and receptors of the RAS are expressed in the myocardium, where they contribute to maladaptive growth or remodeling,

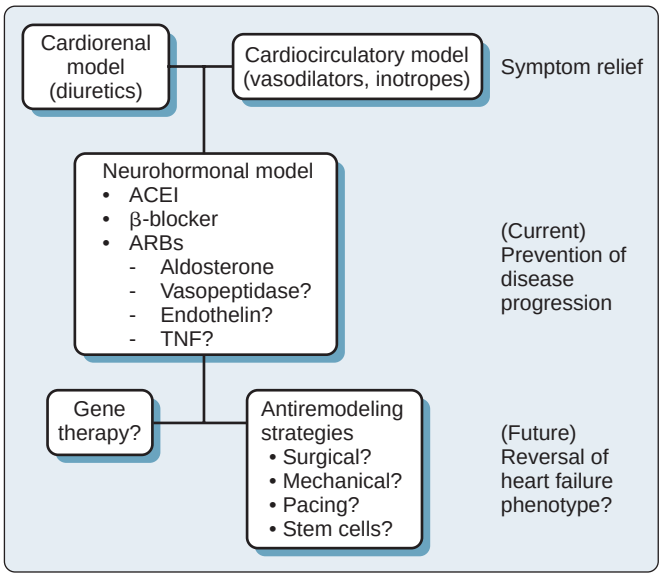

Fig. 11.16 Current and future treatments of heart failure. Current heart failure therapies are focused on prevention of disease progression with drugs that antagonize neurohormonal systems. Future therapies may involve antagonists of other biologically active systems (eg, endothelins, tumor necrosis factor *[TNF]*), and anti-remodeling strategies that may reverse the heart failure phenotype. *ACEI*, Angiotensin-converting enzyme inhibitor; *ARB*, angiotensin-receptor blocker; *NEP*, neutral endopeptidase blocker. *(Modified from Mann DL. a key factor in the progression of HF. Increased expression of mRNA for angiotensinogen, ACE, and Ang II has been identified in the failing human heart.[322] Increased coronary sinus Ang II concentrations were measured in patients with dilated and ischemic cardiomyopathy, signifying a paracrine or autocrine action of the RAS. Moreover, progressive increases in coronary sinus Ang II production correlated with increases in NYHA functional classification of HF.[322] These data

Positive inotropy	Negative chronotropy
Aldosterone secretion	Natriuresis
Catecholamine release	Bradykinin release

provide evidence that intracardiac RAS is involved in the evolution of the disease process.

The effects of Ang II on its AT_1 and AT_2 receptors are well known. The AT_1 receptor is involved in several effects that lead to adverse cardiovascular outcomes. Activation of AT_1 receptors promotes aldosterone and vasopressin secretion with concomitant increases in salt and water reabsorption through the kidneys, vasoconstriction, catecholamine release, and cell growth and proliferation of cardiovascular tissue (Table 11.14). Stimulation of AT_2 receptors results in natriuresis, vasodilation, release of bradykinin and NO, and cell growth inhibition or apoptosis.

The Ang II that is formed locally in the heart acts primarily through AT_1 receptors located on myocytes and fibroblasts, where it participates in the regulation of cardiac remodeling. Through complex cascades of intracellular signal transduction that activate protein transcription factors within the nucleus initiating the creation of RNA transcripts, the long-term effects of intracardiac Ang II on the AT_1 receptor result in cardiomyocyte hypertrophy, fibroblast proliferation, and extracellular matrix deposition[323] (Fig. 11.18). These processes contribute to progressive LV remodeling and LV dysfunction characteristic of HF.

TABLE 11.15 Selected Clinical Trials of ACE Inhibitors in Heart Failure

Angiotensin-Converting Enzyme Inhibitors

Clinical Evidence

Evidence supporting the beneficial use of ACE inhibitors in HF patients comes from various randomized, placebo-controlled clinical trials (Table 11.15). Initially, this class of drugs was evaluated for treatment of symptomatic HF (ie, SOLVD, V-HeFT, and CONSENSUS trials). Patients with NYHA class II to IV HF treated with ACE inhibitors had reductions in mortality ranging from 16% to 31%. ACE inhibitors were also found to improve outcomes for asymptomatic patients with LV systolic dysfunction in the following categories: patients with EFs less than 35% due to cardiomyopathy,[323] patients within 2 weeks after MI with EFs less than 40%,[324] and patients within the first 24 hours of MI regardless of EF.[325]

Results from the Heart Outcomes Prevention Evaluation (HOPE) study further expanded the indications for this class of agents to include asymptomatic, high-risk patients to prevent new-onset HF.[326] In patients with diabetes or peripheral vascular disease and an additional atherosclerotic risk factor but without clinical HF or systolic dysfunction, ramipril (10 mg/day) reduced the HF risk by 23%. The PEACE trial evaluated the use of ACE inhibitors in addition to modern conventional therapy in patients with stable CAD with preserved LV function. The results of this trial did not reveal any decrease in mortality from cardiovascular causes or nonfatal MI compared with placebo.[327]

The use of ACE inhibitors should be considered only in stage A patients who have diabetes or vascular disease and for controlling standard risk factors. In stage B patients or those with reduced EF with or without symptoms, ACE inhibitors are considered first-line therapy (COR 1, LOE A). Since the commencement of these trials, the rationale for the use of ACE inhibitors has expanded from a reduction in the progression of clinical HF through ACE inhibitor–mediated vasodilatory action to acknowledgment that ACE inhibitors also directly affect the cellular mechanisms responsible for progressive myocardial pathology.

Mechanisms of Action

ACE inhibitors act by inhibiting one of several proteases responsible for cleaving the decapeptide Ang I to form the octapeptide Ang II. Because ACE is also the enzyme that degrades bradykinin, ACE inhibitors increase circulating and tissue levels of bradykinin (Fig. 11.19).

ACE inhibitors have several useful effects in chronic HF. They are potent vasodilators through decreasing Ang II and norepinephrine and increasing bradykinin, NO, and prostacyclin. By reducing the secretion of aldosterone and antidiuretic hormone. ACE inhibitors also reduce salt and water reabsorption from the kidney. ACE inhibitors reduce release of norepinephrine from sympathetic nerves by acting on AT_1 receptors at the nerve terminal. In tissue, ACE inhibitors inhibit Ang II production and attenuate Ang II–mediated cardiomyocyte hypertrophy and fibroblast hyperplasia.[328,329]

Clinical evidence supporting an ACE inhibitor–mediated role in cardiac remodeling comes from comparative studies of enalapril versus placebo (ie, SOLVD trial) and enalapril versus hydralazine isosorbide dinitrate (ie, V-HeFT II trial).[330,331] In a subset of the SOLVD study,[330] the placebo group exhibited LV dilation, whereas the enalapril group exhibited a decrease in chamber size for a given LV pressure. In the V-HeFT II trial, survival was better with enalapril than hydralazine/isosorbide dinitrate despite improvements in exercise capacity in the latter group, suggesting that mechanisms other than vasodilation contribute to improved survival with ACE inhibitors.[330]

Chymase also catalyzes the production of Ang II from Ang I within myocardial tissue. The serine protease has an almost 20-fold greater affinity for Ang I than ACE, and it is not influenced by ACE inhibitors.[332] Angiotensin II receptor blockers (ARBs) may add to the inhibition by ACE inhibitors of angiotensin-promoted progression of HF.

ACE inhibitors attenuate insulin resistance, a common metabolic abnormality in HF patients, independent of Ang II activity. Ang II receptor antagonists do not attenuate insulin resistance.[333] ACE inhibitors and ARBs reduce proteinuria (ie, common comorbidity in HF patients) and slow the progression to renal failure in hypertensive patients.[297,334]

Drug Selection and Strategy for Clinical Practice

Treatment guidelines for the use of ACE inhibitors, including appropriate starting and target doses and common side effects, are shown in Table 11.16. Adherence to target doses of ACE inhibitors increases the likelihood of reproducing benefits demonstrated in large-scale HF trials (see Table 11.15).

According to the AHA/ACCF guidelines (see Fig. 11.15), it is reasonable to initiate ACE inhibitor therapy in high-risk patients (stage A), such as those with diabetes or peripheral vascular disease, although the committee acknowledges that further objective studies are needed for this patient group. ACE inhibitor therapy should be initiated in all stage B patients with a recent or remote history of MI and reduced EF to prevent symptomatic HF and reduce mortality and in all stage C HFrEP patients (COR I, LOE A).

Relative contraindications for the use of ACE inhibitors include (1) a history of intolerance or adverse reactions (eg, cough, angioedema, neutropenia, rash); (2) persistent hyperkalemia (>5.5 mEq/L) that cannot be reduced by diet or diuretic adjustment; (3) symptomatic

hypotension; and (4) history of bilateral renal artery stenosis. Small doses of an agent with a short plasma half-life (eg, captopril) are advocated when initiating therapy in patients with marginal BP (ie, systolic BP <90 mm Hg) or reduced renal function (ie, baseline creatinine >2.0 mg/dL).

After it is demonstrated that a patient tolerates inhibition of the RAS, dosing should be adjusted to target doses of a longer-acting agent. In the ATLAS trial, lisinopril in a dose of 32.5 to 35 mg/day had greater efficacy than 2.5 to 5.0 mg/day in patients with symptomatic HF and LV systolic dysfunction (EF <35%).[335] Patients receiving target doses of ACE inhibitors are less frequently hospitalized than those receiving reduced doses.[336] The importance of differences in tissue binding among the various ACE inhibitors remains unclear.

Angiotensin II Receptor Blockers for Heart Failure

Pathophysiology and Mechanism of Action

Although ACE inhibitors reduce mortality, many patients do not tolerate their side effects. ACE inhibitors incompletely antagonize Ang II. These factors have prompted the development of specific Ang II receptor blockers for the pharmacologic treatment of HF[337] (see Fig. 11.19). Non–ACE-generated Ang II within the myocardium contributes to LV remodeling and HF progression through AT_1 receptor effects (see Table 11.14). Selective AT_1 blockers prevent Ang II from acting on the cell, preventing vasoconstriction, sodium retention, release of norepinephrine, and delaying or preventing LV hypertrophy and fibrosis.[338] AT_2 receptors remain unaffected, and their actions, including NO release, remain intact.

Clinical Evidence

Outcome benefits from ARBs were first demonstrated in the ELITE I trial, which showed as a secondary end point a significantly reduced risk of sudden death with losartan (4.8%) compared with captopril (8.7%),[339] despite no between-group differences in the primary end points, renal dysfunction, and hypotension. The follow-up ELITE II trial (Table 11.17), although having greater statistical power than ELITE I, failed to confirm that losartan was superior to captopril in reducing mortality in older patients with HF.[340] In subgroup analyses, the ELITE II trial patients on preexisting β-blockers tended to have less favorable outcomes with losartan than with captopril.

The Valsartan in Heart Failure (Val-HeFT) and Candesartan in Heart Failure Assessment in Reduction of Mortality (CHARM) trials were designed to evaluate whether ARBs plus conventional therapy (including β-blockers, ACE inhibitors, and diuretics) for symptomatic HF provide additional clinical benefit. Although the findings from the Val-HeFT support the use of ARBs in patients with chronic HF who are intolerant to ACE inhibitors, the patients already on ACE inhibitors and β-blockers (93% of their patient population) showed a trend toward an increased risk of death or hospitalization when valsartan was added to their treatment regimen.[313]

In contrast, the CHARM-added trial[341] showed safety for the use of candesartan in combination with ACE inhibitors and β-blockers (ie, 15% relative risk reduction in cardiovascular-related mortality or hospitalization), and in patients intolerant to ACE (ie, alternative group), the relative risk reduction in mortality or hospitalization was 23%. Patients with EFs greater than 40% not receiving ACE inhibition (ie, preserved group) showed no difference in cardiovascular mortality and only a small reduction in HF hospitalizations.[342,343] In the CHARM-overall trial, cardiovascular-related death and hospitalizations were significantly reduced with candesartan use; the relative risk reduction for cardiovascular death was 16%.[312]

Clinical Practice

ARBs are used as alternatives to ACE inhibitors (class I, LOE A) for the treatment of patients with symptomatic HF if there are side effects to ACE inhibitors (eg, persistent cough, angioedema, hyperkalemia, worsening renal dysfunction). An ARB may be used as an alternative to an ACE inhibitor in patients who are already taking an ARB for another reason, such as hypertension, and who subsequently develop HF (class IIa, LOE A). Because ARBs do not affect bradykinin levels, cough and angioedema are rare side effects. Doses and dosing intervals for ARBs studied in large-scale trials are shown in Table 11.18.

Similar to ACE inhibition, ARBs produce dose-dependent decreases in right atrial pressure, PCWP, and SVR. Unlike long-term ACE inhibition,[344] the hemodynamic effects and associated increases in cardiac index are sustained while the plasma levels of Ang II remain suppressed with ARB therapy. Although trials have shown that the addition of an ARB to an ACE inhibitor may further reduce mortality and hospitalization for patients with HFrEF (ie, CHARM-added and V-HeFT trials),[330,341] significant increases in hypotension and renal impairment occurred in the treatment arm. The adverse effects of combining these

two drug classes has been underscored in a systematic, large metaanalysis of patients with symptomatic LV dysfunction.[345] Routine combined use of an ACE inhibitor, ARB, and aldosterone antagonist is not recommended and is potentially harmful.[304]

Aldosterone Receptor Antagonists

Aldosterone, a mineralocorticoid, is another important component of the neurohormonal hypothesis of HF. Although it was previously assumed that treatment with an ACE inhibitor (or ARB) would block the production of aldosterone in patients with HF, elevated levels of aldosterone have been measured despite inhibition of Ang II[346] (see Fig. 11.19).

Adverse effects of elevated aldosterone levels on the cardiovascular system include sodium retention, potassium and magnesium loss, ventricular remodeling (eg, collagen production, myocyte growth, hypertrophy), myocardial norepinephrine release, and endothelial dysfunction[347] (Fig. 11.20). Non-Ang II–mediated aldosterone production may in part result from the hypomagnesemia commonly seen in HF patients.[348] Low extracellular Mg^{2+}, common in chronic illness and as a result of loop diuretics, becomes a stimulus for adrenal aldosterone secretion.[349] Extraadrenal production of aldosterone in myocardial and vascular tissue may also contribute to oxidative, proinflammatory, and prothrombotic signaling pathways (eg, nuclear factor-κB [NF-κB], activator protein 1 [AP-1], plasminogen activator inhibitor 1 [PAI-1]), and maladaptive processes such as LV dilation, perivascular fibrosis, and atherosclerosis.[350–352] Aldosterone produced in the brain increases SNS activity, a central finding in HF.[353]

Given the multiple endocrine and autocrine or paracrine contributions of aldosterone to the neurohormonal hypothesis of HF, the possibility that aldosterone receptor antagonism might halt disease progression became an increasingly attractive hypothesis. Besides the traditional mechanisms of mineralocorticoid receptor blockade, including natriuresis, diuresis, and kaliuresis,[348,354] beneficial nonrenal effects of aldosterone antagonism include decreased myocardial collagen formation,[355] increased myocardial norepinephrine uptake and decreased circulating norepinephrine levels,[355] normalization of baroreceptor function, increased heart rate variability,[356,357] and improved endothelial vasodilator dysfunction and basal NO bioactivity at the vascular level.[358]

TABLE 11.18 Angiotensin Receptor Blockers Evaluated in Large-Scale Trials

Agent	*Half-life (h)*	*Dosing Interval*	*Initial Dose (mg)*	*Target Dose (mg)*
Losartan	6–9	qd	25	50
Valsartan	9	bid	40	160
Irbesartan	11–15	qd	75	150
Candesartan	3.5–4	qd	4	32

Clinical Evidence

Three large-scale trials demonstrated improved outcomes with aldosterone receptor antagonism in chronic HF. The Randomized Aldactone Evaluation Study (RALES), which enrolled more than 1600 symptomatic HF (eg, stage C, NYHA III or IV) patients, showed the efficacy of spironolactone (26 mg/day) in combination with standard therapy (ie, ACE inhibitor, loop diuretic with or without digoxin, and a β-blocker). Regardless of age, gender, and HF cause, the treatment group experienced a 30% reduction in risk for all-cause mortality and in cardiovascular-related mortality compared with standard therapy[318] (Fig. 11.21).

Because β-blockers were used infrequently in this study (10–20%), the role of spironolactone in contemporary management of HF remains unclear. Studies have reported marked increases in hospital admission and death related to hyperkalemia after widespread use of spironolactone.[359] It has been speculated that the K^+-sparing effect of spironolactone and its ability to reduce circulating norepinephrine[360]

and increase NO availability[358] might have reduced the propensity for digitalis-related arrhythmias and the subsequent risk of sudden cardiac death reported in the digitalis trial.[361]

Eplerenone is an aldosterone antagonist that lacks some of spironolactone's common side effects.[362] The Eplerenone Post-acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS), enrolling more than 6600 patients with symptomatic HF within 3 to 14 days after MI, showed that eplerenone (25–50 mg/day) in combination with an ACE inhibitor, loop diuretic, and β-blocker reduced all-cause mortality ($P = .008$), death from cardiovascular causes ($P = .0002$), and hospitalization for cardiovascular events.[319]

In the Eplerenone in Mild Patients Hospitalization and Survival Study in Heart Failure (EMPHASIS-HF) study, Zannad and coworkers[363] addressed the important question of whether aldosterone blockade is clinically useful in patients with mild systolic HF. In a double-blind trial, 2737 patients with NYHA class II HF and an EF of 35% or less were randomized to receive eplerenone (up to 50 mg daily) or placebo in addition to recommended therapy. The trial was stopped prematurely at a mean follow-up of 21 months due to improved benefits in the treatment arm. The primary outcome (ie, composite of death from cardiovascular causes or hospitalization for HF) occurred for 18.3% of patients in the eplerenone group compared with 25.9% in the placebo group (hazard ratio, [HR] =0.63; 95% confidence interval [CI], 0.54 to 0.74; $P < .001$). A total of 12.5% of patients receiving eplerenone and 15.5% of those receiving placebo died (HR = 0.76; 95% CI, 0.62 to 0.93; $P = 0.008$); 10.8% and 13.5%, respectively, died of cardiovascular causes (HR = 0.76; 95% CI, 0.61 to 0.94; $P = .01$). Hospitalizations for HF and for any cause were also reduced with eplerenone.

Because of these findings, the use of aldosterone receptor blockade has been broadened to include patients with mild or moderate systolic HF (NYHA II or III) who have prior cardiovascular hospitalization or elevated levels of B-type natriuretic peptide (BNP), unless contraindicated.[304] The benefits of aldosterone inhibition in these less severe HF patients may be through improvements in endothelial function,[364] exercise tolerance, EF,[365] and attenuation of collagen formation. Successful use of aldosterone antagonists mandates close attention to blood potassium concentrations.[364] Based on these data and the favorable effects of aldosterone antagonism in animal models of infarction,[350] it seems reasonable to expect that aldosterone receptor blockers may find value even in patients with asymptomatic systolic LV dysfunction.

Clinical Practice

Evidence supports aldosterone antagonists for patients with symptomatic HF and patients with LV dysfunction after MI.[319] Aldosterone receptor antagonists should be considered in addition to standard therapy (including ACE inhibitors and β-blockers) in patients with NYHA II disease who have prior cardiovascular hospitalization or elevated BNP levels and those with NYHA IV HF and an EF of 35% or less, unless contraindicated. Class I recommendations also pertain to patients after an acute MI with an EF of 40% or less who develop HF symptoms or who have a history of diabetes, unless contraindicated.[304]

Spironolactone should be initiated at 12.5 to 25 mg/day. Patients should have a normal serum K^+ level (<5.0 mEq/L) and adequate renal function (creatinine ≤2.5 mg/dL in men, creatinine ≤2.0 mg/dL in women, and creatinine clearance >30 mL/min). Regular measurement of electrolytes is mandatory to avoid hyperkalemia. Dosages and dosing intervals should be reduced during episodes of potential dehydration (eg, vomiting, diarrhea) and with concomitant use of pharmacologic agents that may predispose to impairments in renal function (eg, steroidal antiinflammatory agents). In the RALES trial, there was no significant increase in the incidence of severe hyperkalemia (K^+ ≥6.0 mEq/L), and only one death related to hyperkalemia (in the placebo arm).[318] This is in marked contrast to a Canadian time-series analysis that showed an abrupt increase in hyperkalemia-associated morbidity and mortality in association with the publication of the RALES data.[359]

Spironolactone can occupy androgen receptors, leaving unopposed estrogen receptors and predisposing to estrogen-like effects such as painful gynecomastia and menstrual disorders. Because digoxin has estrogen-like properties, its use in combination with spironolactone can also predispose to gynecomastia.[366] This usually does not pose a problem in men because they do not have biologically significant amounts of estrogen. From the EPHESUS data, it appears that the newer aldosterone receptor antagonist, eplerenone, has a lower incidence of hyperkalemia and no evidence of unopposed estrogen receptor-like properties. Unfortunately, eplerenone is many times more expensive than spironolactone.

Renin Inhibition

Although RAAS inhibitors improve prognosis for HFrEF, HF-associated morbidity and mortality remain high. The effect of RAAS blockade may be limited due to the loss of an inhibitory feedback of angiotensin II on renin production. Suppression of Ang II and aldosterone generation by ACE inhibitors or ARBs does not result in persistently decreased ANG II and aldosterone plasma levels.[367] One reason for the reduced effectiveness of RAAS blockers may be the compensatory increase in renin and Ang I levels in response to interruption of the negative feedback activity of Ang II signaling.

Sustained elevations in renin levels after RAAS inhibitors have been associated with worse outcomes.[368,369] Evidence also suggests that these increases in renin may have additional, non-RAAS–dependent effects through activation of the (pro-) renin receptor and its subsequent activation of an intracellular postreceptor cascade that leads to enhanced synthesis of DNA, plasminogen activator inhibitor 1, collagen type I, fibronectin, and transforming growth factor-β_1.[370]

Clinical Evidence

Because ACE inhibitors and ARBs increase renin levels due to the loss of negative feedback of Ang II on renin release and the clinical clues suggesting that high plasma renin levels may ultimately influence the progression of cardiac disease, direct renin inhibitors have been considered in the treatment of HF. The most recently studied renin inhibitor is aliskiren. However, the reputed neurohormonal benefits[371,372] of adding this drug to standard therapy have not translated to improved outcomes in HF patients.

The Aliskiren Trial on Acute Heart Failure Outcomes (ASTRONAUT) trial[373] investigated whether aliskiren, when added to standard therapy, would reduce the rate of cardiovascular death or HF rehospitalization at 6 or 12 months of patients with acute decompensated HF. A total of 1639 patients were randomized to aliskiren or placebo. At 6 months, 24.9% of the aliskiren group (77 cardiovascular deaths, 153 HF rehospitalizations) and 26.5% of the placebo group (85 cardiovascular deaths, 166 HF rehospitalizations) experienced the primary end point (HR = 0.92; 95% CI, 0.76 t0 1.12; $P = .41$). At 12 months, the event rates were 35.0% for the aliskiren group (126 cardiovascular deaths, 212 HF rehospitalizations) and 37.3% for the placebo group (137 cardiovascular deaths, 224 HF rehospitalizations) (HR = 0.93; 95% CI, 0.79 to 1.09; $P = .36$). The rates of hyperkalemia, hypotension, and renal failure were higher in the aliskiren group compared with the placebo group. Among patients hospitalized for HF with reduced LVEF, initiation of aliskiren in addition to standard therapy did not reduce cardiovascular death or HF rehospitalization at 6 months or 12 months after discharge.

An interaction between treatment and diabetes was found. In diabetic patients, aliskiren was associated with greater incidence of cardiovascular death or HF rehospitalization (HR = 1.16; 95% CI, 0.91 to 1.47) and all-cause mortality (HR = 1.64; 95% CI, 1.15 to 2.33), whereas in nondiabetics, an opposite result was found (HR = 0.80; 95% CI, 0.64 to 0.99 and HR = 0.69; 95% CI, 0.50 to 0.94, respectively).[374]

Results from the Aliskiren Trial to Minimize OutcomeS in Patients with HEart failure (ATMOSPHERE) study, the other trial that is testing the safety and efficacy of aliskiren, are expected soon.[375] In this trial, patients with class II to IV systolic failure (EF <35%) and an elevated BNP or N-terminal pro BNP (NT-pro-BNP) concentration were randomized in equal proportions to receive enalapril (10 mg twice daily), aliskiren (300 mg once daily), or a combination of both drugs. The primary end point is delayed time to first occurrence of cardiovascular death or HF hospitalization. Although the development of renin inhibitors has increased our arsenal for modulating the RAAS, their widespread use in HFrEF patients, particularly those with concomitant diabetes, has not been advocated.

Combination Approaches With Renin-Angiotensin System Inhibition

Angiotensin receptor–neprilysin inhibitors (ARNIs) offer treatment for HF that involves neprilysin inhibition and AT_1 receptor blockade. ARNIs can modulate two counterregulatory neurohormonal systems in HF: the RAAS and natriuretic peptide system (Fig. 11.22).[376] Drugs that inhibit the RAAS have been foundational to cardiovascular drug therapy for almost 3 decades. RAAS inhibitors moderate

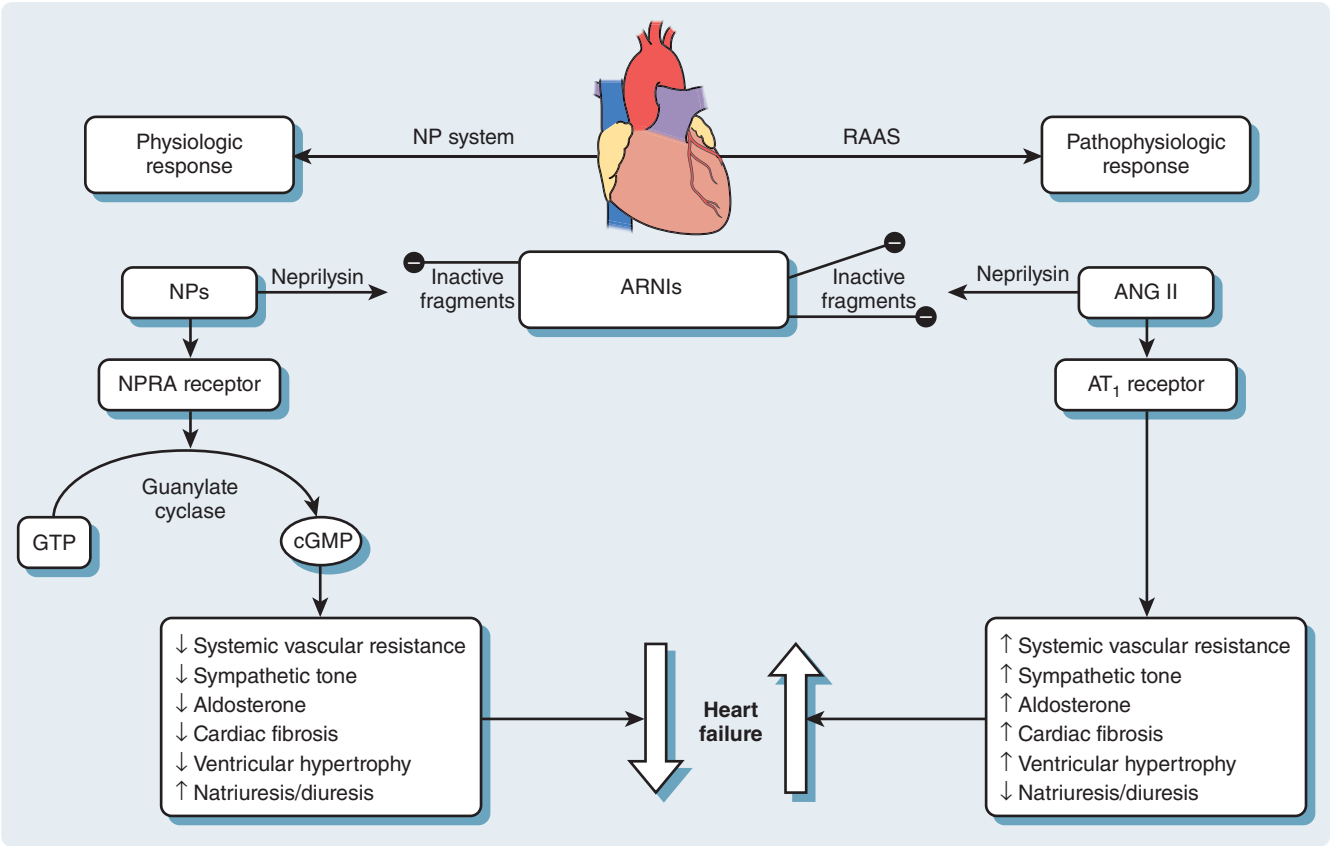

Fig. 11.22 Angiotensin receptor neprilysin inhibitors *(ARNIs)* can modulate two counterregulatory neurohormonal systems in heart failure: the renin-angiotensin-aldosterone system *(RAAS)* and the natriuretic peptide *(NP)* system (eg, atrial NP, B-type NP). *ANG,* angiotensin; *AT_1,* angiotensin I receptor; *cGMP,* cyclic guanosine monophosphate; *GTP,* guanosine-5′-triphosphate; *NPRA,* natriuretic peptide receptor A; ↑, increased; ↓,decreased. *(From Langenickel TH. Angiotensin receptor-neprilysin inhibition with LCZ696: a novel approach for the treatment of heart failure.* Drug Discov Today Ther Strateg. *2012;9:e131.)*

vasoconstriction, myocyte hypertrophy, and myocardial fibrosis, an effect that has translated into clinically meaningful improvements in functional status and survival. Natriuretic peptides, which include atrial natriuretic peptide, BNP, and urodilatin, are secreted by the heart, vasculature, kidney, and CNS in response to increased cardiac wall stress and other stimuli. Natriuretic peptides have potent natriuretic and vasodilatory properties, inhibit the RAAS, reduce sympathetic drive, and have antiproliferative and antihypertrophic effects. Neprilysin inhibition results in an increased concentration of natriuretic peptides. The beneficial effects of RAAS inhibition are likely to be augmented by the enhancement of natriuretic peptide activity.[376]

LCZ696 is the first and most clinically developed agent in the new class of ARNI compounds. The chemical entity comprises anionic moieties of the neprilysin inhibitor prodrug AHU377 and the ARB valsartan in a fixed-dose combination in a 1:1 ratio.[376] In the Prospective Comparison of ARNI with ACEI to Determine Impact on Global Mortality and Morbidity in Heart Failure (PARADIGM-HF) trial, which involved 8399 patients with NYHA class II, III, or IV HF, McMurray and associates[377] reported that LCZ696 was more effective than enalapril in reducing the risks of cardiovascular death (by an incremental 20%), HF hospitalization (by an incremental 21%), and all-cause mortality (by an incremental 16%). Patients' quality of life, as measured on the Kansas City Cardiomyopathy Questionnaire, was significantly improved with ARNI when compared with an ACE inhibitor. LCZ696 was also better tolerated than enalapril, with less likelihood for cough, hyperkalemia, or renal impairment.

Due to the overwhelmingly statistically advantageous effects, the PARADIGM-HF trial was stopped early for the benefit of the HF patients, and in July 2015, the FDA approved the combination valsartan/sacubitril tablet for the treatment of patients with stage C HF with reduced EF (ie, NYHA class II or IV). The drug formerly known as LCZ696 was given the name Entresto.

The recommended starting dose is 49 mg/51 mg given orally twice daily, and the target maintenance dose is 97 mg/103 mg given orally twice daily within 2 to 4 weeks as tolerated. A reduced starting dose of 24 mg/26 mg given twice daily is recommended for patients who are naïve to ACE inhibitors or ARBs or who previously were taking low doses of these RAS inhibitors. The ARNI combination is contraindicated with concomitant use of an ACE inhibitor, and a 36-hour washout period is recommended when switching from an ACE inhibitor to the ARNI drug. Although it can be administered in conjunction with other HF therapies in place of an ACE inhibitor or other ARB, it is contraindicated for patients with diabetes who are taking aliskiren. Among the adverse side effects associated with Entresto, the risk for hypotension and hyperkalemia may be as high as 18% and 12%, respectively.

β-Adrenergic Receptor Antagonists

Sympathetic Nervous System Activation and Its Role in the Pathogenesis of Heart Failure

Activation of the SNS (eg, after MI, for long-standing hypertension), much like increases in RAS activity, contributes to the pathophysiology of HF. SNS activation leads to pathologic LV growth and remodeling. Myocytes thicken and elongate, with eccentric hypertrophy and increases in sphericity. Wall stress is increased by this architecture, promoting subendocardial ischemia, cell death, and contractile dysfunction. Persistent SNS activation leads to altered gene expression, with a shift to a fetal-like phenotype (ie, downregulation of cardiac α-actin and α-myosin heavy chain and upregulation of fetal forms of β-myosin heavy chain). There is downregulation of calcium regulatory proteins, including SR Ca^{2+}-ATPase, and impairment of contractility and relaxation. The activated SNS can also harm myocytes directly through programmed cell death. As myocytes are replaced by fibroblasts, heart function deteriorates from this remodeling.[378] The threshold for arrhythmias may also be lowered, contributing in a deteriorating cycle.

β-Adrenergic Receptor Blockers' Influence on Heart Failure Pathophysiology

In chronic HF, the beneficial effects of long-term β-blockade include improved systolic function and myocardial energetics and reversal of pathologic remodeling. A shift in substrate use from free fatty acids to glucose, a more efficient fuel in the face of myocardial ischemia, may partly explain the improved energetics and mechanics in the failing heart treated with β-blockade.[379] Heart rate, a major determinant of $M\dot{V}O_2$, is reduced by β_1-receptor blockade. β-Blockade is also associated with a change in the molecular phenotype of the heart. Systolic dysfunction of individual myocytes is associated with upregulation of gene expression of natriuretic peptides and fetal-like β-myosin heavy chain and increased expression of SERCA2 (ie, intracellular pump in the SR of muscle) and α-myosin heavy chain (ie, the more efficient, faster, adult isoform).[378] β-Blockade reverses the changes in gene expression with concurrent improvements in LV function.[380] In a dog model of HF, β-blockade also reduced myocyte apoptosis.[381] Chronic β-blockade reduces the harmful effects of excessive SNS activation of the heart and can reverse LV remodeling.

β-Adrenergic blockade can limit the disturbance of excitation-contraction coupling and predisposition to ventricular arrhythmias associated with HF. In the normal heart, the fight or flight response activates the SNS. This stimulates a β-adrenergic receptor signaling pathway in the myocyte that increases phosphorylation of three key components of excitation-contraction coupling: the voltage-gated Ca^{2+} channel (VGCC), the SR Ca^{2+} release channel (ie, ryanodine receptor 2 [RYR2] channel), and the Ca^{2+} uptake pathway (ie, phosphorylation of phospholamban reduces inhibition of the Ca^{2+}-ATPase SERCA2a), ultimately resulting in increased contractility.[382]

In the low-CO failing heart, the SNS is chronically activated. In this hyperadrenergically stimulated heart, excitation-contraction coupling becomes maladaptive due to leaky Ca^{2+} from the SR. This is caused by protein kinase A (PKA)–hyperphosphorylated RYR2 channels that produce a diastolic SR Ca^{2+} leak that conspires with reduced SERCA2a-mediated SR Ca^{2+} uptake (due in part to PKA-hypophosphorylated phospholamban that inhibits SERCA2a) to deplete SR Ca^{2+} and contribute to contractile dysfunction of cardiac muscle (Fig. 11.23).[383,384] Depletion of SR Ca^{2+} stores underlies the reduced contractility of failing cardiac muscle.

Leaky Ca^{2+} may also explain the predisposition to ventricular arrhythmias thought to be initiated by delayed afterdepolarizations.[385] The cardiac RyR2 has a large cytoplasmic structure that serves as a scaffold for modulatory proteins that regulate the function of the channel. PKA phosphorylation of RYR2 dissociates the regulatory protein FKBP 12.6 and regulates the open probability of the channel. In failing hearts, RYR2 is PKA-hyperphosphorylated, resulting in defective channel function due to increased sensitivity of Ca^{2+}-induced activation.

Studies using animal models of HF show that chronic β-blockade may reverse the PKA hyperphosphorylated state and restore the structure and function of the RYR2 Ca^{2+} release channel.[386,387] Another potential benefit of β-adrenergic receptor blockade in the failing heart may be normalization of excitation-contraction coupling, potentially reducing the propensity for arrhythmias.

An evolving concept in the pathophysiology of HF incorporates the negative inotropic action of catecholamines and specifically the role of β_3-adrenoreceptors. The failing heart is resistant to exogenous inotropic stimulation compared with hearts that are not failing. This has been attributed to downregulation of β_1- and β_2-adrenoreceptors due to a hyperadrenergic state.[388,389] However, β_3-adrenoreceptors have been identified in the failing and nonfailing hearts of humans and other mammalian species.[390–392] Unlike the case for β_1- and β_2-adrenoreceptors, β_3-adrenoreceptors are upregulated in HF.[392–394] β_3-Activation decreases contractility. In contrast to the G_s-protein–coupled adenylyl cyclase activation and cAMP-dependent pathway of the β_1- and β_2-adrenoreceptors, the negative inotropy that results from stimulation of β_3-adrenoreceptors appears to result from activation of an NO pathway and an increased intracellular level of cGMP.[395] However, an understanding of the role of β_3-receptors in

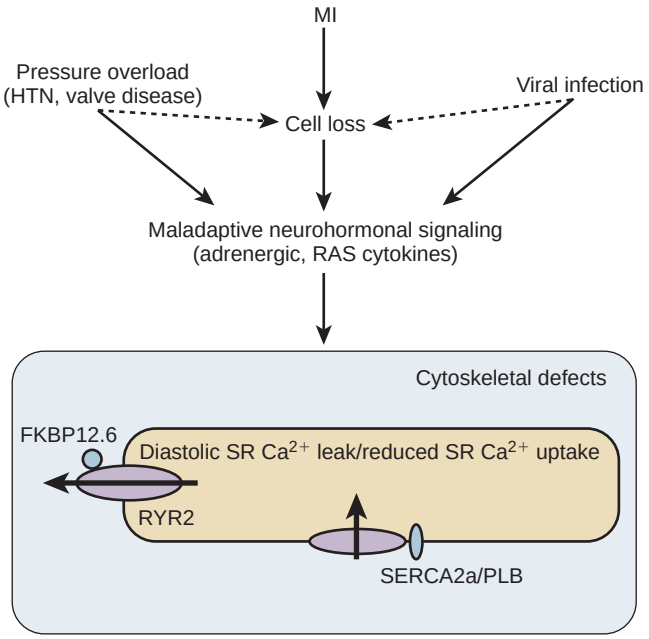

Fig. 11.23 The maladaptive response to cardiac muscle damage from myocardial infarction *(MI)*, viral infection, or pressure overload due to hypertension *(HTN)* or valve disease activates signaling pathways, including the adrenergic, renin-angiotensin *(RAS)*, and cytokine systems, in response to stress. Chronic activation of these pathways in heart failure causes defects in excitation-contraction coupling, including protein kinase A hyperphosphorylation of the cardiac ryanodine receptor *(RYR2)* that results in depletion of the enzyme *FKBP12.6* (which helps to keep the channel closed in diastole) from the channel macromolecular complex, causing a diastolic Ca^{2+} leak that depletes sarcoplasmic reticulum *(SR)* Ca^{2+} and reduces SR Ca^{2+} reuptake by means of *SERCA2a* (ie, intracellular calcium pump). Other defects in the maladaptive response to heart failure include alterations in the cytoskeleton and extracellular matrix (eg, imbalance between matrix metalloproteinases [MMPs] and tissue inhibitors of metalloproteinases [TIMPs]). *PLB*, Phospholamban. *(Modified from Marks AR. A guide for the perplexed: towards an understanding of the molecular basis of heart failure [editorial].* Circulation. *2003;107:1456.)*

the treatment and pathophysiology of HF awaits the arrival of specific β_3-adrenoceptor antagonists.

Clinical Evidence

The use of β-blockers in patients with HF was initially accepted with skepticism because of the perceived risk of decompensation from transient negative inotropic effects. However, data from human and animal studies have shown that β-blockers improve energetics and ventricular function and reverse pathologic chamber remodeling. Although this beneficial biologic process takes 3 months or more to manifest (Fig. 11.24), it translates into improved outcomes (ie, reduced deaths and hospitalizations) for patients with HF. Randomized trials show that metoprolol CR/XL, bisoprolol, and carvedilol (in conjunction with ACE inhibitors) reduce morbidity (ie, hospitalizations) in symptomatic, stage C and D (ie, not in cardiogenic shock) HF patients (ie, NYHA II to IV class) (Table 11.19).[316,317,396,397] Although β-blocker therapy is recommended for asymptomatic HF patients (ie, those with previous MI and reduced EF), evidence from randomized trials is lacking (class I, LOE B).[398]

β-Blockers are classified as being first-, second-, or third-generation drugs based on specific pharmacologic properties. First-generation agents, such as propranolol and timolol, block β_1- and β_2-adrenoreceptors, are considered nonselective, and have no ancillary properties. Second-generation agents, such as metoprolol, bisoprolol, and atenolol, are specific for the β_1-adrenoreceptor subtype but lack additional mechanisms of cardiovascular activity. Third-generation agents, such as bucindolol, carvedilol, and labetalol, block β_1- and β_2-adrenoreceptors and possess vasodilatory and other ancillary properties. Labetalol and carvedilol produce vasodilation by β_1-adrenoreceptor antagonism, whereas bucindolol produces mild vasodilation through a cGMP-mediated mechanism. Carvedilol increases insulin sensitivity,[399] possesses antioxidant effects,[400] and has β_3-adrenoreceptor selectivity.[401,402]

Although it is not clear whether the ancillary properties of third-generation β-blockers translate into better outcomes compared with the second-generation agents, findings from the Carvedilol or Metoprolol European Trial (COMET) suggest that the beneficial effect from β-blockers is not a drug class effect. The study compared carvedilol (25 mg twice daily) with metoprolol tartrate (50 mg twice daily) in symptomatic patients with EFs of 35% or less for 58

TABLE 11.20 Effective β-Blockers for Heart Failure

Agent	*Receptor Selectivity*	*Starting Dose*	*Target Dose*
Metoprolol CR/XL	β_1	12.5 mg qd	200 mg qd
Bisoprolol	β_1	1.25 mg qd	5–10 mg qd
Carvedilol	β_1, β_2, β_3, α_2	3.125 mg qd	25–50 mg qd

months and demonstrated that carvedilol reduced the risk of death significantly more than metoprolol tartrate (all-cause mortality risk reduction: 17%, $P = .0017$; cardiovascular death risk reduction: 20%, $P = .00004$).[403] The superiority of carvedilol over metoprolol may reflect the importance of carvedilol's ancillary effects and pharmacodynamic (half-life) differences.[404]

Findings from the BEST trial confirm that not all β-blockers improve outcomes for patents with HF and suggest that the added benefit from carvedilol may not be a β_2-antagonistic effect because there was no improvement with bucindolol compared with placebo.[397] Whether the selective β_1-specific agents bisoprolol and metoprolol CR/XL exert clinical benefits similar to carvedilol will require additional study. Nonetheless, based on the results of COMET, carvedilol is preferred to conventional metoprolol (not metoprolol CR/XL) for HF treatment.

A metaregression analysis of β-blocker HF trials demonstrated that the magnitude of survival benefit seen with β-blockers was statistically significantly associated with the magnitude of heart rate reduction achieved but not the dosage of β-blocker administered. However, until HF trials randomly assign participants who receive β-blockers to different target heart rates, the optimal heart rate (with target heart rate reduction) remains unknown.[405]

Clinical Practice

Evidence suggests that β-blockers should be given to all HF patients with reduced EFs (<0.40) who are on ACE inhibitors or ARBs unless there is a contraindication. This recommendation is endorsed by the ACC/AHA[398] and the European Society of Cardiology.[406] Patients with ongoing decompensation (ie, requiring intravenous inotropic or vasodilator therapy), overt fluid retention, or symptomatic hypotension should not receive β-blockers. There is no apparent decline in safety or efficacy when β-blockers are given to diabetics with HF. The long-term benefit of β-blocker therapy in patients with coexisting chronic obstructive pulmonary disease is uncertain because they have been excluded from the major clinical trials.

The three agents with clinical trial evidence for improved morbidity and mortality for patients with HF are carvedilol, metoprolol CR/XL, and bisoprolol. Starting doses of β-blockers should be small to minimize worsening of HF symptoms, hypotension, and bradycardia. The dose should be doubled every 1 to 2 weeks, as tolerated, until the target doses shown to be effective in large trials are achieved (Table 11.20). Although it is recommended that β-blocker therapy be continued indefinitely in patients with HF, if it is to be electively stopped, a slow titration period is preferred. Acute withdrawal of β-blocker therapy in the face of high adrenergic tone may result in sudden cardiac death.[407]

The adverse effects of β-blocker therapy include fatigue, dizziness, hypotension, and bradycardia. Because the absolute risk of adverse events is small compared with the overall risk reduction of cardiovascular death, few patients have been withdrawn from β-blocker therapy.[408]

A practical guide to the use of β-blockers in HF patients has been published by McMurray and colleagues[409] All stage C HFrEF patients should be treated with one of the three β-blockers—bisoprolol, immediate- or extended release carvedilol, or sustained-release metoprolol—unless contraindicated,

Hydralazine–Isosorbide Dinitrate

Combination vasodilator therapy with hydralazine and isosorbide dinitrate can interfere with the mechanisms responsible for the progression of HF, particularly that which involves oxidative stress.[410] In addition to biochemical and molecular benefits, the hydralazine–isosorbide dinitrate combination reduces preload and afterload, decreases mitral regurgitation, improves exercise capacity, increases LVEF, and prolongs survival in selected HF populations.[411]

Clinical Evidence

Three major clinical studies have examined the effects of combination therapy with hydralazine and nitrates in the management of HF. In the first Vasodilator–Heart Failure Trial (V-HeFT I), combination vasodilator therapy with hydralazine and isosorbide dinitrate given to male patients with mild to severe HF improved survival compared with the ACE inhibitor prazosin or placebo.[412] However, in V-HeFT II, enalapril had a major benefit on survival in NYHA class II or III patients compared with the combination vasodilator therapy.[331]

Because subanalyses of these studies showed that hydralazine–isosorbide dinitrate produced a marked risk reduction in black patients,[413] the African Americans Heart Failure Trial (AheFT) was designed to prospectively examine the efficacy of this vasodilator combination. The AheFT randomized 1040 self-described African Americans with HF and an abnormal LVEF (only 23% with ischemic heart disease) treated with diuretics, ACE inhibitors, and β-blockers to isosorbide dinitrate (40 mg three times daily) plus hydralazine (75 mg three times daily) or to placebo.[414] Because a significant reduction in mortality rate was observed in isosorbide dinitrate plus hydralazine-treated patients compared with placebo treatment (6% vs 10%, respectively; HR = 0.52; $P = .02$), the study was terminated early, and ACCF/AHA recommendations were initiated.[414]

Clinical Practice

The combination of hydralazine and isosorbide dinitrate should be administered (class I) to improve outcomes for patients self-described as African Americans with moderate or severe symptoms on optimal therapy with ACE inhibitors, β-blockers, and diuretics.[398] The benefit is presumed to be related to an increase in NO bioavailability. The addition of hydralazine and isosorbide dinitrate can be useful in current or prior symptomatic HFrEF patients who cannot be given an ACE inhibitor or ARB because of drug intolerance, hypotension, or renal insufficiency, unless contraindicated (class IIa).[304]

The initial dose of oral isosorbide dinitrate is 20 mg three times daily, with subsequent titration up to a maximal dose of 40 mg three

times daily. Nitrates should be given no more than three times daily, with daily nitrate washout intervals of 12 hours to prevent nitrate tolerance from developing. The initial dose of oral hydralazine in patients with HF is 25 mg three times daily, with subsequent titration up to a maximal dose of 100 mg three times daily. The recommendation for initiation of the fixed combination is 20 mg of isosorbide dinitrate and 37.5 mg of hydralazine hydrochloride given three times daily, with subsequent maximal dosing at 40 mg of isosorbide dinitrate and 75 mg of hydralazine hydrochloride.

Adjunctive Drugs

In addition to ACE inhibitors and β-blockers, diuretics and digoxin are often prescribed for patients with LV systolic dysfunction and symptomatic HF.

Diuretics

For most patients, volume status should be optimized before introduction of β-blockers and ACE inhibitors. Patients with pulmonary congestion often require a loop diuretic in addition to standard therapy. Diuretics relieve dyspnea, decrease heart size and wall stress, and correct hyponatremia from volume overload. However, overly aggressive and especially unmonitored diuretic therapy can lead to metabolic abnormalities, intravascular depletion, hypotension, and neurohormonal activation. Loop diuretics inhibit tubular reabsorption of sodium along the ascending limb of the loop of Henle. Furosemide also reduces preload by increasing vascular capacity.

Diuretics continue to have a role in the management of chronic HF and are usually added to ACE inhibitors, β-blockers, and aldosterone antagonists. However, no RCT has shown a survival benefit for the use of diuretics in HF. Rates of hospitalization or death from worsening HF were significantly greater for HF patients receiving diuretics (other than aldosterone antagonists) than for those not receiving diuretics (relative risk = 1.31, 95% CI, 1.09 to 1.57) in a large post hoc review of data from SOLVD.[415]

Dosing recommendations and kinetic data for the commonly used loop diuretics are provided in Table 11.21. Common side effects of loop diuretics include electrolyte depletion (eg, Na^+, K^+, Mg^+, Ca^{2+}, Cl^-), prolonged action of nondepolarizing muscle relaxants, hyperglycemia, and insulin resistance. Less common side effects include rash, hyperuricemia, and ototoxicity.

Digoxin

Digoxin continues to be useful for patients with symptomatic HF and LV systolic dysfunction despite receiving ACE inhibitor, β-blocker, and diuretic therapy. Digoxin is the only positive inotropic drug approved for the management of chronic HF.

Its indirect mechanism of positive inotropy begins with inhibition of the myocardial sarcolemmal Na^+/K^+-ATPase, resulting in increased intracellular Na^+. This prompts the Na^+/Ca^+ exchanger to extrude Na^+ from the cell, increasing the intracellular concentration of Ca^{2+}. The increased Ca^{2+} available to the contractile proteins increases contractile function.[416]

Besides its inotropic effects, digoxin has important vagotonic and sympatholytic effects. The inhibition of $Na^{+/}K^+$-ATPase in the kidney also decreases sodium reabsorption in the renal tubules.[398] In atrial fibrillation (AF), digoxin slows the rate of conduction at the AV node. In HF patients, it reduces sympathetic efferent nerve activity to the heart and peripheral circulation through direct effects on the carotid sinus baroreceptors.[417] Digoxin increases heart rate variability, an additional beneficial action on autonomic function in the HF patient.[418]

Although these properties are beneficial in controlling the ventricular rate in AF, digoxin has a narrow therapeutic-to-toxicity ratio. Digoxin toxicity is dose dependent and modified by concurrent medications (eg, non–potassium-sparing diuretics) or conditions (eg, renal insufficiency, myocardial ischemia). Ventricular arrhythmias consequent to digoxin toxicity may be caused by calcium-dependent afterpotentials. In patients with intoxication and life-threatening arrhythmias, purified antidigoxin FAB fragments from digoxin-specific antisera provide a specific antidote.[416]

The efficacy of digoxin for symptomatic HF was shown in RCTs. The Digitalis Investigators Group (DIG) trial, enrolling more than 6500 patients with an average follow-up of 37 months, showed that digoxin reduced the incidence of HF exacerbations. Although the study showed no difference in survival in patients with EFs less than 45% receiving digoxin or placebo, the combined end point of death or hospitalization for HF was significantly reduced in patients who received digoxin (27% vs 35%; relative risk = 0.72; 95% CI, 0.66 to 0.79).[361] However, this study revealed a higher incidence of suspected digoxin toxicity in the treatment group.

Efficacy of digoxin in patients with mildly symptomatic HF was shown in pooled results from the Prospective Randomized Study of Ventricular Function (PROVED) and the Randomized Assessment of Digoxin and Inhibitors of Angiotensin-Converting Enzyme (RADIANCE) trials. Patients randomized to digoxin withdrawal had an increased likelihood of treatment failure compared with those who continued to receive digoxin, suggesting that patients with LV systolic dysfunction benefit from digoxin (or at least do not benefit from digoxin withdrawal), even when they have only mild symptoms.[419,420]

Taken together with its narrow therapeutic window, digoxin is deemed reasonable to add to treatment for HF patients with reduced EF who remain symptomatic despite optimal therapy (class IIa). Ideally, serum digoxin concentration should remain between 0.7 and 1.1 ng/mL. In the elderly patient with renal insufficiency, severe conduction abnormalities, or acute coronary syndromes, even a low dose of 0.125 mg/day should be used with extra caution.

Anticoagulation

Patients with chronic HFrEF are at an increased risk for thromboembolic events due to stasis of blood in dilated hypokinetic cardiac chambers and in peripheral blood vessels and possibly due to increased activation of procoagulant factors.[304] Even so, there are no large-scale data to support the routine use of anticoagulants in a HFrEF patient without having AF, a prior thromboembolic event, or a cardioembolic source (class III). However, a class I recommendation does exist for its use in patients with HF who have permanent, persistent, or paroxysmal AF and an additional risk factor for cardiometabolic stroke, including a history of hypertension, diabetes, previous stroke or transient ischemic attack, or age of at least 75 years. The topic is reviewed by Gheorghiade and coworkers.[421]

Other Pharmacologic Therapies for Chronic Heart Failure Management

Vasopressin Receptor Antagonists

Arginine vasopressin (AVP) has been elucidated as one of the mediators involved in the progression of HF. Patients with HF have higher

TABLE 11.21 Loop Diuretics

Drug	*Equivalent Doses*	*Initial Dose*	*Maximal Dose*	*Onset (Intravenous)*	*Diuresis Peak*	*Duration*
Furosemide	40 mg	10–40 mg qd	240 mg bid	10–20 min	90 min	4–5 h
Bumetanide	1 mg	0.5–1.0 mg qd	10 mg qd	Within 10 min	75–95 min	4–5 h
Torsemide	20 mg	50 mg qd	200 mg bid	10 min	60 min	6–8 h
Ethacrynic acid	25 mg	100 mg bid	100 mg bid	10–20 min	90 min	4–5 h

levels of AVP than controls, and this has been shown to be a marker of increased cardiac-related mortality.[422]

The effects of AVP include vasoconstriction through the V_1 receptor and antidiuresis through the V_2 receptor in the kidney. The water retention that occurs in chronic HF due to the activation of the RAS is treated with diuretics, but diuretics are associated with numerous adverse effects (eg, electrolyte imbalance, renal insufficiency, RAS activation). Due their ability to decrease water retention without activating the RAS, vasopressin receptor antagonists are being investigated for use in patients with HF.

Studies of patients with stage C HF comparing Tolvaptan with placebo have revealed the drug's ability to decrease water retention, correct hyponatremia, improve patient-assessed clinical status, and decrease PCWP without causing renal injury (ie, EVEREST and ECLIPSE trials). Vasopressin receptor antagonists may ultimately replace the use of diuretics in patients with HF, but further studies are necessary to determine whether this class of medication can improve outcomes for HF patients.

Anticytokines

In addition to the RAAS and the SNS, other vasoactive mediators and growth factors have been implicated in the progression of HF. Production of inflammatory cytokines (eg, tumor necrosis factor-α [TNF-α], interleukin-6 [IL-6]) is increased in HF patients, and increased blood concentrations of these cytokines have been associated with poor short-term and long-term prognoses.[423]

The value of anti-TNF-α therapy with Etanercept, a TNF-α receptor fusion protein, has been studied in two trials: Randomized Etanercept North American Strategy to Study Antagonism of Cytokines (RENAISSANCE) and Research into Etanercept: Cytokine Antagonism in Ventricular Dysfunction (RECOVER) and in the combined analysis of the Randomized Etanercept Worldwide Evaluation (RENEWAL). However, the trials were terminated prematurely after an interim data analysis showed a lack of benefit. Etanercept had no effect on clinical status and had no effect on the death or HF-related hospitalization end points.[424] Inhibition of anti-proinflammatory cytokines remains only a potential therapy for HF.

Endothelin Receptor Antagonists

The endothelin system may contribute to the progression of HF. Plasma levels of endothelin 1 (ET1) are increased in patients with HF.[425] ET1 produces vasoconstriction of the systemic, renal, pulmonary, and coronary vasculature; remodeling of the myocardium (including myocardial and vascular fibrosis); and neurohormonal activation, and it has proarrhythmic and negative inotropic effects.

After the central role of endothelin in pathogenesis and the beneficial effect of endothelin antagonists in treating experimental HF were defined, clinical studies with endothelin antagonists began.[426,427] The clinical efficacy of endothelin receptor-antagonists (eg, bosentan, enrasentan, darusentan) has been investigated in four clinical trials: REACH-1, ENCOR, ENABLE, and EARTH.[428–430] However, in none of these trials was there a significant difference between endothelin receptor antagonists and placebo with regard to clinical status, all-cause mortality, or HF-related hospitalizations.

Vasopeptidase Inhibitors

In opposition to the endogenous vasoconstrictor systems (ie, Ang II, the adrenergic system, ET1, vasopressin, and aldosterone) are the endogenous vasodilator systems, including NO, endothelium-derived hyperpolarizing factor, prostaglandins, adrenomedullin, and natriuretic peptides. These vasodilating mediators reduce BP, improve sodium and water excretion, reduce growth and fibrosis, inhibit coagulation, and reduce inflammation. However, there is an imbalance that favors vasoconstriction in HF.

The concept of neutral endopeptidase inhibition (ie, major enzymatic pathway for degradation of natriuretic peptides) for the treatment of chronic HF led to two large-scale RCTs, OCTAVE and OVERTURE, that compared the use of omapatrilat with ACE inhibition.[431,432] Although there was no statistically significant advantage with omapatrilat regarding total mortality, the secondary end point of cardiovascular death or HF-related hospitalization was reduced in the omapatrilat group (HR = 0.91; 95% CI, 0.82 to 0.98; P = .012). Concerns regarding the side effect profile of omapatrilat (eg, angioedema), limit its use in HF treatment.

I_F Current Inhibitors

The funny current (I_F current) is the most important current for SA node depolarization. The inward current affects Na^+ and K^+ channels and has a significant effect on heart rate. Ivabradine is the first I_F current inhibitor available for oral use (usually 5 mg daily) in the United States. It has been approved by the FDA for treatment of angina pectoris as an adjunct to other drugs for patients with an increased heart rate, for those who have a contraindication to β-receptor blockers, and for CHF in patients with an increased heart rate.

In a study of 10,917 patients with CAD, EF less than 40%, and a heart rate greater than 70 beats/min, ivabradine administration compared with placebo did not impact mortality but did reduce the incidence of coronary events, MI, and the need for coronary revascularization.[433] In patients with stable coronary disease without HF but an increased heart rate, ivabradine did not reduce mortality or the incidence of nonfatal MI.[434] The drug appears to be well tolerated in patients taking β-blockers for angina pectoris. In patients with coronary stents or coronary revascularization who continue to have angina after the procedure, ivabradine appears to reduce angina episodes due to exercise.

Ivabradine appears to be very effective in patients with HF. In a study of 6558 patients with an EF less than 35% and heart rate greater than 70 beats/min, the drug compared with placebo significantly reduced the incidence of HF death and the readmission rate for HF treatment.[435] All patients were also receiving β-blocker treatment for HF. The most impressive responses were in patients who had the fastest heart rates. Heart rate is a marker for a bad outcome in HF, and reducing the heart rate appears to improve outcomes, likely by reducing ventricular loading conditions.[436] This results in reduced end-systolic and end-diastolic volumes and improved EF.[437]

The drug is well tolerated, with very few episodes of bradycardia or hypotension even when combined with β-blockers. The drug is contraindicated in patients requiring calcium channel blockers, patients with sick sinus syndrome or symptomatic bradycardia, and patients taking drugs that inhibit the CYP3A4 enzymes such as ketoconazole, macrolide antibiotics, cyclosporin, gestodene, and antiretroviral drugs. Heart block, dizziness, and headaches have been reported. The QT interval is not directly prolonged but may lengthen with slowing of the heart rate. An unusual side effect is visual brightness without field cuts, which occurs in a small number of patients and is totally reversible after the drug is discontinued.

Stem Cell Therapy

Stem cell therapy is a potential treatment for HF. Stem cell therapy has shown promise in the treatment for ischemic heart disease in the laboratory and in small clinical studies.[438,439] Autologous bone marrow and peripheral blood stem cells transplanted in patients with acute MI improved cardiac function.[440,441] Although fewer randomized trials of transplantation of blood- or bone marrow–derived stem cells have been performed in the setting of chronic CAD and chronic HF,[442–445] the results show promise, including improvements in regional and global LV function, perfusion, and relief of angina pectoris.[446,447]

The C-CURE clinical trial assessed cardiopoietic stem cell intervention as an adjunct to chronic HF management. This was the first application of guided stem cells for targeted regeneration of a failing organ. Lineage priming of bone marrow stem cells from patients with ischemic HF was shown to be feasible. Administration of derived

autologous cardiopoietic stem cells into the hibernating myocardium of patients with HF was safe. The study also demonstrated consistent improvements in LVEF at 6 months by cardiopoietic stem cell therapy compared with standard of care.[448] Applying findings to clinical care will require additional clinical trials.

Diet and Exercise Therapy

Guidelines highlight patient- and family-centered education on self-care management of HFrEF. Included are dietary restrictions and exercise. Sodium restriction remains important in delaying the progression to HF. The current guidelines recommend a sodium intake of 1500 mg/day by patients with stage A or B disease, but insufficient evidence exists for recommended sodium level restrictions for patients with stages C and D. Nonetheless, the guidelines recommend that some degree of restriction to less than 3000 mg daily is reasonable because most people consume at least 4000 mg of sodium daily.

Regular physical activity is recommended for HF patients who can participate. Cardiac rehabilitation is deemed to be useful for patients with stable HFrEF.[304]

Pharmacologic Treatment of Heart Failure With Preserved Ejection Fraction or Diastolic Heart Failure

Abnormal diastolic ventricular function is a common cause of clinical HF. The incidence of HF with a normal or near-normal EF (≥50%) includes up to 50% of the general HF population.[305] The risk of HFpEF increases with age, approaching 50% among patients older than 70 years.[449] HFpEF is also more common in women and in those with multiple comorbidities, such as hypertension, diabetes, vasculopathy, renal disease, AF, and metabolic syndrome.[450]

In terms of morbidity and mortality, the prognosis associated with the diagnosis of HFpEF is similar to that of HFrEF.[451–454] Because this syndrome carries substantial morbidity (eg, exercise intolerance, poor quality of life, frequent hospitalizations) and reduced survival and results in substantial annual health care expenditures, pharmacotherapy for HFpEF represents one of the current frontiers of clinical cardiovascular medicine.

In contrast to the large, randomized trials that led to the treatment guidelines for HFrEF, the randomized, double-blind, placebo-controlled, multicenter trials enrolling patients with diastolic HF have resulted in neutral results for primary outcomes. Consequently, the treatment of HFpEF remains empiric.

The general pharmacologic approach to treating HFpEF has three main components. First, treatment should reduce symptoms, primarily by lowering pulmonary venous pressure during rest and exercise by carefully reducing LV volume and maintaining atrial-ventricular synchrony or tachycardia control. Second, treatment should target the underlying diseases that cause HFpEF. Ventricular remodeling (eg, myocardial hypertrophy, fibrosis) should be reversed by controlling hypertension, treating ischemia, and controlling glycemia in diabetic patients. Third, treatment should attempt to target the underlying mechanisms that are altered by the disease processes. However, due to our lack of understanding of the pathogenesis of HFpEF, the third goal remains elusive.

Many of the drugs used to treat HFrEF are also used to treat HFpEF. However, the reason for their use and the doses used may be different for diastolic HF. For instance, in diastolic HF, β-blockers may be used to prevent tachycardia and thereby prolong diastolic filling and reduce left atrial pressure[455]; whereas in systolic HF, β-blockers (eg, carvedilol) are used to reverse heart remodeling. Metoprolol-CR/XL may be a better β-blocker choice than carvedilol for HFpEF because an excessively low a BP (as a consequence of carvedilol) may be detrimental for the diastolic HF patient. However, because β-blocker therapy for the treatment of HFpEF has been challenged by exercise metabolic testing data indicating that impaired chronotropic response to exercise contributes to observed exercise intolerance,[456] it is less likely to be chosen as a stand-alone treatment.

Similarly, doses of diuretics or venodilators such as nitrates are much smaller than for HFrEF because the patient who has LV diastolic dysfunction with a small, stiff left ventricle is particularly susceptible to excessive preload reduction, which can lead to LV underfilling, a fall in CO, and hypotension. In patients with severe LV hypertrophy due to hypertension or hypertrophic cardiomyopathy, excessive preload reduction can also create subaortic outflow obstruction. Careful attention is required for symptoms of ventricular underfilling such as weakness, dizziness, near-syncope, and syncope.

Although calcium channel blockers are not a part of the armamentarium for HFrEF patients, they may be beneficial in HFpEF through effects on heart rate, BP control, and purported benefits on lusitropic function. With the exception of rate control in chronic AF, digoxin is not recommended for HFpEF.

Class I recommendations for HFpEF patients include control of systolic and diastolic BP in accordance with clinical practice guidelines (see "Pharmacologic Management of Hypertension") and use of diuretics to relieve symptoms from pressure overload.[304] β-Blockers and ACE inhibitors or ARBs are considered reasonable to use to control BP. Coronary revascularization is considered reasonable in patients with CAD in whom angina or demonstrable myocardial ischemia has an adverse effect on symptomatic HFpEF despite optimal medical therapy. AF is managed according to clinical practice guidelines. The use of an ARB can be considered for these patients to decrease hospitalizations. The routine use of nutritional supplements is not recommended for HFpEF patients.[304]

Trials of Treatment for Heart Failure With Preserved Ejection Fraction

The pharmacologic trials for HFpEF have focused primarily on neurohormonal activation as the underlying pathophysiologic mechanism for the disease process (Table 11.22). However, unlike the benefits observed from blockade of the RAAS and SNS in HFrEF patients, results from the HFpEF trials suggest that neurohormonal stimulation may not be as sustained in patients with symptomatic diastolic dysfunction.

It has been proposed that HFpEF is an integrative physiology disorder for which hemodynamics and the control of blood volume and its distribution are more important than, for instance, the RAAS.[450] Increasingly, data show that skeletal muscle abnormalities may be critical in the disease process.[457–459] Future treatment that integrates multiple targets, such as neuromodulators or pleomorphic drugs with antiinflammatory actions (eg, HMG CoA reductase inhibitors) and exercise training,[460] may prove to be more effective than RAAS blockade in the management of HFpEF. Even so, we review some of the findings from the larger HFpEF trials that have focused on neurohormonal antagonists.

Of all the three large RCTs of ACE inhibitors or ARBs that studied HFpEF, only the CHARM-preserved study found marginal benefit for candesartan in reducing HF hospitalizations (HR = 0.86; 95% CI, 0.74 to 1.0; $P = .051$) over 3 years of follow-up, and none showed benefit for primary end points. In a study by Lund and associates, a modest reduction in the 1-year mortality rate for ACE inhibitor and ARB therapy (propensity score-adjusted HR = 0.90; 95% CI, 0.85 to 0.96; $P < .001$) was found among 16,216 HFpEF community dwellers who were taking ACE inhibitors or ARBs. The mortality reduction was observed particularly in those with an LVEF of 40% to 49%.[461]

The ALDO-DHF study tested the impact of an aldosterone antagonist, spironolactone, in HFpEF, with the primary end points of improved diastolic function and exercise capacity.[462] After 12 months of treatment, spironolactone reduced LV mass and the mitral E/e′ ratio (ratio of mitral inflow and annular early diastolic velocities), although these favorable echocardiographic findings were somewhat attenuated after adjusting for reductions in BP. There was no improvement in the 6-minute walk distance, nor did participants report improvements in quality of life.

TABLE 11.22 Trials of Interventions for Heart Failure With Preserved Ejection Fraction

	Trials							
Parameter	*Japanese DHF*	*ELANDD*	*I-PRESERVE*	*DIG-PEF*	*ALDO-DHF*	*RAAM-PEF*	*RELAX*	*TOPCAT*

From Sharma K, Kass DA. Heart failure with preserved ejection fraction: mechanisms, clinical features, and therapies. *Circ Res.* 2014;115:79.

In a propensity-matched analysis of hospitalized, older HFpEF patients from the Organized Program to Initiate Lifesaving Treatments in Hospitalized Patients with Heart Failure (OPTIMIZE) study, aldosterone antagonists had no effect on all-cause mortality or hospitalization.[463] Moreover, in the large Treatment of Preserved Cardiac Function with Aldosterone Antagonist (TOPCAT) study[464] involving 3445 participants, the primary end point (ie, cardiovascular mortality, aborted cardiac arrest, or hospitalization for HF) was not met. Similar to CHARM-preserved, there was a small but significant decline in hospitalizations.

Given the neutral outcomes from the RAAS antagonist trials, efforts to identify key pathophysiologic perturbations and novel targets in HFpEF continue. For example, the ARNI LCZ696 has been tested for safety and efficacy in HFpEF patients. Neprilysin inhibitors inhibit the breakdown of natriuretic peptides and help to promote myocardial relaxation, diuresis, natriuresis, and modest vasodilation. Prospective comparison of Angiotensin Receptor-neprilysin inhibitor with ARB on Management of Heart Failure (PARAMOUNT) was a phase 2, randomized, double-blind trial that enrolled 301 patients with NYHA class II or III HF, LVEF of 45% or higher, and an NT-pro-BNP level of more than 400 pg/mL.[465] Compared with valsartan alone, patients randomized to LCZ696 had significantly lower NT-pro-BNP levels and at 36 weeks showed decreased left atrial size and a trend toward improved functional class. LCZ696 also appears to reduce TNF-α levels, which correlates with improvements in the cardiac features of HFpEF.[466] The therapeutic potential for ARNIs in the treatment of HFpEF remains promising.

Another pharmacologic intervention tested for HFpEF is PDE5 inhibition. PDE5 metabolizes NO and natriuretic peptide generated cGMP. Because PDE5 is activated in HFpEF, it is reasonable to suspect that it may limit the beneficial NO and natriuretic peptide actions in the heart, vasculature, and kidney.

Redfield and colleagues randomized 216 HFpEF patients to the PDE5 inhibitor sildenafil or placebo in the PhosphodiesterRase-5 Inhibition to Improve Clinical Status and Exercise Capacity in Diastolic Heart Failure (RELAX) study to determine whether exercise capacity (ie, primary end point) improved after 24 weeks of chronic treatment.[467] The study result was neutral, reporting no benefit in the primary end point and no improvement in the 6-minute walk distance or quality of life compared with placebo. Sildenafil was associated with modest worsening of renal function and increases in neurohormonal levels.

Exercise as Treatment for Heart Failure With Preserved Ejection Fraction

Because exercise intolerance is a major symptom in HFpEF patients, interest has focused on the role of exercise training as a treatment modality. In a study involving 53 HFPEF patients randomized to 16 weeks (three times per week) of moderate-intensity aerobic exercise or intention control, Kitzman and coworkers observed increased peak exercise oxygen uptake, 6-minute walk distance, and quality of life scores in the treatment arm.[468] Similar findings were seen in a multicenter study of 40 HFpEF patients randomized to a 32-session, 3-month exercise protocol involving aerobic and resistance training.[469] Whether exercise training improves survival of HFpEF patients remains to be determined.

Acute Heart Failure With Preserved Ejection Fraction

Except in the setting of acute diastolic HF, positive inotropic and chronotropic agents should be avoided because they may worsen diastolic function by increasing contractile force and heart rate or by increasing calcium concentrations in diastole. However, in the short-term management of acute diastolic dysfunction or HF (eg, after cardiopulmonary bypass [CPB]), β-adrenergic agonists (eg, epinephrine) and phosphodiesterase inhibitors (eg, milrinone) enhance calcium sequestration by the SR and thereby promote a more rapid and complete myocardial relaxation between beats.[470,471]

Serelaxin is a synthetic version of the naturally occurring hormone relaxin, which occurs in small amounts in men and women. It is produced in large quantities during pregnancy, in which it is thought to improve blood vessel, kidney, and heart function. The beneficial effects in pregnancy provided the basis for studying serelaxin in patients with HF, in which there are abnormalities in these functions. RELAX-AHF was a randomized, double-blind, controlled trial that evaluated the effects of a 48-hour intravenous infusion of serelaxin on clinical outcomes in 1161 patients admitted to hospital for acute HF. Serelaxin induced similar dyspnea relief in HFpEF and HFrEF patients at day 5 but was more effective in the HFpEF group in the first 24 hours. There were no differences between HFpEF and HFrEF patients in the effect of serelaxin on the secondary end points. Serelaxin had similar benefits on mortality for patients with HFpEF or HFrEF.[472]

Management of Acute Exacerbations of Chronic Heart Failure

Despite good medical management, patients with chronic HF may experience episodes of pulmonary edema or other signs of acute volume overload.[473] Other patients may experience exacerbations of HF associated with acute myocardial ischemia or infarction, hypertension, arrhythmia, worsening valvular dysfunction, infections (including myocarditis), or failure to maintain an established drug or dietary regimen. These patients may require hospitalization for intensive management if initial treatments fail to relieve their symptoms.

Fonarow and associates[474] described a risk stratification system for in-hospital mortality among acutely decompensated hospitalized HF patients using data from a national registry. Low-, intermediate-, and high-risk patients with mortality rates ranging from 2.1% to 21.9% were identified using blood urea nitrogen (BUN), creatinine, and systolic BP levels on admission. These patients require all of the standard medications outlined in previous sections, need more intensive diuretic therapy, and may require infusions of vasodilators or positive inotropic drugs.

Vasodilators

In the absence of systemic hypotension, intravenous vasodilators may be used to treat dyspnea in patients with decompensated chronic HF. Vasodilators reduce ventricular filling pressures and SVR while increasing SV and CO. NTG is commonly used for this purpose and has been studied in numerous clinical trials.[473] It is primarily a venodilator, reducing preload and improving symptoms of pulmonary vascular congestion. It is often initially effective at relatively small doses (20–40 μg/min) but frequently requires progressively increasing doses to counteract tachyphylaxis. NTG is associated with dose-dependent arterial hypotension.[475]

Nitroprusside acts as a systemic venodilator and arteriodilator and a pulmonary vasodilator. Efficacy data are limited, and administration of nitroprusside requires frequent BP monitoring, preferably with an arterial line, because of its potential for producing marked hypotension.[304] Nitroprusside therapy also carries a small risk of thiocyanate toxicity, particularly in the setting of renal insufficiency.

Nesiritide

BNP is a 32–amino acid peptide that is mainly secreted from the cardiac ventricles.[476] In normal healthy subjects, BNP concentrations in blood increase with age and are greater in women than men. Physiologically, BNP functions as a natriuretic and diuretic. It also serves as a counterregulatory hormone to Ang II, norepinephrine, and endothelin by decreasing the synthesis of these agents and by direct vasodilation.

As the clinical severity of HF increases, the concentrations of BNP in blood also increase.[476] Measurements of BNP in blood have been used to evaluate new-onset dyspnea to distinguish between lung disease and HF. Because BNP concentrations in blood increase with decreasing LVEF, measurements of this mediator have been used to estimate prognosis. BNP concentrations decline in response to therapy with ACE inhibitors, Ang II antagonists, and aldosterone antagonists.

Nesiritide, a recombinant BNP, was approved in 2001 and is indicated for patients with acute HF and dyspnea with minimal activity. Nesiritide produces arterial and venous dilation through increasing cGMP levels. Nesiritide does not increase heart rate and has no effect on cardiac inotropy. It has a rapid onset of action and a short elimination half-life (ie, 15 minutes). Initial studies showed that nesiritide reduced dyspnea associated with acute decompensated HF similar to NTG but without development of acute tolerance and with fewer adverse events than NTG.[477,478] Compared with dobutamine, nesiritide was associated with fewer instances of ventricular tachycardia (VT) or cardiac arrest.[479]

In the ADHERE registry of more than 65,000 episodes of acute decompensated HF, treatment with nesiritide or a vasodilator was associated with a 0.59 odds ratio for mortality compared with milrinone or dobutamine.[480] However, subsequent metaanalyses suggested that nesiritide may not offer a compelling safety advantage but instead may be associated with an increased incidence of adverse side effects, including renal failure and death, when administered to patients with acutely decompensated chronic HF.[481,482] These data prompted the FDA to convene an expert panel that made several recommendations, including that nesiritide be used only for hospitalized patients with acute decompensated HF and that the agent not be used to enhance diuresis or protect the kidneys.[483]

Designed to examine efficacy and safety concerns, the ASCEND-HF trial was a multicenter, randomized, double-blind, placebo-controlled trial of nesiritide in addition to standard care for acute HF. Nesiritide had a small but statistically insignificant effect on dyspnea at 6 and 24 hours. It neither increased nor decreased mortality or rehospitalization. It was not associated with worsening renal function. It was associated with increased rates of hypotension.[484] Overall, nesiritide and the other nitrovasodilators may be considered as adjuvants to diuretic therapy to reduce dyspnea in patients with acute HF without systemic hypotension.

Inotropes

Positive inotropic drugs, principally dobutamine or milrinone, have long been used to treat decompensated HF despite the lack of data showing an outcome benefit for their use.[473] In the past, some chronic HF patients received intermittent infusions of positive inotropic drugs as part of their maintenance therapy. Small studies consistently demonstrate improved hemodynamic values and reduced symptoms after administration of these agents to patients with HF. Studies comparing dobutamine with milrinone for advanced decompensated HF showed large differences in drug costs, favoring dobutamine, and only small hemodynamic differences, favoring milrinone.[485]

Nevertheless, placebo-controlled studies suggest there may be no role for discretionary administration of positive inotropes to patients with chronic HF.[486] In one study, 951 hospitalized patients with decompensated chronic HF who did not require intravenous inotropic support were assigned to receive a 48-hour infusion of milrinone or saline. All patients received ACE inhibitors and diuretics as deemed necessary. Total hospital days did not differ between groups, but those receiving milrinone were significantly more likely to require intervention for hypotension or to have new atrial arrhythmias. A subanalysis of the results found that patients suffering from ischemic cardiomyopathy were particularly subject to adverse events from milrinone (42% incidence of death or rehospitalization vs 36% for placebo).[487]

Positive inotropic drug support can be recommended only when there is no alternative. Dobutamine and milrinone continue to be used to treat low CO in selected patients with decompensated HF.

Alternative Therapies

When drug treatment proves unsuccessful, HF patients may require invasive therapy, including ultrafiltration for diuresis, ventricular assist devices, biventricular pacing, coronary bypass with or without surgical remodeling, or cardiac orthotopic transplantation. These treatment options are beyond the scope of this chapter[304,488] (see Chapters 4, 5, 20, 25, 28, 32, and 33).

Low-Output Syndrome

Acute HF is a frequent concern of the cardiac anesthesiologist, particularly at the time of separation from CPB. New-onset ventricular dysfunction with a low CO after aortic clamping and reperfusion is a condition with more pathophysiologic similarity to cardiogenic shock than to chronic HF, and it is typically treated with positive inotropic drugs, vasopressors (or vasodilators) if needed, or mechanical assistance.[489,490] The latter more commonly takes the form of intraaortic balloon counterpulsation and less commonly includes one of the several available ventricular assist devices (see Chapters 28, 33, and 36).

Causes

Most patients undergoing cardiac surgery with CPB experience a temporary decline in ventricular function, with a recovery to normal function in roughly 24 hours. Pathophysiologic explanations must acknowledge the usually temporary nature of the low-output syndrome after CPB. It likely results from one of three processes, all related to inadequate oxygen delivery to the myocardium: acute ischemia, hibernation, or stunning. All three processes can be expected to improve with adequate revascularization and moderate doses of positive inotropic drugs, consistent with the typical progress of the cardiac surgery patient. All three processes can be expected to be more troublesome in patients with preexisting chronic HF, pulmonary hypertension, or arrhythmias.

Risk Factors for Low-Output Syndrome After Cardiopulmonary Bypass

The need for inotropic drug support after CPB can often be anticipated based on data available in the preoperative medical history, physical examination, and imaging studies. In a series of consecutive patients undergoing elective CABG, it was observed that increasing age, decreasing LVEF, female sex, cardiac enlargement on the chest radiograph, and prolonged duration of CPB were associated with an increased likelihood that the patient would be receiving positive inotropic drugs on arrival in the intensive care unit.[491] Similarly, in a study of patients undergoing mitral valve surgery, independent predictors of low-CO syndrome were urgency of the case, LVEF less than 40%, NYHA class IV, a body surface area of 1.7 m^2 or less, ischemic mitral valve pathology, and CPB time.[492]

Another study of patients undergoing aortic valve surgery identified renal failure, LVEF less than 40%, shock, female gender, and increasing age as independent risk factors.[493] Data from an intraoperative transesophageal echocardiographic examination may also help identify patients who are more likely to need inotropic support. Patients with a decreased wall motion score index or those with moderate or severe mitral regurgitation may need inotropic support.[494]

Drugs for Treating Low-Output Syndrome

Although all positive inotropic drugs increase the strength of contraction in noninfarcted myocardium, the mechanisms of action are different. The drugs can be divided into those that increase cAMP (directly or indirectly) as their mechanism of action and those that do not. The agents that do not depend on cAMP form a diverse group, including cardiac glycosides, calcium salts, calcium sensitizers, and thyroid hormone. In contrast to chronic HF, cardiac glycosides are not used for this indication due to their limited efficacy and narrow margin of safety. Calcium salts continue to be administered for ionized hypocalcemia and hyperkalemia, common occurrences during and after cardiac surgery. Increased Ca^{2+} concentrations in buffer solutions bathing cardiac muscle in vitro unquestionably increase inotropy. However, despite long-standing contrary opinions, studies suggest that doses of $CaCl_2$ of 5 to 10 mg/kg do not increase cardiac index in patients recovering from cardiac surgery.[495,496]

Levosimendan is an inodilator that increases cardiac contractility by calcium sensitization of troponin C. Because levosimendan does not increase the intracellular Ca^{2+} concentration, it does not impair

diastolic cardiac function. Peripheral and coronary vasodilatation due to its effects on ATP-sensitive K^+ channels provides afterload reduction and improved coronary perfusion. These combined effects result in improvement of myocardial contractility without an increase in $M\dot{V}O_2$.

Another attractive feature of this inotropic agent is that its effects are not diminished by β-blockade.[497] It is indicated for the short-term treatment of severe chronic HF when conventional therapy is not sufficient, but it is being increasingly studied in cardiac surgical settings with favorable results.[498]

There are conflicting reports regarding the effect of levosimendan on mortality rates for patients with acutely decompensated HF. Four major double-blind, randomized clinical trials have evaluated the ability of levosimendan to decrease mortality rates for these patients. Only two of the trials (ie, LIDO and RUSSLAN studies) have shown a clear decrease in mortality rates compared with a placebo or dobutamine.[497,499] In the REVIVE II study, there was a statistically insignificant higher mortality rate for the levosimendan group compared with placebo. In the SURVIVE study, there was no significant difference in survival between levosimendan and dobutamine.[500] In a metaanalysis, levosimendan significantly reduced mortality rates in cardiology and cardiac surgery settings compared with dobutamine and placebo.[501]

Levosimendan is an acceptable choice for patients with acutely decompensated HF after hypovolemia has been corrected. Suggested dosing includes an infusion with or without a loading dose of 6 to 12 μg/kg for 10 minutes, followed by 0.005 to 2 μg/kg per minute for no more than 24 hours. Loading doses are not recommended for patients with low-normal BP (eg, SBP <100 mm Hg). Without a loading dose, maximal effect of the drug occurs after 4 hours. Infusions should not continue for longer than 24 hours due to levosimendan's active metabolites, which can accumulate and produce refractory hypotension and tachycardia.

Intravenous thyroid hormone (liothyronine [T_3]) has been studied extensively as a positive inotrope in cardiac surgery. Multiple studies support the existence of euthyroid sick syndrome with persistent reduced concentrations of T_3 in blood after cardiac surgery in children and adults.[495] Data suggest that after ischemia and reperfusion, T_3 increases inotropy faster than and as potently as isoproterenol.[502] Nevertheless, RCTs have failed to show a clinical benefit for T_3 after CABG.[503,504]

cAMP-dependent agents are the mainstays of positive inotropic drug therapy after cardiac surgery. There are two main classes of agents: PDE inhibitors and β-adrenergic receptor agonists. PDEs in clinical use around the world include enoximone, inamrinone, milrinone, olprinone, and piroximone. Comparisons among the agents have failed to demonstrate important hemodynamic differences.[505] Reported differences are related to pharmacokinetics and rare side effects, typically observed with chronic oral administrations during clinical trials.

All members of the class produce rapid increases in contractile function and CO and decreases in SVR. The effect on BP depends on the pretreatment state of hydration and hemodynamics, but the typical response is a small decrease in BP. There is no effect on heart rate or a small increase.

Inamrinone and milrinone are effective, first-line agents in patients with reduced preoperative LV function.[506,507] One of the few studies in which outcome was assessed after use of positive inotropic agents confirmed that prophylactic use of milrinone in children undergoing correction of congenital heart disease improved outcomes in terms of length of stay and incidence of low-output syndrome.[508] Milrinone, the most commonly used member of the class, is most often dosed at a 50 μg/kg loading dose and 0.5 μg/kg per minute maintenance infusion. It is often given in combination with a β-adrenergic receptor agonist.

Among the many β-adrenergic receptor agonists, the agents most often given to patients recovering from cardiac surgery are dopamine, dobutamine, and epinephrine. Dopamine has long been assumed to have dose-defined receptor specificity. At small doses (0.5–3 μg/kg per minute), it is assumed to have an effect mostly on dopaminergic receptors. At intermediate doses, β-adrenergic effects are said to predominate, and at doses of 10 μg/kg per minute or greater, β-adrenergic receptor effects predominate. Nevertheless, the relationship between dose and blood concentration is poorly predictable, even in normal volunteers, as was shown by MacGregor and colleagues.[509] This makes it unlikely that the dose-response relationship is as consistent as has been described in textbooks for the past 20 years. Moreover, dopamine is a relatively weak inotrope that has a predominant effect on heart rate rather than on SV.[510]

Dobutamine is a selective β-adrenergic receptor agonist. Most studies suggest that it causes less tachycardia and hypotension than isoproterenol.[511,512] It has been frequently compared with dopamine, in which dobutamine's greater tendency for pulmonary and systemic vasodilation is evident.[510] Dobutamine has a predominant effect on heart rate compared with SV, and as the dose is increased more than 10 μg/kg per minute there are further increases in heart rate without changes in SV.[513]

Epinephrine is a powerful adrenergic agonist, and like dopamine, it demonstrates different effects depending on the dose. At small doses (10–30 ng/kg per minute), despite an almost pure β-adrenergic receptor stimulus, there is almost no increase in heart rate.[496,514] Clinicians have long assumed that epinephrine increases heart rate more than dobutamine administered at comparable doses. In patients recovering from cardiac surgery, the opposite is true; dobutamine increases heart rate more than epinephrine.[514]

Other β-adrenergic agonists are used in specific circumstances. For example, isoproterenol is often used after cardiac transplantation to exploit its powerful chronotropy and after correction of congenital heart defects to exploit its pulmonary vasodilatory effects.[515] Norepinephrine is used to counteract profound vasodilation.[516] Outside of North America, dopexamine, a weak dopaminergic and β-agonist with a pronounced tendency for tachycardia, is sometimes used.[517]

Left Atrial Drug Administration

Based on an appeal to common sense, clinicians faced with severe cardiac depression in a severely ill patient undergoing cardiac surgery sometimes administered potentially vasoconstricting agents (eg, epinephrine, norepinephrine) into the left heart circulation through a left atrial catheter to avoid adverse effects on the pulmonary vascular resistance. Fullerton and colleagues confirmed the usefulness of this approach by showing that left atrial administration of epinephrine produced greater CO and reduced pulmonary artery pressure more than the same dose of epinephrine administered into the right atrium.[518]

Assist Devices

A small fraction of patients undergoing cardiac surgery develop acute HF refractory to drug treatment. For these patients, available options include intraaortic balloon counterpulsation, extracorporeal membrane oxygenation (or extracorporeal carbon dioxide elimination), and right- or left-heart assist devices as destination therapy or as a bridge to transplantation[488] (see Chapters 25, 28, 33, and 36).

Pharmacotherapy for Cardiac Arrhythmias

Perhaps the most widely used electrophysiologic and pharmacologic classification of antiarrhythmic drugs is that proposed by Vaughan Williams (Table 11.23).[519] There is, however, substantial overlap in pharmacologic and electrophysiologic effects of specific agents among the classes, and the linkage between observed electrophysiologic effects and the clinical antiarrhythmic effect is often tenuous. Likewise, especially in class I, there may be considerable diversity within a single class. Other antiarrhythmic drugs are not included in this classification such as digitalis, the classic antiarrhythmic for chronic AF, or adenosine, a drug with potent antiarrhythmic effects mediated by a specific class of membrane receptors.[520,521]

The Cardiac Arrhythmia Suppression Trial (CAST) questions the appropriateness of treating arrhythmias with antiarrhythmic agents in

TABLE 11.23 Classification of Antiarrhythmic Drugs

	Type of Antiarrhythmic Drug			
Effects	*I (Membrane Stabilizers)*	*II (β-Adrenergic Receptor Antagonists)*	*III (Drugs Prolonging Repolarization)*	*IV (Calcium Antagonists)*
Pharmacologic	Fast channel (Na^+) blockade	β-Adrenergic receptor blockade	Uncertain: possible interference with Na^+ and Ca^{2+} exchange	Decreased slow–channel calcium conductance
Electrophysiologic	Decreased rate of V_{max}	Decreased V_{max}, increased APD, increased ERP, and increased ERP:APD ratio	Increased APD, increased ERP, increased ERP:ADP ratio	Decreased slow–channel depolarization; decreased ADP

APD, Action potential duration; *ERP*, effective refractory period; V_{max}, maximal rate of depolarization.

TABLE 11.24 Subgroup of Class I Antiarrhythmic Drugs

	Subgroup		
Electrophysiologic Activity	*IA*	*IB*	*IC*
Phase 0	Decreased	Slight effect	Marked decrease
Depolarization	Prolonged	Slight effect	Slight effect
Conduction	Decreased	Slight effect	Markedly slowed
ERP	Increased	Slight effect	Slight prolongation
APD	Increased	Decreased	Slight effect
ERP/APD ratio	Increased	Decreased	Slight effect
QRS duration	Increased	No effect during sinus rhythm	Marked increase
Prototype drugs	Quinidine, procainamide, disopyramide, diphenylhydantoin	Lidocaine, mexiletine, tocainide	Lorcainide, encainide, flecainide, aprinidine

APD, Action potential duration; *ERP*, effective refractory period.

certain groups of patients.[522] The CAST study was designed to test the hypothesis that suppression of ventricular ectopy seen after MI reduces the subsequent incidence of sudden death. Patients were eligible for the study if they had ventricular ectopy without sustained VT after MI. The study required documented suppression of the ventricular ectopy with the class IC drugs encainide and flecainide. The primary study end points were death or cardiac arrest caused by arrhythmia.

After 22 months of enrollment (of a planned 36 months), the Data and Safety Monitoring Board recommended discontinuation of the encainide and flecainide limbs of the study because of apparent excess mortality in those two treatment groups. Among the 1498 patients assigned to the encainide and flecainide groups, there were 89 deaths (63 in the active drug subgroups and 26 in the placebo subgroups; $P < .0001$). The mechanism of excess mortality was thought to be precipitation of proarrhythmia due to facilitation of reentry, especially during ischemic episodes. After this study, the use of sodium channel blockers was not recommended, especially for low-risk patients after MI. Encainide is no longer available, but flecainide still is used for supraventricular tachyarrhythmias and documented life-threatening ventricular arrhythmias.

Although the class I and especially subclass IC agents are most commonly known for their proarrhythmic effects, the other classes are not devoid of this side effect. Bretylium initially causes the release of norepinephrine, and an increased incidence of ventricular arrhythmias often is seen when therapy is initiated. In one study, the rate of arrhythmias was significant when different doses of bretylium were used.[523] For the first week after initiation of sotalol, a nonspecific β-adrenergic blocker that is considered a class III arrhythmic agent, there is an increased incidence of torsades de pointes. The proarrhythmic effects appear to be increased in the setting of hypokalemia, bradycardia, CHF, and a history of sustained ventricular dysfunction (Box 11.6).[524]

Chronic antiarrhythmic therapy should be initiated only after careful evaluation of the risks and benefits of the intervention. The appropriate use of intravenous antiarrhythmic agents with sudden-onset arrhythmias is not clear. Life-threatening ventricular arrhythmias must be treated. Patients at low risk for arrhythmic events may not benefit from therapy, and as learned from CAST, mortality rates may increase with some of these agents. High-risk patients may be treated more safely in some cases by implantation of internal cardioverter-defibrillators.[525]

BOX 11.6 DRUGS THAT CAN PRODUCE TORSADES DE POINTES

- Amiodarone
- Disopyramide
- Dofetilide
- Ibutilide
- Procainamide
- Quinidine
- Sotalol

Class I Antiarrhythmic Drugs: Sodium Channel Blockers

Class I drugs inhibit the fast inward depolarizing current carried by sodium ions. Because of the diversity of other effects of the class I drugs, a subgroup of the class has been proposed[526] (Table 11.24). Whether the depression of fast inward current of the sodium channel produces the primary antiarrhythmic effect of all class I drugs is controversial. Other proposed mechanisms involve abolishing reentry by improving conduction in the reentry pathway. However, shortening the APD in ventricular pathways and improving conduction of premature impulses by shortening the refractory period of the action potential also can decrease the likelihood for reentry.[527–529]

Class IA Drugs

Quinidine

In addition to the electrophysiologic effects summarized in Table 11.25, quinidine decreases the slope of phase 4 diastolic depolarization at low concentrations and increases threshold potential at high concentrations.[530] Quinidine depresses cardiac contractility, which in combination with an indirect α-adrenergic blockade can reduce arterial pressure. This hypotensive effect is the principal limitation to intravenous administration of quinidine.

Electrocardiographic (ECG) effects of quinidine include an increase in the sinus rate, which is perhaps a reflex response to vasodilation

TABLE 11.25 Diastolic Heart Failure Treatments

Goal	*Management Strategy*	*Recommended Doses*
Reduce the Congestive State		
Prevent fluid retention and reduce blood pressure	Salt restriction Diuretics (avoid reductions in cardiac output) ACE inhibitors Angiotensin II receptor blockers	Sodium, <2 g/day Furosemide, 10–120 mg Hydrochlorothiazide, 12.5–25 mg Enalapril, 2.5–40 mg Lisinopril, 10–40 mg Candesartan, 4–32 mg Losartan, 25–100 mg
Target Underlying Cause		
Control hypertension (<130/80 mm Hg)	Antihypertensive agents	β-Blockers, ACE inhibitors, all receptor blockers: dose according to published guidelines
Restore sinus rhythm	Atrioventricular sequential pacing	—
Prevent tachycardia	β-Blockers, calcium channel blockers	Atenolol, 12.5–100 mg Metoprolol, 25–100 mg Diltiazem, 120–540 mg
Treat aortic stenosis	Aortic valve replacement	—
Target Underlying Mechanisms		
Promote regression of hypertrophy and prevent myocardial fibrosis	Renin-angiotensin axis blockade (theoretical)	Enalapril, 2.5–40 mg Lisinopril, 10–40 mg Captopril, 25–150 mg Candesartan, 4–32 mg Losartan, 50–100 mg Spironolactone, 25–75 mg Eplerenone, 25–50 mg

ACE, Angiotensin-converting enzyme.

and cardiac depression. Conduction through the AV node may be enhanced or depressed, or it may not change, depending on the interplay of the direct slowing effect and the anticholinergic effect of quinidine. Infranodal conduction is slowed, and at high concentrations, bundle branch block, complete AV block, or asystole may result. The QT interval possibly is prolonged by sympathetic activation.[531]

Clinically, quinidine is used primarily in oral form to treat atrial and ventricular arrhythmias. However, quinidine may substantially accelerate the ventricular response rate in AF or flutter. Its use in these conditions should be preceded by β-blockade or digitalization. Acceleration of ventricular response rate is a function of the direct slowing of the atrial rate produced by quinidine and its indirect anticholinergic effects. The decreased frequency of atrial depolarization allows a greater percentage of impulses to be conducted through the AV node to depolarize the His bundle.

Quinidine may be administered orally or intramuscularly. The gastrointestinal absorption of quinidine is good, and plasma levels peak 1 to 2 hours after oral administration. Quinidine has an elimination half-life of 6 to 7 hours. A dose every 6 or 8 hours is appropriate, although shortening the dosage interval may maintain a stable plasma concentration more effectively than increasing the dosage. Typical maintenance doses are 300 to 600 mg, and therapeutic plasma concentrations range from 2 to 6 μg/mL.[532] Quinidine gluconate (200 mg given intramuscularly) is the preferred dose.

Quinidine is 70% to 80% protein bound in plasma, with much of that caused by hemoglobin. Administration of quinidine substantially increases the plasma concentrations of digoxin, probably by releasing the glycoside from protein-binding sites.[533] Elimination of quinidine is primarily by hepatic metabolism (ie, hydroxylation), although about 20% is excreted unchanged by the kidney. Renal excretion is achieved by glomerular filtration and tubular secretion, and it depends on urinary pH; excretion is decreased up to 50% when urine is alkaline.[534]

The most serious toxic effect of quinidine is cardiac and is largely a function of its conduction effects. Monitoring the QRS duration and QT interval is a useful guide to therapy; a 50% increment in either should prompt a reduction in dose. Various degrees of conduction block at the atrial and ventricular levels may occur, including asystole. Quinidine syncope probably is related to a proarrhythmia produced by QT-interval prolongation and may not be dose related.[535] Symptoms of tinnitus, visual disturbance, and gastrointestinal irritation progressing to severe CNS symptoms (eg, headache, diplopia, photophobia, confusion, psychosis) are part of the spectrum of cinchonism produced by quinidine, by other cinchona alkaloids such as quinine, and by salicylates. Thrombocytopenia may occur with quinidine, and hypersensitivity to quinidine may appear as fever, anaphylaxis, or bronchospasm, which can be severe.

Procainamide

Electrophysiologic effects of procainamide include decreased maximal velocity (V_{max}) and amplitude during phase 0, decreased rate of phase 4 depolarization, and prolonged ERP and APD.[536] Clinically, procainamide prolongs conduction and increases the ERP in atrial and His-Purkinje portions of the conduction system, which may prolong PR interval and QRS complex durations, but the QT interval is lengthened less than with quinidine. As with quinidine, AV nodal ERP may be decreased by indirect anticholinergic side effects.

Procainamide is used to treat ventricular arrhythmias and to suppress atrial premature beats to prevent the occurrence of AF and atrial flutter. It has been useful for chronic suppression of premature ventricular contractions (PVCs), but it may be supplanted for this use by class IB drugs such as mexiletine. Quinidine and procainamide reduce the frequency of the short-coupling interval (<400 ms) PVCs and thereby reduce the frequency of VT or VF created by the R-on-T phenomenon.[537]

Administered intravenously, procainamide is an effective emergency treatment for ventricular arrhythmias, especially after lidocaine failure, but amiodarone has become a more popular drug for intravenous suppression of ventricular arrhythmias. Dosage is 100 mg, or approximately 1.5 mg/kg given at 5-minute intervals until the therapeutic effect is obtained or a total dose of 1 g or 15 mg/kg is given (Boxes 11.7 and 11.8). Arterial pressure and the electrocardiogram should be monitored continuously during loading and administration stopped if significant hypotension occurs or if the QRS complex is prolonged by 50% or more. Maintenance infusion rates are 2 to 6 mg/min to maintain therapeutic plasma concentrations of 4 to 8 μg/mL.[536]

Oral administration of procainamide has a 75% to 95% absorption rate, and plasma levels peak after 1 to 2 hours.[538] The elimination half-life of procainamide is 3 to 4 hours, and the oral dosage interval is similar. Sustained-release preparations are available. Oral dose requirements are on the order of 50 mg/kg per 24 hours or 400 to 600 mg every 3 to 4 hours.[539] Decreasing the dosage interval rather than increasing the dose may be a better method of producing a stable increase in plasma concentrations without creating peak levels that are toxic. Sustained-release forms of procainamide are available.

Procainamide has hepatic and renal routes of elimination, with each route approximately equal in magnitude. Hepatic metabolism occurs by acetylation and may be fast or slow in individual patients as a result of genetic variations.[540] The primary metabolite, *N*-acetylprocainamide, has antiarrhythmic and toxic side effects, and it is excreted almost entirely by the kidney.[541] The clinical importance is that patients with impaired hepatic or renal function or with diminished perfusion of either organ, as in CHF, have markedly impaired elimination of procainamide. Recommended dosages for patients with renal impairment or CHF are a loading dose of 12 mg/kg given over 1 hour, with a maintenance dose of 1.4 mg/kg per hour.[542]

Toxic side effects of procainamide are related to dose and plasma concentration, a function of total dose and rate of administration during the loading technique. Serious cardiac toxicity usually requires plasma concentrations greater than 12 μg/ml. *N*-acetylprocainamide levels should be monitored. The likelihood of producing proarrhythmia as a result of QT_c prolongation is less with procainamide than with quinidine.[543] Procainamide also may produce gastrointestinal

BOX 11.7 INTRAVENOUS SUPRAVENTRICULAR ANTIARRHYTHMIC THERAPY

Class I Drugs

Procainamide (IA): converts acute atrial fibrillation, suppresses PACs and precipitation of atrial fibrillation or flutter, converts accessory pathway SVT; 100 mg IV loading dose every 5 minutes until arrhythmia subsides or total dose of 15 mg/kg (rarely needed) with continuous infusion of 2 to 6 mg/min.

Class II Drugs

Esmolol: converts or maintains slow ventricular response in acute atrial fibrillation; 0.5 to 1 mg/kg loading dose with each 50 μg/kg per minute increase in infusion, with infusions of 50 to 300 μg/kg per minute. Hypotension and bradycardia are limiting factors.

Class III Drugs

Amiodarone: converts acute atrial fibrillation to sinus rhythm; 5 mg/kg IV over 15 minutes.

Ibutilide (Convert): converts acute atrial fibrillation and flutter.
- Adults (>60 kg): 1 mg IV given over 10 minutes; may repeat once.
- Adults (<60 kg) and children: 0.01 mg/kg IV given over 10 minutes; may repeat once.

Vernakalant: 3 mg/kg over 10 minutes in acute-onset atrial fibrillation; if no conversion; wait 15 minutes and then repeat with 2 mg/kg over 10 minutes. Hypotension may occur in a few patients.

Class IV Drugs

Verapamil: slow ventricular response to acute atrial fibrillation; converts AV node reentry SVT; 75–150 μg/kg IV bolus.

Diltiazem: slow ventricular response in acute atrial fibrillation; converts AV node reentry SVT; 0.25 μg/kg bolus, then 100–300 μg/kg/h infusion.

Other Therapy

Adenosine: converts AV node reentry SVT and accessory pathway SVT; aids in diagnosis of atrial fibrillation and flutter. Increased dosage required with methylxanthines, decreased use required with dipyridamole.
- Adults: 3–6 mg IV bolus, repeat with 6–12 mg bolus.
- Children: 100 μg/kg bolus, repeat with 200 μg/kg bolus.

Digoxin: maintenance IV therapy for atrial fibrillation and flutter; slows ventricular response.
- Adults: 0.25 mg IV bolus followed by 0.125 mg every 1–2 hours until rate is controlled; not to exceed 10 μg/kg in 24 hours.
- Children (<10 years): 10–30 μg/kg load given in divided doses over 24 hours.
- Maintenance: 25% of loading dose.

AV, Atrioventricular; *IV*, intravenous; *PACs*, premature atrial contractions. *SVT*, supraventricular tachycardia.

BOX 11.8 INTRAVENOUS VENTRICULAR ANTIARRHYTHMIC THERAPY

Class I Drugs

Procainamide (IA): 100 mg IV loading dose every 5 minutes until arrhythmia subsides or total dose of 15 mg/kg (rarely needed) with continuous infusion of 2 to 6 mg/min.

Lidocaine (IB): 1.5 mg in divided doses given twice over 20 minutes with continuous infusion of 1 to 4 mg/min.

Class II Drugs

Propranolol: 0.5 to 1 mg given slowly up to a total β-blocking dose of 0.1 mg/kg; repeat bolus as needed.

Metoprolol: 2.5 mg given slowly up to a total β-blocking dose of 0.2 mg/kg; repeat bolus as needed.

Esmolol: 0.5 to 1.0 mg/kg loading dose with each 50 μg/kg/min increase in infusion, with infusions of 50 to 300 μg/kg/min. Hypotension and bradycardia are limiting factors.

Class III Drugs

Bretylium: 5 mg/kg loading dose given slowly with a continuous infusion of 1 to 5 mg/min. Hypotension may be a limiting factor.

Amiodarone: 150 mg over 10 minutes IV; then 1 mg/min for 6 hours; then 0.5 mg/min for the next 18 hours. Repeat bolus as needed.

Other Therapy

Magnesium: 2 g of $MgSO_4$ over 5 minutes; then continuous infusion of 1 g/h for 6–10 hours to restore intracellular magnesium levels.

From Royster RL. *Diagnosis and Management of Cardiac Disorders.* ASA Refresher Course Lectures. Park Ridge, IL: American Society of Anesthesiologists; 1996.

disturbances, CNS symptoms (ie, headache and sleep disturbance), rash, and agranulocytosis. Among patients receiving procainamide chronically, antinuclear antibodies develop in 50% to 70%, and approximately one-half have fever, myalgia, rash, pleuritis, or pericarditis similar to that seen with lupus erythematosus, although renal and CNS effects are rare.[544] They are more common among patients who are slow acetylators. After discontinuation of the drug, lupus-like symptoms resolve slowly.

Intramyocardial distribution of procainamide, especially during ischemia or infarction, is an important component of its therapeutic effect. In a canine infarction model, procainamide increased ERP more in ischemic than in nonischemic myocardium.[545] The pharmacokinetic profiles of procainamide are different for ischemic and nonischemic regions of myocardium; tissue concentrations of procainamide decline more rapidly in the latter.[546]

Disopyramide

Although disopyramide is chemically different from quinidine and procainamide, electrophysiologic effects of the three drugs are similar. Conduction through the AV node may be facilitated slightly by disopyramide because of its indirect vagolytic effect.[547] Accessory pathway conduction may be slowed in patients with Wolff-Parkinson-White syndrome.[548] Disopyramide is a potent negative inotropic drug, and after intravenous use, SVR reflexively increases.[549]

Disopyramide is therapeutically effective against supraventricular and ventricular tachyarrhythmias. However, as with quinidine and procainamide, disopyramide should not be used for ventricular tachyarrhythmias caused by prolonged QT syndrome. The marked negative inotropic and anticholinergic effects limit the usefulness of the drug.

When given orally, 80% of disopyramide is absorbed, and steady-state therapeutic plasma concentrations of 2 to 4 μg/mL can be achieved with 100 to 200 mg given orally every 6 hours.[550] The elimination half-life is approximately 7 hours, and elimination occurs equally by hepatic and renal mechanisms; hepatic or renal insufficiency may necessitate smaller doses.[551] Disopyramide is approximately 30% to 50% protein bound at plasma concentrations of 3 μg/mL.[547]

Toxicity of disopyramide is most frequently anticholinergic in origin, with symptoms of gastrointestinal upset, visual disturbance, and urinary tract obstruction, which may be marked in elderly men with prostatic hypertrophy. Unless there is LV failure, cardiovascular complications are infrequent, but recurrent CHF is seen in up to 50% of patients with a history of CHF.[549] Conduction system toxicity resembles that with quinidine.

Class IB Drugs

Lidocaine

First introduced as an antiarrhythmic drug in the 1950s, lidocaine has become the clinical standard for the acute intravenous treatment of

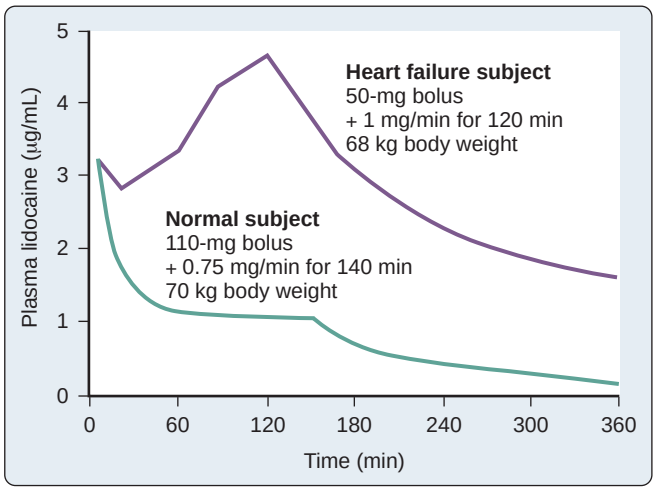

Fig. 11.25 Difference between plasma level responses to infused lidocaine in a normal person and a patient with heart failure. The accumulation of lidocaine in patients with depressed hepatic metabolism is dramatically illustrated. *(From American Heart Association.* Textbook of Advanced Cardiac Life Support. *Dallas, TX: American Heart Association; 1987.)*

ventricular arrhythmias except those precipitated by an abnormally prolonged QT interval.[552–555] Lidocaine may be one of the most useful drugs in clinical anesthesia because it has local and general anesthetic properties in addition to an antiarrhythmic effect.[556]

The direct electrophysiologic effects of lidocaine produce virtually all of its antiarrhythmic action. Lidocaine depresses the slope of phase 4 diastolic depolarization in Purkinje fibers and increases the VF threshold.[557] In Purkinje fibers, lidocaine increases transmembrane potassium conductance but does not affect resting membrane potential or threshold potential.[558] At less negative (partially depolarized) initial membrane potentials, lidocaine decreases fast-channel (Na^+) responses through an increase in background outward potassium flux, an effect directly related to extracellular potassium concentration.[559,560] Lidocaine may be ineffective in patients with hypokalemia.[561]

Conduction velocity is not affected by lidocaine in normal tissue, but it is significantly decreased in ischemic tissue.[562] The effects of lidocaine on APD vary by conduction system location. In atrial tissues, there is little or no effect. In Purkinje fibers, APD is markedly decreased, and the magnitude of the decrease is directly proportional to normal APD.[528] Because lidocaine decreases APD, its antiarrhythmic effect has been attributed to improved conduction in ectopic foci, which decreases the likelihood of reentry, but it has been shown that lidocaine slows conduction in these areas and decreases reentrant ventricular ectopy after experimental infarction.[533,563]

The clinical pharmacokinetics of lidocaine is well described. The distribution and elimination half-lives of lidocaine are short, approximately 60 seconds and 100 minutes, respectively.[564] Hepatic extraction of lidocaine is about 60% to 70%, and essentially all lidocaine is metabolized because the urine contains negligible amounts of unchanged lidocaine.[532] Hepatic metabolism produces monoethylglycine xylidide and glycine xylidide, both of which possess antiarrhythmic effects. Metabolic products are eliminated by the kidney, and accumulation of the monoethyl metabolite is related to the toxicity of intravenous lidocaine.[565–567] In patients with impaired hepatic function or blood flow (eg, those with CHF), the dose requirement is approximately 50% of that for healthy persons (Fig. 11.25 and Table 11.26; see Box 11.8).

Therapeutic plasma levels of lidocaine range from 1.5 to 5 μg/mL; signs of toxicity are common with concentrations greater than 9 μg/mL.[566] Various intravenous dosages can be used, but the important factor is to rapidly achieve steady-state therapeutic plasma concentrations. An initial bolus dose of 1 to 1.5 mg/kg should be followed immediately by a continuous infusion of 20 to 50 μg/kg per minute

TABLE 11.26 Potential Effects of Pathophysiologic Changes in Congestive Heart Failure on Drug Disposition

Pathology	*Pharmacokinetic Sequelae*

↑ Sympathetic activity	↓ Drug distribution
↑ Plasma norepinephrine Altered regional perfusion	↓ Intramuscular absorption
↓ Peripheral perfusion	Volume of distribution
Changes in extracellular fluid volume and protein binding	↑ or ↓
Visceral congestion	↓ Drug metabolism

↓, Decreased; ↑, increased.

to prevent the therapeutic hiatus produced by the rapid redistribution half-life of lidocaine. Infusion increments should be accompanied by additional bolus doses to immediately increase the plasma level.

The major toxic effect of lidocaine is associated with the CNS and manifests as drowsiness and disorientation, which progress to agitation, muscle twitching, and hearing abnormalities and culminate in seizures. Lidocaine can be an effective general anesthetic agent, and cases of coma with electroencephalographic silence similar to brain death patterns have been produced by an overdose of lidocaine and have resolved completely on discontinuation of the drug. The direct CNS effect of lidocaine and other local anesthetics is anticonvulsant.[568–570]

Local anesthetic–induced seizures do not produce permanent damage to the CNS as long as cardiovascular and respiratory complications of the seizure are prevented. Pharmacologically, benzodiazepines are superior to barbiturates (eg, thiopental) for stopping local anesthetic–induced seizure activity. Drug therapy alone is insufficient, and airway control, ventilation, and especially oxygenation are paramount to prevent CNS morbidity.

Mexiletine and Tocainide

Mexiletine and tocainide have electrophysiologic effects similar to those of lidocaine (ie, decreases in APD and ERP but little effect on conduction). Mexiletine has little effect on the QT interval. Hemodynamic effects are minor and consist primarily of small decreases of LV dP/dt and increases of LVEDP.[571] Small decreases of CO, SVR, and BP have been reported. However, even in patients with CAD, acute MI, or valvular heart disease, hemodynamic effects are clinically insignificant.[572–575]

The antiarrhythmic effects decrease the frequency of acute and chronic ventricular ectopy but not supraventricular arrhythmias. Mexiletine may decrease symptomatic ventricular arrhythmias in patients not responding to other therapy and may be more effective than lidocaine when used intravenously to suppress PVCs and VT in acute MI.[576–579] Administered orally, mexiletine also may be effective prophylaxis for PVCs and VT, but it may less effectively suppress closely coupled PVCs.[580–582] Mexiletine may be used in children and in patients with a long QT syndrome.

Pharmacokinetics of orally administered mexiletine reveals a bioavailability of 85%, with 70% of the drug protein bound. The volume of distribution of mexiletine is 2.5 times that for other antiarrhythmics.[583] Elimination half-life is 10 hours and is suitable for dosage regimens of two or three times per day.[584] Mexiletine is eliminated by hepatic metabolism, with less than 10% renally excreted unchanged in the urine. The hepatic metabolism is accelerated with microsomal enzyme induction and predictably decreased with hepatic disease, but overall metabolism is unaffected by renal failure.[585,586]

The usual dosage of mexiletine is 200 mg every 8 hours, which can be increased to 400 mg but should not exceed 1200 mg/day. Effective plasma levels of mexiletine range from 0.5 to 2 μg/mL, but there is wide individual variation of the dosage required to achieve that concentration.

Adverse effects of mexiletine include nausea, dysarthria, dizziness, paresthesia, tremor, vomiting, and sweating. Adverse reactions to

mexiletine are dose related and may occur at serum concentrations at the high end of the therapeutic range, which requires careful titration of the drug in patients. The incidence rate of minor reactions is 30%, and the incidence rate of severe reactions (ie, vomiting, confusion, and hypotension) is 19% when the plasma concentration is greater than 2 μg/mL.[587]

Diphenylhydantoin

Diphenylhydantoin (DPH) or phenytoin is unique among class IB drugs in that it has a potent central sympatholytic effect that decreases cardiac sympathetic efferent nerve activity.[588,589] Its electrophysiologic effect in many ways bridges the IA and IB classification. In normal conduction system cells, DPH decreases V_{max} and the amplitude of phase 0, but this effect is weaker than with other class IA drugs.[590] DPH does not decrease intraventricular conduction or prolong the QT interval, but it shortens APD.[591] DPH effectively can abolish the delayed afterpotentials associated with digitalis intoxication.[592,593] In cells partially depolarized from cold, hypoxia, or cardiac glycoside administration, DPH increases maximal diastolic potential, V_{max} of phase 0, and the conduction velocity.[594] DPH exerts its antiarrhythmic effect by increasing the ERP/APD ratio and by decreasing automaticity; both effects are enhanced in partially depolarized cells.

The drug is used to treat the atrial and ventricular arrhythmias produced by cardiac glycoside toxicity and in some patients with arrhythmias due to prolonged QT syndrome. It is less effective for other supraventricular arrhythmias and for suppressing chronic ventricular ectopy. The drug also is useful in children for preventing late postoperative arrhythmias after surgical correction of congenital heart disease such as junction ectopic tachycardia.[595]

Intravenous loading of DPH is accomplished in much the same way as with procainamide. Doses of 50 to 100 mg (0.5 to 1.5 mg/kg) are given at 5-minute intervals until therapeutic effects are obtained, up to a total dose of 1 g (15 mg/kg); the usual therapeutic plasma concentration is 8 to 10 μg/mL.[596] The drug undergoes primary hepatic metabolism, with urinary excretion of unchanged DPH accounting for only 5% of the total dose.[597] Patients with impaired hepatic or renal function should be expected to have greater plasma concentrations of DPH for a given dose, and the dose should be reduced to prevent toxicity.

With intravenous administration, a depressor effect is seen with depressed contractile function and a moderate increase of LVEDP.[598,599] These effects may in part result from the solvents used for the injectable preparation (ie, propylene glycol and ethyl alcohol).[600] Infusion rates greater than 50 mg/min in adults have produced cardiovascular collapse, VF, and death.[601] Other side effects include visual disturbances (ie, nystagmus and blurring), nausea, dysarthria, and cerebellar ataxia. Chronic DPH use produces gingival hyperplasia, macrocytic anemia, and dermatologic disorders.

Class IC Drugs

Flecainide

Flecainide depresses phase 0, delays repolarization in canine ventricular myocardium, and increases intracardiac monophasic APD in humans. The sodium channel depressant effects are slow onset and offset, and they are use dependent. Because it also can inhibit the slow calcium channel, the drug has properties of multiple classes.[602] Minimal changes occur in ventricular or atrial refractoriness, but the drug can markedly change accessory pathway refractoriness. The QT interval changes are also minimal.

This drug is indicated for life-threatening ventricular arrhythmias, supraventricular arrhythmias, and AF. It also is effective in patients with the Wolff-Parkinson-White syndrome. Chronic clinical studies have shown that PVCs and VT are effectively suppressed.[603] Flecainide is probably the most effective antiarrhythmic at eliminating premature depolarizations, but as CAST showed for certain patient populations, PVC suppression may not always be in the patient's best interest. Intravenous flecainide was effective in treating junctional ectopic tachycardia, converting all seven patients to sinus rhythm within 16 hours.[604]

Flecainide decreases LV dP/dt and CO experimentally.[605] Clinical studies have shown no effects of oral flecainide on BP, echocardiographic parameters, or exercise tolerance.[603,605,606] However, patients with depressed ventricular function may be more susceptible to the negative inotropic effects of flecainide.

Flecainide is well absorbed after oral administration, with a plasma half-life of 20 hours. The drug is 85% excreted renally in an unchanged form or as an inactive metabolite. Effective plasma concentrations range from 0.2 to 1.0 μg/mL. Dosages range from 100 to 200 mg given twice daily. The dose should be reduced in renal failure or HF. Flecainide increases serum digoxin and propranolol levels, whereas propranolol, quinidine, and amiodarone can increase flecainide levels.

Adverse effects are usually minor at doses that have a significant therapeutic effect, but the QT interval has been prolonged with induction of polymorphic VT, and the CAST study showed definite increases in mortality after MI.[607] Confusion and irritability rarely occur.

Propafenone

Propafenone blocks the fast sodium current in a use-dependent manner. It also has a slow offset like flecainide. Propafenone blocks β-receptors and is a weak potassium channel blocker.[608] This drug usually slows conduction and prolongs refractoriness of most cardiac conduction system tissue. Propafenone is indicated for life-threatening ventricular arrhythmias, various supraventricular arrhythmias, and AF. In one study, a single 600-mg oral dose of propafenone converted 76% of patients in AF.[609] Propafenone was more effective than placebo in preventing atrial tachyarrhythmias after cardiac surgery with combined intravenous and oral therapy.[610]

Propafenone is well absorbed orally and is highly protein bound, with an elimination half-life of 6 to 8 hours. Therapeutic serum levels are 0.2 to 1.5 μg/mL. The metabolites of propafenone are active and demonstrate significant action potential and β-blocking effects. A small percentage of patients poorly metabolize the drug, and the metabolites of these patients exhibit greater β-blocking properties.

The drug has fewer proarrhythmic problems than flecainide, likely because of the β-blocking effects, which tend to decrease arrhythmic traits of antiarrhythmic drugs. Worsening of bronchospastic lung disease has occurred, and in a small percentage of patients, dizziness, blurred vision, taste issues, and some gastrointestinal complaints may develop.

Moricizine

Moricizine is a potent sodium channel blocker with mild potassium-blocking effects. It prolongs AV node, His bundle–ventricular conduction time, and QRS duration. It has little effect on atrial tissue. The drug is indicated for life-threatening ventricular arrhythmias and is as effective as some of the other class I agents.

Moricizine is highly protein bound and its bioavailability is only 35%. Serum levels do not correlate with therapeutic activity. The elimination half-life is 1 to 3 hours, with the drug eliminated by hepatic and renal routes. Dosage is 300 mg every 8 hours. Dosage may be changed to every 12 hours for patients with hepatic or renal disease or patients with CHF.

Adverse effects include tremor, headache, vertigo, dizziness, and gastrointestinal side effects of nausea, vomiting, and diarrhea. Proarrhythmic episodes can occur in up to 15% of patients. In the CAST study, the moricizine limb was continued after the encainide and flecainide limbs were stopped, and analysis of the moricizine-treated patients showed an increase in mortality.[611]

Class II Drugs: β-Adrenergic Receptor Antagonists

β-Adrenergic receptor blockers are very effective antiarrhythmics in patients during the perioperative period or patients who are critically ill because many of their arrhythmias are adrenergically mediated.

Propranolol

Propranolol was the first major β-receptor-blocking drug to be used clinically. Propranolol is very potent but is nonselective for β_1- and β_2-receptor subtypes. It possesses essentially no ISA. Because it interferes with the bronchodilating actions of epinephrine and the sympathetic stimulating effects of hypoglycemia, propranolol is less useful in patients with diabetes or bronchospasm. These difficulties with propranolol stimulated the search for β-receptor—blocking drugs with receptor subtype specificity, such as metoprolol, esmolol, and atenolol.

The electrophysiologic effects of β-receptor antagonism are decreased automaticity, increased APD (primarily in ventricular muscle), and a substantially increased ERP in the AV node. β-Blockade decreases the rate of spontaneous (phase 4) depolarization in the SA node; the magnitude of this effect depends on the background sympathetic tone. Although resting heart rate is decreased by β-blockade, inhibition of the increase of heart rate in response to exercise or emotional stress is much more marked. Automaticity in the AV node and more distal portions of the conduction system is also depressed. β-Blockade affects VF threshold variably, but it consistently reverses the fibrillation threshold-lowering effect of catecholamines.

In addition to β-blockade, propranolol decreases the background outward current of potassium, and at greater concentrations, it inhibits inward sodium current. Because of similarity to class I activity, these effects have been called *membrane-stabilizing activity* or quinidine-like effects. In very high concentrations (1000–3000 ng/mL), this effect increases depolarization threshold in Purkinje fibers.[126] Although effective β-blockade is achieved at propranolol concentrations of 100 to 300 ng/mL, concentrations of 1000 ng/mL may be required to control ventricular arrhythmias.[612] Propranolol decreases intramyocardial impulse conduction in acutely ischemic myocardium but does not do so in normal myocardium.[613]

Pharmacokinetic results show that absorption after oral administration is virtually 100%, but bioavailability is impaired by first-pass hepatic metabolism, which accounts for approximately two thirds of the administered dose. The degree of hepatic extraction varies greatly, which probably accounts for the great variability of the plasma concentration produced by a given oral dose of propranolol. The hepatic extraction of propranolol is a saturable process, and bioavailability improves with increased oral dose or with chronic therapy.[614] Propranolol is 90% to 95% protein bound in plasma, which further confounds the use of plasma concentration as a guide to therapy.[615] Propranolol is metabolized before excretion; one product, 4-hydroxypropranolol, has a β-blocking potency similar to that of propranolol, but a short half-life prevents this metabolic product from contributing significantly to the therapeutic effect of propranolol.[616]

The elimination half-life of orally administered propranolol is 3 to 4 hours, but it is increased during chronic therapy as a result of saturation of hepatic metabolic processes.[617] CPB alters the kinetics of propranolol. Heparinization doubles the free fraction of propranolol, an effect that is reversed after protamine administration. This effect probably results from an increase of free fatty acid concentration produced by heparin, which decreases the protein binding of propranolol.[618]

Major toxic side effects of propranolol are related to β-blockade. Cardiac toxicity includes CHF (uncommon without other causes of ventricular dysfunction) and depressed AV conduction. Complete heart block and asystole have occurred in patients with preexisting AV nodal or intraventricular conduction abnormalities. Sudden discontinuation of β-blockade therapy may precipitate a withdrawal syndrome of excessive β-adrenergic activity as a result of the altered sensitivity associated with chronic blockade. Responses to normal levels of sympathetic activity are exaggerated as the β-blockade declines, likely because of increased receptor density or upregulation of the β receptor.[619,620] Increased airway resistance results from β_2-receptor blockade by propranolol, and this can precipitate severe pulmonary compromise in the asthmatic patient. The hypoglycemic action of insulin is accentuated by propranolol because the sympathomimetic effect of hypoglycemia is blocked. Adverse effects perhaps not related to β-receptor blockade include CNS disturbances such as insomnia, hallucinations, depression, and dizziness and minor allergic manifestations such as rash, fever, and purpura.

An appropriate intravenous dose for acute control of arrhythmias is 0.5 to 1.0 mg titrated to therapeutic effect up to a total of 0.1 to 0.15 mg/kg. Stable therapeutic plasma concentrations of propranolol can be obtained with a continuous intravenous infusion. An effective level of β-blockade may be obtained with a continuous infusion of approximately 3 mg/h in adult postoperative patients previously receiving chronic treatment. However, with the availability of esmolol, a propranolol infusion is no longer necessary.

Metoprolol

Metoprolol is a relatively selective β-receptor antagonist. The potency of metoprolol for β_1-receptor blockade is equal to that of propranolol, but metoprolol exhibits only 1% to 2% of the effect of propranolol at β_2-receptors.[621]

Like propranolol, metoprolol is rapidly and efficiently absorbed after oral administration, but its first-pass extraction by the liver is lower, and 40% of the administered dose reaches the systemic circulation. Plasma half-life after oral administration is approximately 3 hours. Metoprolol is 90% metabolized; hydroxylation and *O*-demethylation are the primary pathways. The metabolites lack β-receptor effects. As with acetylation of procainamide, the rate of hydroxylation of metoprolol is genetically determined. Slow hydroxylators have a markedly prolonged elimination of the parent drug and greater plasma concentrations.[622]

Toxicity of metoprolol is related primarily to its limited β_2-antagonist activity. Metoprolol increases airway resistance and decreases the forced expiratory volume in patients with asthma, although to a lesser extent than does propranolol at equipotent β_1-antagonist doses. In contrast to propranolol, metoprolol does not inhibit the bronchodilation of isoproterenol. Metoprolol impairs β-receptor–mediated insulin release, and the signs of hypoglycemia are masked as with propranolol. Other side effects of metoprolol are similar to those of propranolol.

Metoprolol is useful for treating supraventricular and ventricular arrhythmias that are adrenergically driven. The primary advantage of metoprolol is its relative lack of most of the bronchoconstrictive effects in patients with chronic obstructive pulmonary disease. Acute intravenous dosage is 1.0 mg titrated to therapeutic effect up to 0.1 to 0.2 mg/kg.

Intravenous therapy may be more effective than oral therapy in preventing AF after cardiac surgery.[623] Another study compared oral carvedilol and oral metoprolol and found carvedilol more effective in preventing AF after on-pump CABG surgery.[624]

Esmolol

Esmolol is a cardioselective β_1-receptor antagonist with an extremely brief duration of action.[625] In anesthetized dogs, esmolol infused at 50 μg/kg per minute produced a steady-state β-blockade that was completely reversed 20 minutes after stopping the infusion.[626] Esmolol has only minimal ISA and membrane-stabilizing activity, and in conscious dogs, it has no effect on LVEDP, BP, heart rate, CO, or SVR, but at 5 to 60 μg/kg per minute, it does decrease LV dP/dt. The decreased contractility fully resolves by 20 minutes after the infusion.

Electrophysiologic effects of esmolol are those of β-adrenergic receptor antagonism. In open-chest dogs, esmolol infused at 300 μg/kg per minute increased SA node recovery time and Atrial–His bundle (AH) conduction interval, but not the His bundle–ventricular (HV) interval. ERP was increased in the AV node, but this effect does not occur in vitro at β-blocking concentrations.

Esmolol is rapidly metabolized in blood by hydrolysis of its methyl ester linkage. Its half-life in whole blood is 12.5 to 27.1 minutes in dogs and humans, respectively. The acid metabolite possesses a slight degree (1500 times less than esmolol) of β-antagonism. Esmolol is not affected by plasma cholinesterase; the esterase responsible is located in erythrocytes and is not inhibited by cholinesterase inhibitors, but it is

deactivated by sodium fluoride. Of importance to clinical anesthesia, no metabolic interactions between esmolol and other ester molecules are known. Esmolol dosages up to 500 μg/kg per minute have not modified neuromuscular effects of succinylcholine.[627]

In patients with asthma, esmolol (300 μg/kg per minute) only slightly increases airway resistance. In patients with chronic obstructive pulmonary disease who received esmolol, no adverse pulmonary effects have occurred.[628] In a multicenter trial that compared esmolol with propranolol for the treatment of paroxysmal supraventricular tachyarrhythmia (PSVT), esmolol was equally efficacious and had the advantage of a much faster termination of the β-blockade.[629] Esmolol has become a useful agent in controlling sinus tachycardia in the perioperative period, a time when a titratable and brief β-blockade is highly desirable.

Dosing begins at 25 μg/kg per minute and is titrated to effect up to 250 μg/kg per minute. Doses greater than this may cause significant hypotension because of reduced CO in patients. Esmolol is especially effective in treating acute-onset AF or flutter perioperatively, and it results in acute control of the ventricular response and conversion of the arrhythmia to sinus rhythm.

Landiolol, an ultrashort-acting β-blocker, similar to esmolol but with greater cardioselectivity and a shorter half-life (4 minutes), is undergoing investigation.[630] The drug is efficacious in converting 89% of patients who developed AF or flutter to sinus rhythm.[631] Landiolol reduced the incidence of AF when given prophylactically after cardiac surgery.[632]

Class III Drugs: Potassium Channel Blockers and Agents That Prolong Repolarization

Amiodarone

Amiodarone is a benzofuran derivative that was initially introduced as an antianginal drug and was subsequently found to have antiarrhythmic effects. The drug has a wide spectrum of effectiveness, including supraventricular,[633] ventricular,[634,635] and preexcitation arrhythmias (see Boxes 11.7 and 11.8).[633–636] It also may be effective against VT and VF refractory to other treatment.[637] Amiodarone has been approved by the AHA as the first-line antiarrhythmic in cardiopulmonary resuscitation.[638] Amiodarone may be effective prophylactically in preventing AF after surgery.[633] It also can decrease the number of shocks in patients who have implantable cardioverter-defibrillators compared with other antiarrhythmic drugs.[639]

Amiodarone used in an isolated rabbit SA node preparation increased APD and decreased the slope of diastolic (phase 4) depolarization, which depressed SA node automaticity.[640] Amiodarone prolongs repolarization and refractoriness in the SA node, in atrial and ventricular myocardium, in the AV node, and in the His-Purkinje system.[641] Resting potential and myocardial automaticity are minimally affected, but ERP and absolute refractory period are prolonged.[642] Amiodarone blocks inactive sodium channels in Purkinje fibers, which significantly depresses phase 0.[641] In anesthetized dogs, amiodarone decreases AV junctional and SA nodal automaticity and prolongs intranodal conduction.[643]

There are substantial differences in the electrophysiologic effects of acute and chronic amiodarone administration. Acutely, the drug slightly increases ERP of the His-Purkinje system and ventricular myocardium. The QTc is not prolonged by acute intravenous administration despite myocardial concentrations similar to those with chronic oral therapy.[644] However, chronic oral administration significantly increases QTc.[645] Although AV nodal ERP increases with acute intravenous amiodarone therapy, the increase is greater after chronic use. In other cardiac tissue, there is little or no change in ERP after intravenous administration, but after chronic oral use, ERP is increased globally and the AH and HV conduction times are increased.[646]

The electrophysiologic effects of chronic amiodarone treatment mimic those of thyroid ablation.[647] Moreover, the repolarization effects of the drug are reversed by T_3 administration. This suggests that among the basic effects of amiodarone is the blockade of the cardiac effect of T_3. This mechanism has been proposed as an alternative to the active metabolite accumulation theory to account for the slow onset of the antiarrhythmic effect of amiodarone.[646]

Amiodarone increases the amount of electric current required to elicit VF (ie, increase in the VF threshold). In most patients, refractory VT is suppressed by acute intravenous use of amiodarone. This effect has been attributed to a selectively increased activity in diseased tissue, as has been seen with lidocaine.[648] Amiodarone also has an adrenergic-receptor (α and β) antagonistic effect produced by a noncompetitive mechanism; the contribution of this effect to the antiarrhythmic action of the drug is unknown.[649]

Hemodynamic effects of intravenous amiodarone (10 mg/kg) include decreased LV dP/dt, maximal negative dP/dt, mean aortic pressure, heart rate, and peak LV pressure after coronary artery occlusion in dogs. CO was increased despite the negative inotropic effect as a result of the more marked decrease in LV afterload.[650] Clinical effects are similar; a 5-mg/kg intravenous dose during cardiac catheterization decreased BP, LVEDP, and SVR and increased CO, but it did not affect heart rate. Chronic amiodarone therapy is not associated with clinically significant depression of ventricular function in patients without LV failure. Hemodynamic deterioration may occur in some patients with compensated CHF, perhaps because of the antiadrenergic effects of the drug.[651]

The pharmacokinetics of amiodarone is notable for the low bioavailability, very long elimination half-life, relatively low clearance, and large volume of distribution. Oral absorption of amiodarone is slow, with peak plasma levels occurring 3 to 7 hours after ingestion.[652] Bioavailability varies and is low, ranging from 22% to 50%. The hepatic extraction ratio is only 0.13, and the major limit to bioavailability may be incomplete absorption. Amiodarone has a large volume of distribution, estimated as 1.3 to 65.8 L/kg; plasma clearance rates range from 0.14 to 0.60 L/min.[653] Plasma half-life after chronic oral therapy is reported as 14 to 107 days; therapeutic and steady-state plasma concentrations are slowly achieved with maintenance oral administration at 9.5 to 30 days, respectively.[654]

Because steady-state plasma levels are achieved slowly, loading techniques have been developed. Patient-specific pharmacokinetic data have been used to prescribe loading infusion rates of 0.5 to 3.9 mg/min and maintenance rates of 0.5 to 1.0 mg/min to produce plasma levels of 0.5 to 2.5 μg/mL during maintenance infusion. This dosage reduced VT by 85%, paired PVCs by 74%, and isolated PVCs by 60%.[655] A comparison of onset of antiarrhythmic effect of oral loading (800 mg/day for 7 days, then 600 mg/day for 3 days) and intravenous (5 mg/kg for 30 minutes) plus oral (as for oral alone) administration demonstrated that the combined intravenous and oral loading technique had a more rapid therapeutic effect with a lower total amiodarone dose.[656] In acute situations with stable patients, a 150-mg intravenous bolus is followed by a 1.0-mg/min infusion for 6 hours and then 0.5 mg/min thereafter. In CPR, a 300-mg intravenous bolus is given and repeated with multiple boluses as needed if defibrillation is unsuccessful.

Adverse reactions to amiodarone are numerous. Photosensitivity of the skin occurs in 57% of patients without apparent relation to dose or plasma level.[657] Other skin manifestations include abnormal pigmentation (ie, slate gray) and an erythematous, pruritic rash. Corneal microdeposits occur in most patients taking amiodarone chronically, although visual symptoms are uncommon.

Pulmonary side effects are more severe.[658–661] Clinical features include exertional dyspnea, cough, and weight loss. Hypoxia may occur; pulmonary function studies show decreased total lung capacity and diffusion rate. Chest radiographic findings are diffuse bilateral interstitial infiltrates, which histologically may be fibrosing alveolitis. Pulmonary effects may resolve with discontinuation of treatment or with dose reduction. The pathophysiologic mechanism of these pulmonary effects is unknown but may be related to abnormal production of phospholipid. The overall incidence rate of pulmonary toxicity is up to 6%, with a mortality rate among affected patients of 20% to 25%. There are case reports of an increased risk for acute respiratory distress

syndrome when amiodarone is used before CPB, but this association has not been proved.

Thyroid abnormalities are associated with amiodarone. The frequencies of hyperthyroidism and hypothyroidism range from 1% to 5% and 1% to 2%, respectively.[649] Amiodarone contains two iodine atoms per molecule, or 75 mg of organic iodide per 200 mg of drug, and 10% of that amount may become free iodine. The iodine alone does not account for the thyroid abnormalities because intake of an amount of inorganic iodine equivalent to that ingested with chronic amiodarone intake does not have the same effect. Heart rate is not increased during hyperthyroidism associated with amiodarone, probably because of its antiadrenergic effects. Amiodarone therapy increases thyroxine (T_4) and reverse T_3, but it only slightly decreases T_3.[662,663]

Despite relatively widespread use of amiodarone, anesthetic complications infrequently have been reported. In two case reports, bradycardia and hypotension were prominent.[664,665] One of the reports described profound resistance to the vasoconstrictive effects of β-adrenergic agonists.[665] The slow decay of amiodarone in plasma and tissue makes such adverse reactions possible long after discontinuing its administration. Because T_3 can reverse electrophysiologic effects of amiodarone, T_3 possibly could be used to reverse hemodynamic abnormalities, such as those described in these two case reports, although this theory has not been tested. Epinephrine is more effective than dobutamine or isoproterenol in reversing amiodarone-induced cardiac depression.[666]

An RCT of amiodarone administered 6 days before and 6 days after cardiac surgery demonstrated significant reductions in atrial tachyarrhythmias and ventricular arrhythmias in patients of different ages and in different types of cardiac surgical procedures.[667] There were no differences in hospital mortality rates between groups.

A study in CABG surgery patients showed that amiodarone was more effective in converting AF than placebo.[668] All patients in this study received β-blockers. In children with postoperative junctional ectopic tachycardia, amiodarone was effective in converting or slowing the heart rate in all 18 study patients.[669] Prophylactic amiodarone has also reduced the incidence of AF in lung resection[670] but did not reduce the incidence of AF in cardiac valvular surgery.[671]

Bretylium

Bretylium has had supply problems over the past 5 years, and in 2011, the FDA placed it on a discontinued drug list. It was not discontinued due to safety issues and is still available in some countries outside the United States.

Bretylium is a quaternary ammonium compound that produces a biphasic cardiac response after acute intravenous administration. Initially, norepinephrine is displaced from adrenergic nerve endings, and there are attendant increases in BP, SVR, and cardiac automaticity. After 20 to 30 minutes, this response wanes, and the adrenergic-blocking effects of bretylium predominate.[672–674] The latter effects depend on uptake of bretylium by adrenergic neurons, but inhibition of its adrenergic-blocking effects does not impair the antiarrhythmic effect.

The direct electrophysiologic effect of bretylium is prolongation of the ventricular ERP. The electrophysiologic effect correlates with the myocardial rather than the plasma concentrations of bretylium.[675] Bretylium delays conduction of premature impulses from normal myocardium to the border of ischemic zones and decreases the disparity between the excitation thresholds of adjoining zones of ischemic and normal myocardium. Bretylium increases the electric current required to induce VF and may spontaneously convert VF to sinus rhythm.[676] The antiarrhythmic effect of bretylium is undiminished by cardiac denervation or chronic reserpine treatment, which indicates that the antiarrhythmic effects are dissociated from the antiadrenergic effects.[677,678] Bretylium also decreases the amount of electrical current required to produce defibrillation.[679]

Results of clinical trials of bretylium in acute cardiac arrest are inconsistent. In one study in which it was compared with lidocaine, bretylium did not have a better antiarrhythmic effect, improve resuscitation, or lower mortality rates.[680] In another study, bretylium (10 mg/kg) was used as a first-line treatment for out-of-hospital VF and significantly improved the outcome from resuscitation; lidocaine administered after bretylium also decreased the incidence of recurrent VF.[681] In the acute setting, bretylium is effective prophylaxis against VF.[642,682–685]

Clinical indications for bretylium include refractory VT or VF. For VF, bretylium is administered as a 5- to 10-mg/kg intravenous bolus, which can be repeated to a total dose of 30 mg/kg if VF persists. The antifibrillatory effect may require some time to develop, and full resuscitative efforts should continue for at least 20 to 30 minutes after bretylium has been administered. Administration for recurrent VT is similar to that for VF. Continuous infusion of 2 mg/min may be used to maintain plasma levels. As with VF, the effect of bretylium in VT may take 20 to 30 minutes to manifest.

Adverse reactions to bretylium include nausea and vomiting in conscious patients. During chronic therapy, postural hypotension may develop, but it is reduced by tricyclic drugs, which block uptake of bretylium by adrenergic neurons.

Sotalol

Sotalol is classified as a class III agent, but it also has class II β-adrenergic–blocking properties. Sotalol was first synthesized as a β-blocker and was initially used to treat angina and hypertension. The antiarrhythmic effect quickly was recognized, and the antiarrhythmic actions then were evaluated. Sotalol prolongs refractoriness in atrial and ventricular tissues because of blockade of the delayed rectifier potassium current. The β-blocking effects result in decreased heart rate and increased refractory periods at the atrial and ventricular levels.[686] It is indicated for life-threatening ventricular arrhythmias and AF.

Sotalol exists as a mixture of the D and L isomers, which have different mechanisms of action. Sotalol can be administered orally or intravenously. Oral bioavailability is greater than 90%. The drug is poorly bound to plasma protein and undergoes renal excretion with an elimination half-life of 12 hours when renal function is normal. The usual starting oral dose is 80 to 160 mg every 12 hours. Peak plasma concentration is seen within 4 hours.[687]

Sotalol has been used to treat supraventricular and ventricular tachyarrhythmias. Sotalol was found to be superior to class I agents in preventing the recurrence of ventricular arrhythmias.[688] To investigate the contribution of the β-blocking property to the efficacy of sotalol, class I agents with or without β-blocker were compared with sotalol.[689] Sotalol was more effective in preventing the recurrence of arrhythmias than class I agents with or without β-blockers. However, the mortality rates were similar when sotalol was compared with the combined class I drug and β-blocker regimen. Sotalol also is effective in the prevention of PSVTs.[690]

Sotalol administration is not without side effects. A large, prospective study of D-sotalol (not the mixture of D and L isomers) in patients with reduced LV function was terminated early because of an increased mortality rate in the treatment group.[691]

D-Sotalol lacks a significant β-adrenergic receptor–blocking property, which may explain the findings. Sotalol administration is associated with increased risk for torsades de pointes and QT-interval prolongation. Female patients and patients with renal failure are at increased risk for the proarrhythmic side effects.

Ibutilide

Ibutilide fumarate is a methanesulfonanilide antiarrhythmic agent that is approved for the conversion of atrial flutter and AF to sinus rhythm. Ibutilide prolongs the cardiac refractory period at the atrial and ventricular levels by activating a slow inward sodium current.[692] Ibutilide may cause the blockade of the rapid outward delayed rectifier potassium current, which also leads to prolongation of the cardiac refractory period.[693] In vitro and at high dose, ibutilide may shorten the action potential, although this effect has not been observed clinically. Ibutilide may also predispose to the formation of after depolarizations, which may be involved in the development of torsades de pointes.

Ibutilide is administered intravenously, is 40% protein bound, and undergoes hepatic metabolism. Of the eight metabolites, only one has slight antiarrhythmic activity. The pharmacokinetics of ibutilide is linear. Extravascular distribution is rapid, and systemic clearance is high, with the elimination half-life ranging from 2 to 6 hours.[694] The usual dose is 1 mg administered over 10 minutes. This may be followed by a second dose of 0.5 to 1 mg.

In one study, 0.015 mg/kg of ibutilide administered intravenously over 10 minutes resulted in conversion to sinus rhythm of about 45% of patients with atrial flutter longer than 3 hours in duration or AF 3 hours to 90 days in duration.[695] The arrhythmia was terminated in 3% of patients receiving placebo. The mean time to termination of arrhythmia was 19 minutes from the start of the infusion. In this study, termination of arrhythmias was unaffected by an enlarged left atrium, decreased EF, valvular heart disease, or use of concomitant medications such as β-blocking agents and digoxin.

In another study, the safety and efficacy of repeated intravenous doses were evaluated.[696] The investigators found a conversion rate similar to that in the previously described study. They found that efficacy was greater in atrial flutter than AF (63% vs 31%). In AF, conversion rates were greater in patients with shorter arrhythmia duration or a normal left atrial size. However, the duration of arrhythmias in all patients in this study was less than 45 days. Conversion rates of AF or flutter are enhanced with the concurrent use of magnesium.[697]

Cardiovascular side effects occur in about 25% of patients treated with ibutilide, compared with 7% for the placebo-treated group.[698] Torsades de pointes occurred in 4.3% of these patients. Most of the proarrhythmic activity was seen within 1 hour of termination of the infusion, reflecting the short half-life and lack of metabolites with significant antiarrhythmic properties. Bradycardia, low body weight, and a history of CHF predicted the occurrence of torsades de pointes. Electrolyte abnormalities and acquired prolonged QT interval should be corrected before ibutilide therapy.

Dofetilide

Dofetilide blocks the rapid component of the delayed rectifier potassium current of repolarization without slowing conduction. Similar to ibutilide, dofetilide has a profound effect on prolonging the QT interval. Atrial tissue is more affected by dofetilide's electrophysiologic effects than ventricular tissue. Dofetilide is indicated for acute conversion and chronic suppression of AF.[699]

Dofetilide is available only as an oral formulation and results in 90% bioavailability. About 50% of the drug is excreted in the urine, with an elimination half-life of 8 to 12 hours. Several drugs increase dofetilide serum concentrations, including verapamil, cimetidine, and ketoconazole. These drugs should be avoided or used with caution in combination with dofetilide.

Dosing is 0.125 to 0.5 mg twice daily and should be performed during ECG monitoring and measuring of the QT interval. QT prolongation with polymorphic VT can occur in up to 4% of patients. Electrolyte abnormalities should be corrected before administering this drug. Patients with prolonged QT intervals or a history of torsades de pointes should not receive chronic therapy. The concurrent use of magnesium enhanced the conversion of AF or atrial flutter with dofetilide and theoretically may reduce the incidence of QT prolongation.[700] No patients who received magnesium in this study developed torsades de pointes.

Dronedarone

Dronedarone was developed as an antiarrhythmic drug with a molecular structure and electrophysiologic effects similar to those of amiodarone but with more effect on atrial tissue and fewer side effects.[701] The main structural change is the replacement of iodine with a methane sulfonyl group that reduces the incidence of thyroid side effects and decreases the tissue accumulation, which should reduce the drug's half life, volume of distribution, and organ toxicity.

Dronedarone is available orally, is well absorbed, and has an elimination half life of 12 to 24 hours.[702] Oral dosing is 400 mg twice daily. First-pass metabolism in the liver accounts for 85%, and the drug is highly protein bound. Digoxin, statin, and cyclosporin levels increase with dronedarone and should be monitored. Grapefruit and verapamil may increase levels and should be avoided. The serum creatinine level may rise due to impaired tubular secretion. The drug may increase liver enzymes, and there have been several case reports of severe hepatotoxicity. Prolongation of the QT interval and proarrhythmias do not appear to be a problem.

Clinical trials have demonstrated that dronedarone maintains sinus rhythm and reduces the ventricular response in AF compared with placebo. The drug has also reduced mortality rates and reduced the incidence of stroke compared with placebo in AF. The reason for the reduced stroke rate was not clear. However, in patients with reduced LV function, dronedarone increased the risk of CHF and early death.[703] When compared with amiodarone, dronedarone had fewer adverse events that resulted in discontinuation of the drug, but amiodarone was more effective in maintaining sinus rhythm. In patients with permanent AF, dronedarone increased the risk of stroke, mortality, and hospitalization.[704] Dronedarone is not a first-line drug for AF and flutter and should not be used in patients with HF or in those with permanent AF.[705]

Vernakalant

Vernakalant is an antiarrhythmic drug approved for use in Europe but not in the United States for the acute conversion of AF but not atrial flutter.[706] The drug blocks atrial sodium and potassium channels and prolongs the atrial ERP duration. It is more effective at faster heart rates, which is different from other class III drugs.[707]

Vernakalant is available intravenously and orally. Intravenous drug is 89% metabolized by the liver, and 11% is renally excreted, with an elimination half-life of 3 hours.[706] The drug is not highly bound to proteins and does not appear to interact with other drugs, which typically could increase vernakalant serum levels.

An intravenous bolus dose of 3 mg/kg is given over 10 minutes, with a repeat dose of 2 mg/kg over 10 minutes given in 15 minutes if AF persists. [707] Significant side effects are rare, with hypotension occurring in only 6% of patients. Vernakalant does not appear to cause any significant clinical effects in the ventricular conducting system in humans, but in animal studies, there were mild sodium and potassium blocking effects in ventricular tissue. There appear to be no effects on QT prolongation, although in all clinical trials, patients with QT prolongation were excluded.

Clinical trials have demonstrated vernakalant to be extremely effective in the rapid conversion of acute-onset AF in nonsurgical and postoperative cardiac surgical patients.[708] Its speed of conversion is similar to that of ibutilide, but it has an acute safety profile similar to amiodarone (Table 11.27). More safety studies are needed before approval in the United States.[709]

Class IV Drugs: Calcium Channel Antagonists

Although the principal direct electrophysiologic effects of the three main chemical groups of calcium antagonists (ie, verapamil, a benzoacetonitrite; nifedipine, a dihydropyridine; and diltiazem, a benzothiazepine) are similar, verapamil and diltiazem are the primary antiarrhythmics.

As with other transmembrane ionic channels, the calcium channel is conceptualized as macromolecular protein that spans the ion-impermeable lipid bilayer of the membrane (Fig. 11.26). The channels exhibit selectivity for a particular ionic species and for specific transmembrane electrical potential ranges to control the permeability of the pore.[197] The decreased membrane potential produced by depolarization increases the permeability of the Ca^{2+} channel and permits Ca^{2+} to pass down its concentration gradient into the cell. Conversely, the gate closes on repolarization. This mechanism has been called the *voltage-dependent* or *voltage-gated* channel. In cardiac tissue, the Ca^{2+} channel is also controlled by membrane β-adrenergic receptors; activation of β_1 receptors recruits additional Ca^{2+} channels

TABLE 11.27 Comparison of Vernakalant and Ibutilide

Parameter	*Vernakalant*	*Ibutilide*
Vaughan-Williams class	Class III	Class III
Mechanism of action	Prolongation of refractoriness	Prolongation of refractoriness
Atrial selectivity	Yes	No
Effectiveness in acute AF	About 50% converted in 90 min	About 50% converted in 90 min
Effectiveness in AFI	No	Yes
Median time to conversion	11 min	30 min
Proarrhythmic effect	None to minimal	Risk of ventricular proarrhythmias (TdP, 1.7%)
Contraindications	SBP <100 mm Hg: severe aortic stenosis; heart failure (NYHA III or IV); ACS in the last 30 days; QTc prolongation	Heart failure (III or IV), recent ACS, QTc prolongation, coadministration with class I AADs and other QT-prolonging drugs, hypokalemia
Dosing regimen (intravenous)	3 mg/kg over 10 min followed by a second infusion of 2 mg/kg over 10 min if arrhythmia persists	1 mg over 10 min followed by a second infusion of 1 mg over 10 min if arrhythmia persists

AADs, antiarrhythmic drugs; *ACS*, acute coronary syndrome; *AF*, atrial fibrillation; *AFI*, atrial flutter; *NYHA*, New York Heart Association; *SBP*, systolic blood pressure; *TdP*, torsades de pointes.

Modified from Bronis K, Metaxa S, Koulouris S, Manolis AS. Vernakalant: review of a novel atrial selective antiarrhythmic agent and its place in current treatment of atrial fibrillation. *Hosp Chronicles.* 2012;7, 171.

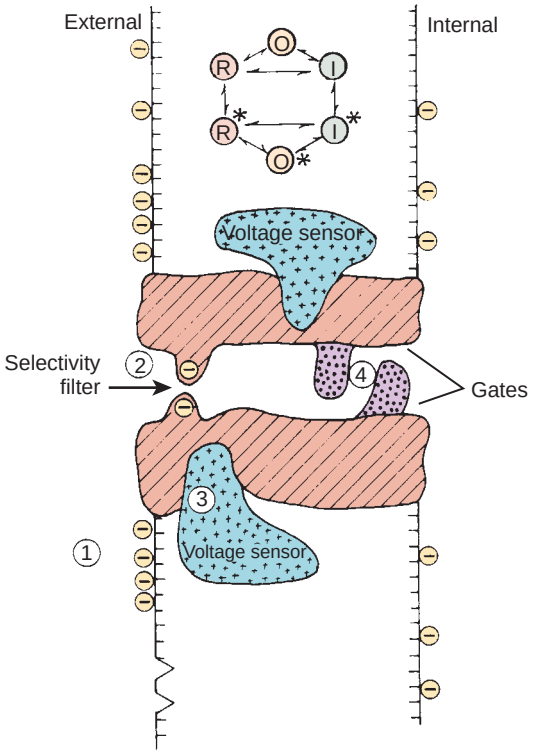

Fig. 11.26 Calcium channel depicted as a proteinaceous membrane pore. A selectivity filter *(2)* confers ion selectivity by specific molecular dimension and change density characteristics. Voltage sensor components *(3)* link membrane depolarization with channel opening and closing by the gating mechanism *(4)*. Negatively charged sites on the external surface serve as calcium binding sites *(1)*. *(From Triggle DJ. Biochemical pharmacology of calcium blockers. In: Flaim SF, Zelis R, eds.* Calcium Blockers: Mechanisms of Action and Clinical Applications. *Baltimore, MD: Urban & Schwarzenberg; 1982:121–134.)*

to the open or active state, and the channels are called *receptor-operated* channels.[710]

Based on studies with the sodium channels in the giant axons of squid, three activity states of the Ca^{2+} channel have been distinguished: resting, open, and inactive. The resting state of the Ca^{2+} channel is characterized by a closed activation *(d)* gate on the external surface of the membrane and an opened inactivation *(f)* gate on the internal surface (Fig. 11.27).[711] Depolarization triggers the open state when the *d* gate relaxes to permit Ca^{2+} influx and triggers the slower closure of the (*f*) gate, which when complete blocks further Ca^{2+} influx; the resulting inactive state persists until complete repolarization resets both gates. For the Ca^{2+} channel, the time constant for the transition from the resting to the open state is 520 ms, that from the open to the inactive state is 30 to 300 ms, and that from the inactive to the resting state is 30 to 300 ms.[712]

The use dependence seen with Ca^{2+} antagonists is the direct relation between the antagonist effect and the frequency of tissue activation. In cardiac tissue, the negative inotropic and Ca^{2+} channel blocking properties of verapamil depend on transmembrane potential and stimulation frequency; the inhibitory activity increases with increased frequency and with partial depolarization.[713] The findings may indicate that verapamil interacts primarily with the inactive (depolarized) state of the Ca^{2+} channel. The activation state of the membrane is less important for the inhibitory action of nifedipine.

The lipophilic nature of Ca^{2+} channel antagonists is important to their effect. In skinned cardiac cells, D600, a congener of verapamil, is ineffective, which appears to indicate a primary effect of the drug at the plasma membrane.[714] Likewise, quaternary ammonium derivatives of D600 and nifedipine, which are highly ionized and therefore less lipophilic, are also less effective Ca^{2+} channel antagonists.[713] The data indicate that perhaps the locus of activity of these Ca^{2+} channel antagonists is the internal surface of the channel or within the membrane itself.

The drugs commonly classified as Ca^{2+} channel antagonists, typified by verapamil, diltiazem, nifedipine, and nicardipine, exhibit specificity for vascular smooth muscle and cardiac tissues, but within the group, specificity for these tissues varies. Nifedipine and nicardipine (and other dihydropyridines) are more potent in smooth muscle than cardiac tissue, whereas verapamil and diltiazem are more potent in cardiac tissue.[715,716] Although Ca^{2+} channel antagonism is the dominant effect of these agents, at sufficiently high ($>10^{6}$ M) concentrations, other effects become notable. For example, verapamil and D600 at concentrations greater than 10^{6} M inhibit sodium channel activity and receptor binding at muscarinic, adrenergic, and opiate receptors.[717] The effects do not exhibit stereoselectivity, as does Ca^{2+} channel–specific action.[718]

Verapamil and Diltiazem

Verapamil and diltiazem have been used extensively in the treatment of supraventricular arrhythmias, AF, and atrial flutter. They are especially effective at preventing or terminating PSVT by blocking impulse transmission through the AV node by prolonging AV nodal conduction and refractoriness.[719] They are also useful in the treatment of AF and atrial flutter by slowing AV nodal conduction and decreasing the ventricular response. The effect on ventricular response is similar to that of the cardiac glycosides, although the onset is more rapid and acutely effective for control of tachycardia in patients.[720,721]

In the perioperative period, verapamil is a useful antiarrhythmic agent. In one study of anesthetized patients, it successfully controlled a variety of supraventricular and ventricular arrhythmias.[721] However, verapamil should be used with caution intraoperatively because significant cardiac depression may occur in conjunction with inhalation anesthetics.[722,723]

A significant precaution in the use of verapamil and diltiazem to treat PSVT involves preexcitation of the AV node in Wolff-Parkinson-White

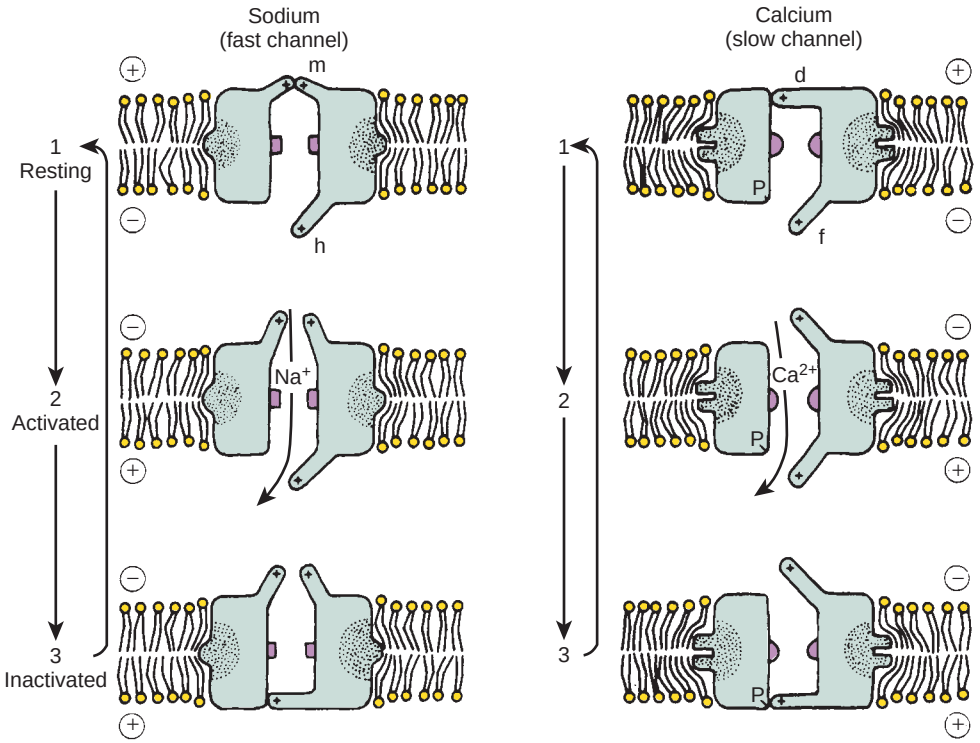

Fig. 11.27 Schematic depiction of the calcium channel in the sarcolemmal membrane. The upstroke (phase 0) of the action potential, which allows rapid entry of sodium into the cell, opens the activation gates *(m)* in the sodium channel. The resulting change in transmembrane potential closes the inactivation gate *(h),* which stops sodium influx but maintains a refractory state in the cell membrane until repolarization. Similar processes occur in the calcium channel activation gate *(d)* and inactivation gate *(f),* except that at least some of the steps in slow channel activation require phosphorylation *(P)* by a cyclic adenosine monophosphate protein kinase. Changes in the conformation of the channel proteins provide the three functional states of the channel: resting (ie, closed and able to open) *(1)*; activated (ie, open) *(2)*; and inactivated (ie, closed and unable to open in response to depolarization) *(3). (From Katz AM, Messineo FC. Lipids and membrane function: implications in arrhythmias.* Hosp Pract. *1981;16:49.)*

syndrome. If PSVT is orthodromic (ie, anterograde conduction through the AV node and retrograde over the accessory pathway) with a narrow or normal QRS complex, verapamil has a high success rate by blocking anterograde AV nodal conduction. If the PSVT is antidromic (ie, anterograde conduction through accessory pathway and retrograde over the AV node) with a widened QRS complex, successful blockade with verapamil is unlikely because it has little effect on refractoriness or conduction in accessory pathways.

Atrial flutter and AF also may occur in Wolff-Parkinson-White syndrome. In this setting, agents that shorten the ERP of the accessory pathway or increase the ERP in the AV node (eg, digitalis, verapamil) often increase the ventricular response and may precipitate VF.[724] Class I and III drugs (eg, procainamide, amiodarone) are more effective in slowing the ventricular response in AF with an accessory pathway (see Chapter 4).

Electrophysiologic effects of verapamil and diltiazem are seen predominantly in tissues in which phase 0 or 4 depolarization is largely calcium dependent (ie, SA and AV nodes). Discharge rate and recovery time in the SA, AV conduction time, and AV node ERP are prolonged. Clinically, the QRS complex and QT_c interval are not significantly affected, but AH (but not HV) conduction time is prolonged. Electrophysiologic effects of verapamil have been shown in anesthetized dogs to correlate with plasma concentration; the AH interval was prolonged at lower concentrations than were necessary to slow the SA node or to produce AV block.[725]

As with several other antiarrhythmic drugs, the pharmacokinetics of intravenously and orally administered verapamil differ. The hepatic extraction of orally administered verapamil is extensive; as a result, its bioavailability, which is normally low, is increased significantly by liver disease.[241] After intravenous administration of verapamil, plasma clearance approximates splanchnic blood flow rate, and because of its lipophilic nature, the apparent volume of distribution is large. Elimination half-life of verapamil is approximately 5 hours, but it may be longer with chronic administration, perhaps because of saturation of hepatic metabolic pathways. A principal metabolite, norverapamil, is biologically active, accumulates to concentrations equal to those of verapamil during chronic therapy, and has a longer half-life (8 to 13 hours).[726] Excretion of verapamil after metabolism is renal (65–70%), but 3% to 4% is excreted unchanged.[724] Metabolism involves *n*-dealkylation and *O*-demethylation with norverapamil (ie, one-eighth of the Ca^{2+} channel–blocking potency of verapamil) as the major metabolite.[715] Verapamil and metabolites are highly protein bound (90%).

Verapamil dosage for acute intravenous treatment of PSVT is 0.07 to 0.15 mg/kg over 1 minute, with the same dose repeated after 30 minutes if the initial response is inadequate (10 mg maximum). Because the cardiovascular depressant effects of the inhalation anesthetics involve inhibition of calcium-related intracellular processes, the interaction of verapamil and these anesthetics is synergistic. In one large clinical series, verapamil given during steady-state halothane anesthesia transiently decreased BP and produced a 4% incidence of PR-interval prolongation.[727] In laboratory studies, verapamil interacts similarly with halothane, enflurane, and isoflurane to mildly depress ventricular function and to slow AV conduction (ie, PR interval).[722] AV block can occur and may be refractory. AV block can occur when verapamil is combined with β-blockers.

Diltiazem in doses of 0.25 to 0.30 mg/kg administered intravenously and followed by a titratable intravenous infusion of 10 to 20 mg/h is rapid acting and efficacious in controlling ventricular response rate in new-onset AF and atrial flutter.[728,729] The prophylactic use of intravenous diltiazem can reduce the incidence of postoperative supraventricular arrhythmias after pneumonectomy and cardiac surgery.[730] Diltiazem also may have a role in treating ventricular arrhythmias. In an experimental model, diltiazem was protective against VF with acute cocaine toxicity.[731]

Another adverse effect of verapamil is the potentiation of neuromuscular blockade. In two laboratory studies, verapamil depressed twitch height response to indirect stimulation.[732,733] Although the exact presynaptic or postsynaptic site of the block was not determined, the qualitative similarity of the effect to that of pancuronium suggested an effect at the neuromuscular junction. At clinically relevant doses of verapamil, the effect is slight, but the clinical potential for synergistic interaction with residual muscle relaxants seems substantial. Cautious clinical attention to neuromuscular function is necessary to safely use verapamil in patients who are receiving or have recently received muscle relaxants.

Diltiazem proved equally as effective as amiodarone in managing postoperative AF occurring after lung resection surgery.[734] Another study of coronary artery surgery demonstrated that diltiazem prophylaxis reduced the incidence of AF when administered intravenously or orally.[735]

Other Antiarrhythmic Agents

Digoxin

The primary therapeutic use of digitalis drugs is to slow the ventricular response during AF or atrial flutter, which occurs because of a complex combination of direct and indirect actions on the AV node. The primary direct pharmacologic effect of digitalis is inhibition of the membrane-bound Na^+/K^+-ATPase. This enzyme provides the chemical energy necessary for the transport of sodium (out) and potassium (in) during repolarization. The glycosides bind to the enzyme in a specific saturable way that inhibits enzyme activity and impairs the active transport of sodium and potassium. The net result is a slight increase in intracellular sodium and a corresponding decrease in intracellular potassium concentration. The sodium exchanges for calcium, resulting in a relatively weak inotropic effect.

In Purkinje fibers, digoxin increases the slope of phase 4 depolarization and decreases resting potential or maximal diastolic potential so that the initiation of depolarization (phase 0) begins at a less negative potential; the V_{max} and the conduction velocity of the action potential are lower. The phase 4 effect is inversely related to extracellular potassium concentration. At low concentrations of potassium, the increased rate of phase 4 depolarization is augmented, and automaticity increases, which may partially explain the increased risk for digoxin-related toxicity during hypokalemia or pronounced potassium fluxes, such as during cardioversion or in the period immediately surrounding CPB. At concentrations approaching toxicity, digoxin produces delayed afterpotentials, which may be sufficient to reach threshold and trigger depolarization.[736–738] The direct action of therapeutic concentrations of digoxin in Purkinje fibers decreases conduction velocity and increases ERP.

In specialized conduction fibers in the SA and AV nodes, similar electrophysiologic effects occur; in both regions, however, the dominant effects are indirect and mediated by the autonomic nervous system. In atrial and ventricular muscle, direct effects resemble those in Purkinje fibers. The indirect effects of digitalis, notably a decreased APD, account for the decreased QT interval on the electrocardiogram. Effects of this drug during phases 2 and 3 of the action potential account for the characteristic downward convexity of the ST segment.[739]

Digoxin increases vagal efferent activity, the origin of which may correlate with increased sensitivity of arterial baroreceptors and increased carotid sinus nerve activity or be related to an effect on the central vagal nuclei.[740–743] SA node sensitivity to acetylcholine may be enhanced by digoxin. In high concentrations, digoxin may decrease SA and AV nodal sensitivities to catecholamines and sympathetic stimulation, although this may be because of increased sympathetic efferent activity produced by the CNS (ie, medulla) effects of digoxin and the inhibition of norepinephrine uptake at peripheral sympathetic nerve terminals.[741,742] The decreased sinus rate seen with digoxin in part results from increased vagal efferent activity and decreased sympathetic tone.

The AV node is the portion of the conduction system most strongly influenced by the direct and indirect effects of digoxin. Conduction through the AV node is slowed, and the ERP of the AV node is lengthened by digoxin. In toxic concentrations, digoxin can effectively block AV nodal transmission.

In atrial tissue, the direct and indirect (vagal) effects of digoxin are opposed. The direct effect is an increase in APD, but the indirect effect (mediated by acetylcholine release) is marked decreases in APD and ERP. At therapeutic concentrations, the indirect effect predominates, which makes the atria responsive to higher stimulation frequencies.[739] The frequency of atrial impulses arriving at the AV node usually is increased, which leads to frequent partial depolarization of the AV node (ie, concealed conduction). This effect and the increased AV nodal ERP produced by direct effects, vagal effects, and sympatholytic effects result in a net decrease in the frequency of impulses that successfully traverse the AV node to depolarize the His-Purkinje system.

The main preparation of cardiac glycosides available is digoxin. Digoxin reaches peak effects in 1.5 to 2 hours but has a significant effect within 5 to 30 minutes. For undigitalized patients, the initial dose is 0.5 to 0.75 mg of digoxin, with subsequent doses of 0.125 to 0.25 mg. The usual total digitalizing dose is 0.75 to 1.0 mg administered by the intravenous route. Digoxin is approximately 25% protein bound, and the therapeutic range of plasma concentrations is 0.5 to 2.0 ng/mL.

Adenosine

Adenosine is a virtually ubiquitous endogenous nucleoside that has potent electrophysiologic effects in addition to having a major physiologic role in regulation of vasomotor tone.[743] Adenosine is unique in that it is produced as an intermediate metabolite of adenosine monophosphate. It has an extremely short half-life in plasma (on the order of 1.5 to 2 seconds) because of metabolism by adenosine deaminase to inosine or by adenosine kinase to adenosine monophosphate. Both enzymes are contained within the intracellular cytosolic compartment, indicating a rapid transmembrane transport system for adenosine. Inhibition of this transport system by dipyridamole markedly enhances the cardiac effects of adenosine.

The important cardiac electrophysiologic effects of adenosine are mediated by the A_1 receptor and consist of negative chronotropic, dromotropic, and inotropic actions. Adenosine decreases SA node activity, AV node conductivity, and ventricular automaticity. In many ways, these effects mimic those of acetylcholine. The A_1 receptor is linked to the ionic channel for K^+ and Ca^{2+} and to adenylyl cyclase through the guanine nucleotide–binding inhibitory protein (G_i). Activation of the A_1 receptor in the SA and AV nodes activates the outward acetylcholine-adenosine–regulated potassium current. In ventricular myocardium, adenosine antagonizes the stimulation of the inward Ca^{2+} current produced by catecholamines. The primary antiarrhythmic effect of adenosine is to interrupt reentrant AV nodal tachycardia, and this effect most likely is related to the potassium current effects.

For clinical use, adenosine must be administered by a rapid intravenous bolus in a dose of 100 to 200 μg/kg, although continuous intravenous infusions of 150 to 300 μg/kg per minute have been used to produce controlled hypotension. For practical purposes, in adults, a dose of 3 to 6 mg is given by intravenous bolus followed by a second dose of 6 to 12 mg after 1 minute if the first dose was not effective. This therapy rapidly interrupts narrow-complex tachycardia caused by AV nodal reentry.[744]

Comparison with verapamil has shown adenosine to be equally effective as an antiarrhythmic, but with the advantages of fewer adverse hemodynamic effects, a faster onset of action, and a more rapid elimination so that undesired effects are short-lived.[745] The median effective close range (MD_{50}) of adenosine for reentrant supraventricular arrhythmias in children is 100 to 150 μg/kg.[746]

Potassium

Because of the close relationship between extracellular pH and potassium, the primary mechanism of pH-induced arrhythmias may be alteration of potassium concentration. Hypokalemia and hyperkalemia are associated with cardiac arrhythmias, but hypokalemia is more common perioperatively in cardiac surgical patients and is more often associated with arrhythmias.[747] Decreasing the extracellular potassium concentration increases the peak negative diastolic potential, which appears to decrease the likelihood of spontaneous depolarization. However, because the permeability of the myocardial cell membrane to potassium is directly related to extracellular potassium concentration, hypokalemia decreases cellular permeability to potassium. This prolongs the action potential by slowing repolarization, which slows conduction, increases the dispersion of recovery of excitability, and predisposes to the development of arrhythmias.

ECG correlates of hypokalemia include appearance of a U wave and increased P-wave amplitude.[748] The arrhythmias most commonly associated with hypokalemia are premature atrial contractions, atrial tachycardia, and supraventricular tachycardia. Hypokalemia also accentuates the toxicity of cardiac glycosides.

Moderate hyperkalemia, in contrast, increases membrane permeability to potassium, which increases the speed of repolarization and decreases APD, reducing the tendency to arrhythmias. An increased potassium concentration also affects pacemaker activity. The increased potassium permeability caused by hyperkalemia decreases the rate of spontaneous diastolic depolarization, which slows heart rate and, in the extreme case, can produce asystole. The repolarization abnormalities of hyperkalemia lead to the characteristic ECG findings of T-wave peaking, prolonged PR interval, decreased QRS amplitude, and a widened QRS complex.[749] AV and intraventricular conduction abnormalities result from the slowed conduction and uneven repolarization.

Treatment of hyperkalemia is based on its magnitude and on the clinical presentation. For life-threatening, hyperkalemia-induced arrhythmias, the principle is rapid reduction of extracellular potassium concentration, a treatment that does not acutely decrease total body potassium content. Calcium chloride (10 to 20 mg/kg given by intravenous infusion) directly antagonizes the effects of potassium on the cardiac cell membranes. Sodium bicarbonate in dose of 1 to 2 mEq/kg or a dose calculated from acid-base measurements to produce moderate alkalinity (pH ≈ 7.45 to 7.50) will shift potassium intracellularly. A change in pH of 0.1 unit produces a 0.5- to 1.5-mEq/L change of potassium concentration in the opposite direction. An intravenous infusion of glucose and insulin has a similar effect; glucose at a dose of 0.5 to 2.0 g/kg with insulin in the ratio of 1 unit to 4 g of glucose is appropriate. Sequential measurement of serum potassium levels is important with this treatment because marked hypokalemia can result. Loop diuretics and potassium-binding resins promote excretion of potassium, although the effects are less rapid than with the previously mentioned modalities.

With chronic potassium deficiency, the plasma level poorly reflects the total body deficit. Because only 2% of total body potassium is in plasma and total body potassium stores may be 2000 to 3000 mEq, a 25% decline in serum potassium from 4 to 3 mEq/L indicates an equilibrium total body deficiency of 500 to 800 mEq, replacement of which should be undertaken slowly.

Acute hypokalemia frequently occurs after CPB as a result of hemodilution, urinary losses, and intracellular shifts,[750] with the latter perhaps relating to abnormalities of the glucose-insulin system seen with nonpulsatile hypothermic CPB.[751] With frequent assessment of serum potassium concentrations and continuous ECG monitoring, potassium infusion at rates of up to 10 to 15 mEq/h may be administered to treat serious hypokalemia.

Magnesium

Magnesium deficiency is a relatively common electrolyte abnormality in critically ill patients, especially in chronic situations. Hypomagnesemia is associated with a variety of cardiovascular disturbances, including arrhythmias.[752,753] Sudden death from CAD, alcoholic cardiomyopathy, and CHF may involve magnesium deficiency.[752–754]

Functionally, magnesium is required for the membrane-bound Na^+/K^+-ATPase, which is the principal enzyme that maintains normal intracellular potassium concentration. Not surprisingly, the ECG findings seen with magnesium deficiency mimic those seen with hypokalemia: prolonged PR and QT intervals, increased QRS duration, and ST-segment abnormalities. As with hypokalemia, magnesium deficiency predisposes to the development of the arrhythmias produced by cardiac glycosides.[755,756] Magnesium is effective as an adjuvant in the treatment of patients with a prolonged QT syndrome and torsades de pointes.[757]

Arrhythmias induced by magnesium deficiency may be refractory to treatment with antiarrhythmic drugs and electrical cardioversion or defibrillation. Adjunctive treatment of refractory arrhythmias with magnesium has been advocated even when magnesium deficiency has not been documented.[758] Magnesium deficiency is common in cardiac surgery patients because of the diuretic agents these patients are often receiving and because magnesium levels decrease with CPB because of hemodilution of the pump. Magnesium lacks a counterregulatory hormone to increase magnesium levels during CPB, in contrast to the hypocalcemia that is corrected by parathyroid hormone. The results of magnesium administration trials involving CABG have been conflicting. Some studies have shown a benefit, and others have not in regard to reducing the incidence of postoperative arrhythmias.

Magnesium has been studied alone and in combination with other drugs in the prophylaxis and treatment of perioperative arrhythmias. In younger patients with good LV function, magnesium reduced the incidence of AF after CABG surgery.[759] Magnesium supplementation after CPB in which the serum magnesium level returned to normal reduced the incidence of AF.[760] A protocol using magnesium as first-line therapy and amiodarone as backup therapy appears effective in management of arrhythmias after surgery, as well as in critically ill patients.[761,762] Combination therapy with magnesium and sotalol after CABG reduced the incidence of AF.[763] A metaanalysis of 15 RCTs showed magnesium to be effective at preventing AF in coronary artery surgery.[764] However, magnesium added to oral β-blocker prophylaxis did not reduce the incidence of atrial arrhythmias.[765]

12 Electrocardiographic Monitoring

LEON FREUDZON, MD | SHAMSUDDIN AKHTAR, MBBS | MARTIN J. LONDON, MD | PAUL G. BARASH, MD

KEY POINTS

1. The electrocardiogram reflects differences in transmembrane voltages in myocardial cells that occur during depolarization and repolarization within each cycle.
2. Processing of the electrocardiogram occurs in a series of steps.
3. Where and how electrocardiographic (ECG) electrodes are placed on the body are critical determinants of the morphology of the ECG signal.
4. ECG signals must be amplified and filtered before display.
5. How accurately the clinician places ECG leads on the patient's torso is probably the single most important factor influencing clinical utility of the electrocardiogram.
6. The ST segment is the most important portion of the QRS complex for evaluating ischemia.
7. Use of inferior leads (II, III, aVF) allows superior discrimination of P-wave morphology and facilitates visual diagnosis of arrhythmias and conduction disorders.
8. Electrolyte abnormalities typically cause changes in repolarization (ST-T-U waves).

As late as 1970, the electrocardiographic (ECG) monitor was not considered an integral part of monitoring strategies in the perioperative period. As a matter of fact, luminaries in the specialty regarded the use of ECG monitoring as "questionable value because of possible iatrogenic problems." Concern was also expressed that the anesthesiologist's attention would be diverted from the patient.[1] Currently, monitoring the electrocardiogram is a fundamental standard of monitoring of the American Society of Anesthesiologists.[2] Despite the introduction of more sophisticated cardiovascular monitors such as the pulmonary artery catheter and echocardiography, the electrocardiogram (coupled with blood pressure measurement) serves as the foundation for guiding cardiovascular therapeutic interventions in the majority of anesthetic cases.[3] It is indispensable for diagnosing arrhythmias, acute coronary syndromes, and electrolyte abnormalities (particularly of serum potassium and calcium) and in the detection of some forms of genetically mediated electrical or structural cardiac abnormalities (eg, Brugada syndrome) (Box 12.1).[4]

One of the most important changes in electrocardiography is the widespread use of computerized systems for recording electrocardiograms. Bedside units are capable of recording diagnostic-quality 12-lead electrocardiograms that can be transmitted over a hospital network for storage and retrieval. Most of the electrocardiograms in the United States are recorded by digital, automated devices, equipped with software, that can measure ECG intervals and amplitudes and can provide virtually instantaneous interpretation. However, various automated systems may have different technical specifications that can result in significant differences in the measurement of amplitudes, intervals, and diagnostic statements.[5,6] The diagnostic specificity and sensitivity of the electrocardiogram to diagnose a particular abnormality are also not consistent. For example, finite limits are defined by the relationship between sensitivity and specificity (usually inversely related) for detecting obstructive coronary artery disease (CAD). During exercise testing, the 12-lead electrocardiogram has a mean sensitivity of only 68% and a specificity of 77%.[7,8] The resting 12-lead electrocardiogram is even less sensitive and specific.[8] In this chapter, the theory and the operating characteristics of ECG hardware used in the perioperative period are presented to facilitate proper use and interpretation of monitoring data. Sources of artifacts, changes associated with respirations, electrolyte disturbances, and medications are also discussed.

Historical Perspective

An extensive review of the history of electrocardiography is beyond the scope of this chapter. However, several excellent reviews were published in honor of the centennial of the first recording of the human electrocardiogram.[9–14] Willem Einthoven is universally considered the father of electrocardiography (for which he won the 1924 Nobel Prize for Medicine/Physiology). Many of the basic clinical abnormalities in electrocardiography were first described using the string galvanometer (eg, bundle branch block, delta waves, ST-T wave changes with angina). It was used until the 1930s, when it was replaced by a system using vacuum tube amplifiers and a cathode ray oscilloscope. With advances in electrical engineering technology, the devices became more compact, portable, and user friendly. In 1950s, a portable direct writing ECG cart was introduced. The first analog-to-digital (A/D) conversion systems for the electrocardiogram were introduced in the early 1960s, although their off-line use was impractical and restricted until the late 1970s. In the 1980s, microcomputer technology became widely available and is now standard for all diagnostic and monitoring systems. Further improvement in hardware and software design led to the development of automated ST-analysis algorithms and their use in routine clinical practice.

Basic Electrophysiology and Electrical Anatomy of the Heart

The electrocardiogram is the final result of a complex series of physiologic and technologic processes.[15] Physiologically, the electrocardiogram reflects differences in transmembrane voltages in myocardial cells that occur during depolarization and repolarization within each cycle. Ionic currents are generated as a result of ionic fluxes across cell membranes in myocardial cells during depolarization and repolarization. The cardiac cells are contiguous and electrically connected by ion channels (gap junctions), which allow the ion current to pass through the cells and spread depolarization.[16] Thus the membrane potential changes in the heart can be considered a single depolarization that propagates through the whole heart and assumes different forms along the way.[16] The pattern and sequence of depolarization that occur in the heart are depicted in Fig. 12.1. Many different types and subtypes of ion channels are involved in the synchronized generation of electrical

activity in the heart. Of note are the sodium, potassium, calcium, and chloride channels.[15–17] Detailed discussion of these channels is beyond the scope of this chapter.

At any point in time, the electrical activity of the heart is composed of differently directed electrical forces. However, these currents are synchronized by cardiac activation and recovery sequences to generate a cardiac electrical field in and around the heart that varies with time during the cardiac cycle. This cardiac electrical field passes through various internal structures such as lungs, blood, and skeletal muscles. The currents also reach the skin and are detected by the electrodes that are placed in specific locations on the body. The electrodes are uniquely configured to produce different ECG patterns or waveforms. The direction and strength of a lead vector depend on the geometry of the body and on the varying electric impedances of the tissues in the torso.[18,19] As expected, placement of electrodes on the torso is distinct from direct placement on the heart because the localized signal strength that occurs with direct electrode contact is markedly attenuated and altered by torso inhomogeneities that include thoracic tissue boundaries and variations in impedance of different tissues. The standard 12-lead electrocardiogram records potential differences (represented as change of voltage over time) among prescribed sites on the body surface that vary during the cardiac cycle.[4]

The first deflection noted on the electrocardiogram is caused by atrial depolarization and is called the P wave. Although the depolarization of the sinoatrial node precedes the atrial depolarization (see Fig. 12.1), the potentials from these pacemaker cells are too small to be detected on surface electrocardiogram. The width of the P wave reflects the time taken for the wave of depolarization to spread over both the right and left atria. In comparison with the ventricular action potential, the atrial action potential is narrower and has a less prominent plateau. The duration of atrial contraction is thus shorter, and this permits another action potential to occur sooner and makes the atria prone to a very high rate (atrial flutter). The repolarization atrial wave is rarely seen in the normal electrocardiogram because it is buried in the much larger QRS wave.

The electrocardiogram returns to its baseline between the end of atrial depolarization and the commencement of the QRS complex, which is the start of the QRS ventricular depolarization. This interval is called the PR interval. Although this period may seem electrically silent, it is a time of significant electrical activity. During this period the wave of depolarization that started in the sinoatrial node is propagated through the atrioventricular (AV) node, AV bundle, right and left bundle branches, and Purkinje fibers (see Fig. 12.1).

The QRS complex is generated by potential differences that originate from the rapid depolarization of the ventricular myocardium (phase 0). The duration of the QRS complex (ventricular depolarization) is very similar to that of the P wave (atrial depolarization). However, the amplitude of the QRS complex is significantly greater than that of the P wave because the ventricular mass is much larger than that of atria. The duration of the QRS complex can be increased

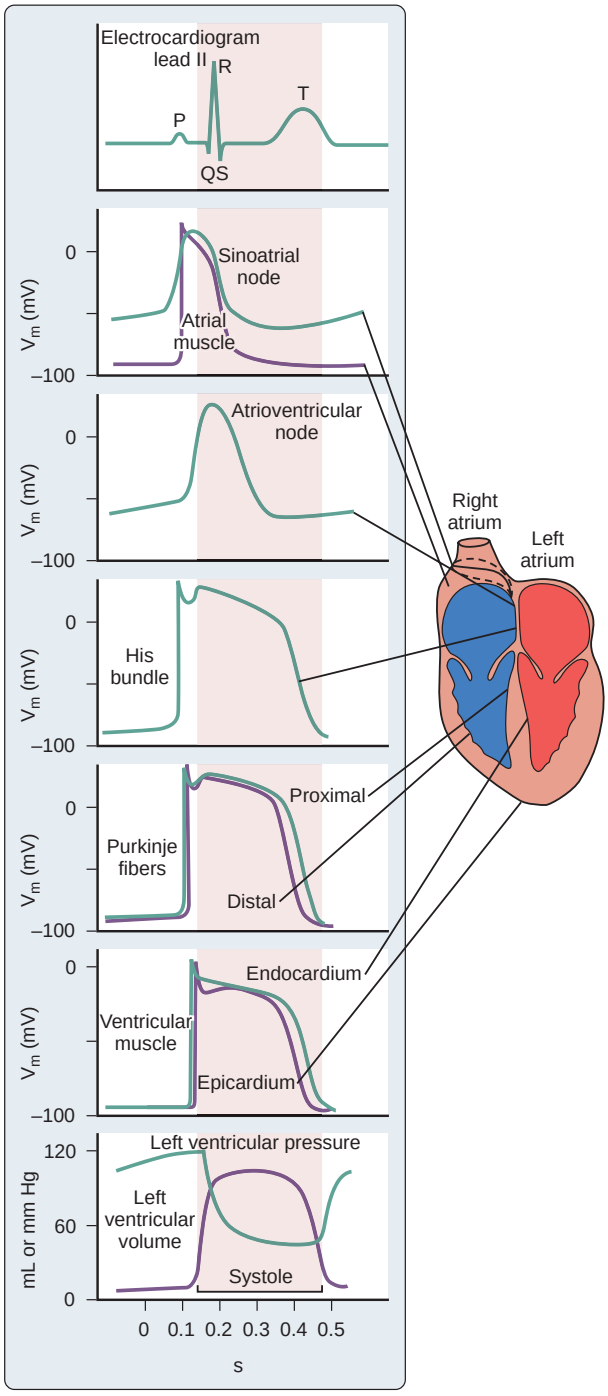

Fig. 12.1 The action potential of an automatic cell such as the sinoatrial node differs from that of the ventricular muscle cell in that the cell slowly depolarizes spontaneously during phase 4. The inward current If is responsible for diastolic depolarization. The action potential in a Purkinje cell has the fastest rate of depolarization, 400 to 800 V/s. When the cell is stimulated, an action potential results from a rapid influx of sodium ions (inward current) into the cell (phase 0). Phase 1 includes a notch caused by the "early outward current," Ito, which is a transient potassium (K) efflux, probably activated by an intracellular calcium increase. Phase 2 is the plateau of the action potential resulting principally from calcium entry (inward currents I_{CaL} and I_{CaT}) through the slow channel of the cell membrane. During phase 3, repolarization of the cell occurs (outward current IK1), whereas during phase 4, the sodium entering during phase 0 is actively pumped out of the cell. In a ventricular muscle cell, unlike in the automatic cells, no spontaneous phase 4 depolarization occurs. *(From Lynch C, Lake CL. Cardiovascular anatomy and physiology. In: Youngberg J, Lake C, Roizen M, et al, eds.* Cardiac, Vascular, and Thoracic Anesthesia. *Philadelphia: Churchill Livingstone; 2000:87.)*

when conduction through one of the bundle branches is blocked or a ventricle is depolarized by an ectopic focus that depolarizes one of the ventricles sooner than the other.

The QRS wave is followed by a period when the electrocardiogram returns to the baseline that is called the ST segment. It is a time when the ventricle is completely depolarized and is represented by phase 2 of the action potential (see Fig. 12.1). Even though the ventricles are depolarized, the electrocardiogram does not record any positive or negative waveforms because the whole ventricles are depolarized and no potential difference exists among sites. The electrocardiogram does not measure absolute level of membrane potential but records only the potential differences.[15] The same explanation also holds true for the T-P segment, which represents a time when the ventricles are fully repolarized; hence no significant potential difference is recorded on a surface electrocardiogram.

A T wave is generated by repolarization of the ventricles. Repolarization proceeds slowly and is not caused by a propagated wave; the T wave therefore is broad and of longer duration. The T wave is also a positive wave, although it represents repolarization. This is because the repolarization current is in the opposite direction from depolarization, moving from the epicardium to the endocardium. It is influenced by many local factors such as electrochemical potentials, temperature, adrenergic state, myocardial blood supply, myocardial hypertrophy, and scarring.[20]

The time between the onset of the QRS complex and the end of the T wave is called the QT interval and gives a useful measure of ventricular action potential duration. The duration of QT interval varies with heart rate and must be adjusted to improve detection of repolarization abnormalities. This "corrected" QT interval or QTc is usually less than 400 ms, and patients with a QTc interval greater than 450 ms are at risk for ventricular tachyarrhythmias.[21] Measurement of this interval can be used to evaluate for certain diseases or effects of certain medications on ventricular repolarization. QT-interval prolongation is very important clinically because delayed repolarization is a substrate for arrhythmias and sudden death.

Sometimes a small (0.5-mm) positive deflection can be seen after the T wave but before the next P wave. This is called a U wave. The source of the U wave is unknown. Three common theories regarding its origin are (1) delayed repolarization of Purkinje fibers, (2) prolonged repolarization of midmyocardial "M-cells" (specialized midmyocardial cells with prolonged action potentials), and (3) afterpotentials resulting from mechanical forces in the ventricular wall.[15]

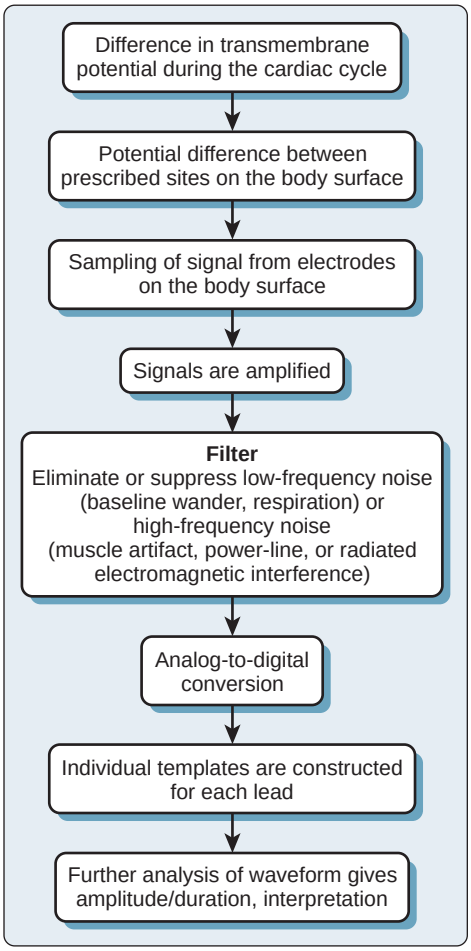

Fig. 12.2 Schematic representation of the processes resulting in recording of the electrocardiogram.

Technical Aspects of the Electrocardiogram

Most clinicians assume that the electrocardiogram is a relatively simple technical device. However, an extensive amount of advanced electrical theory underlies both the recording and display of the ECG signal. Digital signal processing (DSP) is now universally used, and the average ECG unit incorporates several microprocessors. Anesthesiologists should familiarize themselves with the theory behind ECG acquisition, to maximize rational clinical application and appreciate its clinical limitations. In this section, the basics of electrocardiography are presented, with brief consideration of the major components involved in the faithful rendition of the surface electrocardiogram, working from the skin and electrodes progressively to the final output on the screen. The reader is referred to technical reviews for more detail.[4,5,12,22–25]

Processing of the electrocardiogram occurs in a series of steps as shown in Fig. 12.2.[4] These steps include the following[4]:

1. Signal acquisition, including filtering
2. Data transformation, or rendition of data for further processing, including finding the complexes, classifying the complexes into "dominant" and "nondominant" (ectopic) types, and forming an average or median complex for each lead
3. Waveform recognition, which is the process for identification of the onset and offset of the diagnostic waves
4. Feature extraction, which is the measurement of intervals and amplitudes and is used for bedside 12-lead ECG machines
5. Diagnostic classification

Diagnostic classification may be heuristic (ie, deterministic, or based on experience-based rules) or statistical in approach.[26]

Signal Acquisition and Power Spectrum of the Electrocardiogram

To appreciate ECG signal acquisition it is relevant to consider an ECG signal in terms of its amplitude (or voltage) and its frequency components (generally called its phase). Voltage considerations differ depending on the signal source. Surface recording involves amplification of smaller voltages (on the order of 1 mV) at the recording sites closer to the heart beneath the electrically resistant layers of the skin (eg, endocardial, esophageal, and intratracheal leads). The "power spectrum" of the electrocardiogram (Fig. 12.3) is derived by Fourier transformation, in which a periodic waveform is mathematically decomposed to its harmonic components (sine waves of various amplitudes and frequencies).

The fundamental frequency for the QRS complex at the body surface is approximately 10 Hz, and most of the diagnostic information is contained at frequencies lower than 100 Hz in adults. Spectra representing some of the major sources of artifact must be eliminated during the processing and amplification of the QRS complex.[24] The frequency of each of these components can be equated to the slope of the component signal.[6] The R wave with its steep slope is a high-frequency component (100 Hz), whereas P and T waves have lesser slopes and are lower in frequency (1–2 Hz). The ST segment has the lowest frequency, not much different from the "underlying" electrical (ie, isoelectric) baseline of the electrocardiogram. Before the introduction of DSP, accurately displaying the ST segment presented significant

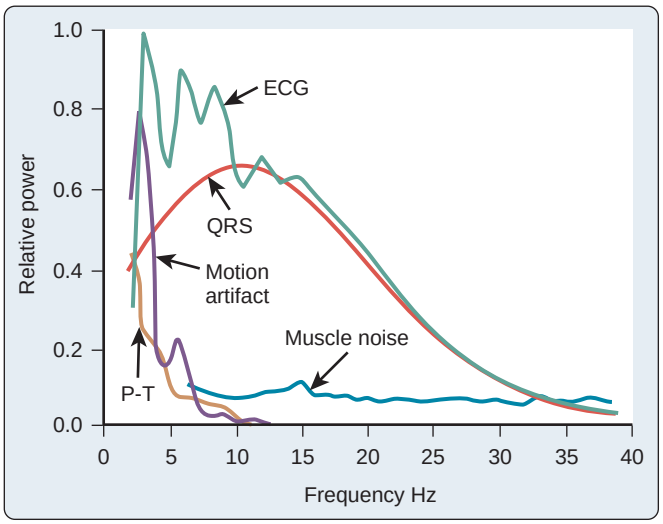

Fig. 12.3 The typical power spectrum of the electrocardiogram signal (obtained during ambulatory monitoring), including its subcomponents and common artifacts (ie, motion and muscle noise). The power of the P and T waves *(P-T)* is low frequency, and the QRS complex is concentrated in the midfrequency range, although residual power extends up to 100 Hz. *(From Thakor NV. From Holter monitors to automatic defibrillators: developments in ambulatory arrhythmia monitoring.* IEEE Trans Biomed Eng. *1984;31:770.)*

TABLE 12.1 Range of Signal Frequencies Included in Different Phases of Processing in an Electrocardiographic Monitor

Processing	*Frequency Range*
Display	0.5 (or 0.05)–40 Hz
QRS detection	5–30 Hz
Arrhythmia detection	0.05–60 Hz
ST-segment monitoring	0.05–60 Hz
Pacemaker detection	1.5–5 kHz

technical problems, particularly in the operating room and for ECG monitoring units in critical care units.

Although the overall frequency spectrum of the QRS complex does not appear to exceed 40 Hz, many components of the QRS complex, particularly the R wave, can exceed 100 Hz. The American Heart Association (AHA) recommended a bandwidth of 0.05 to 100 Hz for monitoring and detection of myocardial ischemia.[4] Very-high-frequency signals of particular clinical significance are pacemaker spikes. Their short duration and high amplitude present technical challenges for proper recognition and rejection to allow accurate determination of the heart rate. The frequencies of greatest importance for optimal ECG processing are presented in Table 12.1.[5]

Digital Signal Processing of the Electrocardiogram

Processing of the ECG signal by a digital electrocardiograph involves initial sampling of the signal from electrodes on the body surface. Nearly all current-generation ECG machines convert the analog ECG signal to digital form before further processing. The foundation of DSP is the A/D converter, which samples the incoming "continuous" analog signal (characterized by variable amplitude or voltage over time) at a very rapid rate, thus converting the sampled voltage into binary numbers, each of which has a precise time index or sequence. Higher sampling rates (10,000–15,000/s or higher) help detect pacemaker output reliably, which is typically less than 0.5 ms in duration. Several technical recommendations regarding low-frequency filtering and high-frequency filtering were published by the AHA.[4]

Computerized ECG processing has been adapted to all major clinical applications of the electrocardiogram. The earliest application of A/D signal processing occurred during exercise tolerance testing, in which significant motion artifact and electromyographic noise made acquisition of a "clean" ECG signal difficult. Outside the exercise treadmill laboratory, computer processing allows automated analysis of the diagnostic 12-lead electrocardiogram.[27] The reader is referred elsewhere for more detailed discussions of this technology, and to the reports of the scientific council of the AHA on standardization and specifications for automated electrocardiography and bedside monitors.[4,27–30]

Formation of a Representative Single-Lead Complex

After A/D conversion, the resultant data bits are inspected by a microprocessor using a form of mathematical construct to determine where reference points ("fiducial points") are located. A common method locates the point of most rapid change in amplitude (located on the down slope of the R wave). This process characterizes the baseline QRS complex (QRS recognition) and provides a "template" on which subsequent beats are overlaid (beat alignment) and averaged (signal averaging). This not only allows visual display of the QRS complex and quantification of its components, but also eliminates random electrical noise and wide complex beats that fail to meet criteria established by the fiducial points.

QRS waveform amplitudes and durations are subject to beat-to-beat variability and to respiratory variability between beats. Digital electrocardiograms can adjust for respiratory variability and decrease beat-to-beat noise to improve the measurement precision in individual leads by forming a representative complex for each lead. Signal averaging is a critical component of this process. By using this technique, noise is reduced proportionally by the square root of the number of beats averaged.[4] Thus a 10-fold reduction in noise is accomplished by averaging only 100 beats. Automated measurements are made from these representative templates, not from measurement of individual complexes. Average complex templates are formed from the average amplitude of each digital sampling point for selected complexes. Median complex templates are formed from the median amplitude at each digital sampling point. As a result, measurement accuracy strongly depends on the fidelity with which representative templates are formed.

Because of the proprietary nature of this technology (the specific algorithms used are patented), the methods used vary by manufacturer. Consequently, the processed QRS complexes may vary in the "quality" of representation (ie, if noise or aberrant beats are averaged into the complex, they will vary from the raw analog complex). The averaging process involves comparison of the voltages at a particular time point between the incoming complex and the template. Although the easiest method is to use the mean difference between voltages to update the "template," the most accurate method is to use the median (because it is less affected by outliers, such as aberrant beats or other signals that have escaped QRS matching)[4] (Fig. 12.4).

A feature incorporated into most monitors is a visual trend line from which deviations in the position of the ST segment can be rapidly detected, a feature that can aid online detection of ischemia. In addition, nearly all monitors display on-screen numeric values for the position of the ST segment used for ischemia detection (generally 60–80 ms after the J point), although the specific fiducial point used (based on heart rate), can be adjusted by the clinician (Fig. 12.5).

History and Description of the 12-Lead System

Where and how ECG electrodes are placed on the body are critical determinants of the morphology of the ECG signal. Lead systems have been developed based on theoretical considerations and references to anatomic landmarks that facilitate consistency among individual patients (eg, standard 12-lead system). Einthoven established electrocardiography using three extremities as references: the left arm (LA), right arm (RA), and left leg (LL). He recorded the difference in

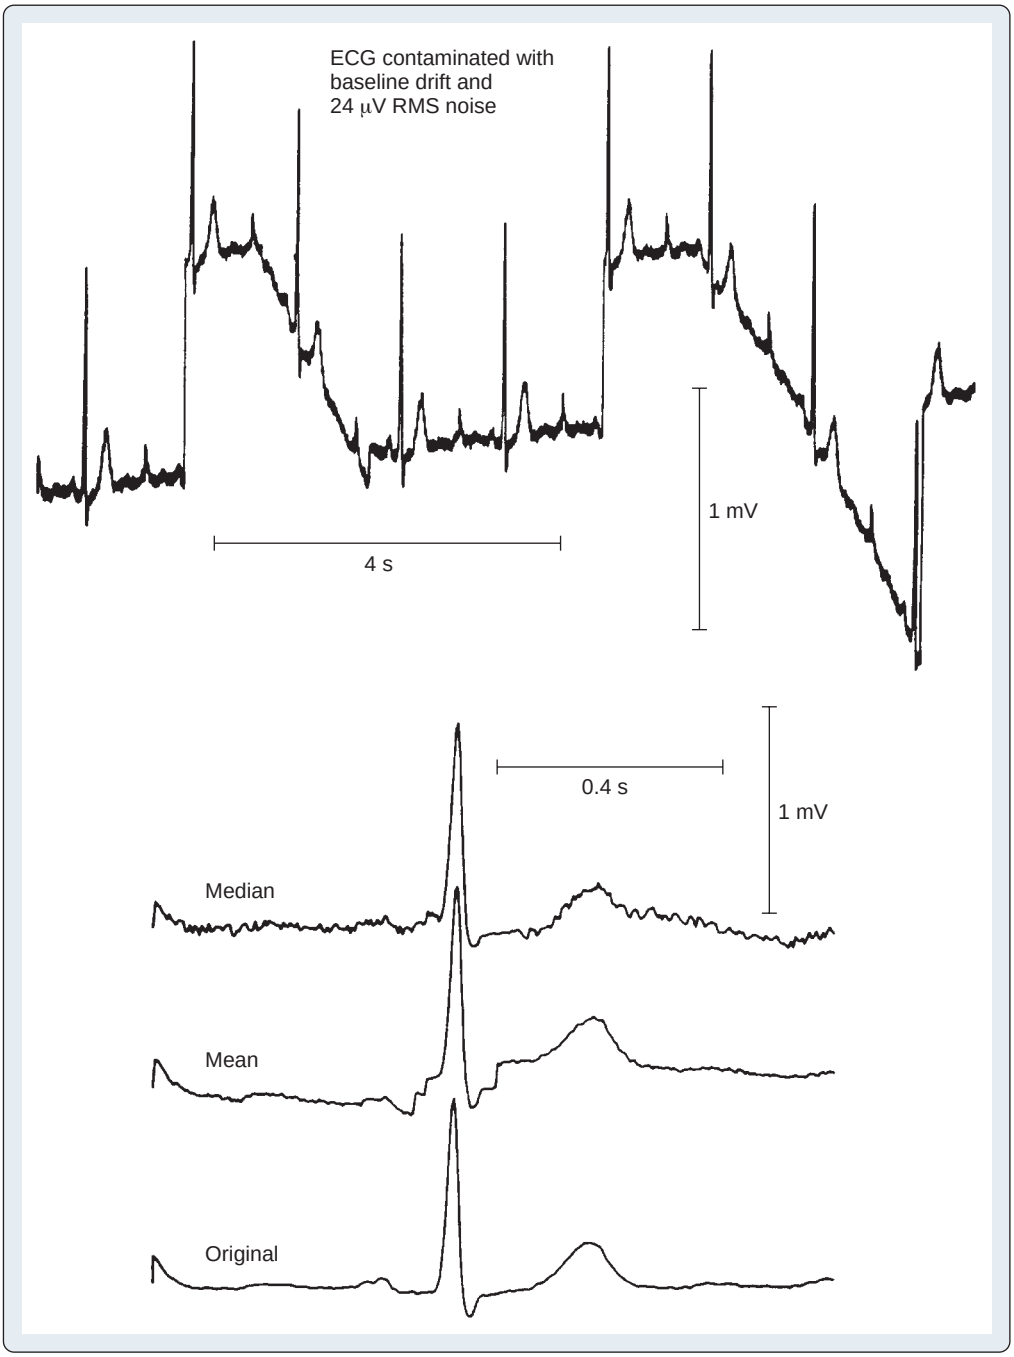

Fig. 12.4 Effects of averaging techniques on resolution of an electrocardiographic signal heavily contaminated with baseline and electrical noise. Despite a greater degree of baseline and electrical noise, median averaging results in a more accurate rendition of the original signal. Notice the abnormal J-point elevation in the mean averaged complex. *RMS,* Root mean square. *(From Froelicher VF. Special methods: computerized exercise ECG analysis. In:* Exercise and the Heart. *Chicago: Year Book; 1987:36.)*

potential between the LA and RA (lead I), between the RA and LL (lead II), and between the LA and LL (lead III) (Fig. 12.6). Because the signals recorded were differences between two electrodes, these leads were called bipolar. The RL served only as a reference electrode. Because the Kirchhoff loop equation states that the sum of the three voltage differential pairs must equal zero, the sum of leads I and III must equal lead II.[23]

The positive or negative polarity of each of the limbs was chosen by Einthoven to result in positive deflections of most of the waveforms and has no innate physiologic significance. He postulated that the three limbs defined an imaginary equilateral triangle with the heart at its center. Wilson refined and introduced the precordial leads into clinical practice. To implement these leads, he postulated a mechanism whereby the absolute level of electrical potential could be measured at the site of the exploring precordial electrode (the positive electrode). A negative pole with zero potential was formed by joining the three limb electrodes in a resistive network in which equally weighted signals cancel each other out. He called this the central terminal, and

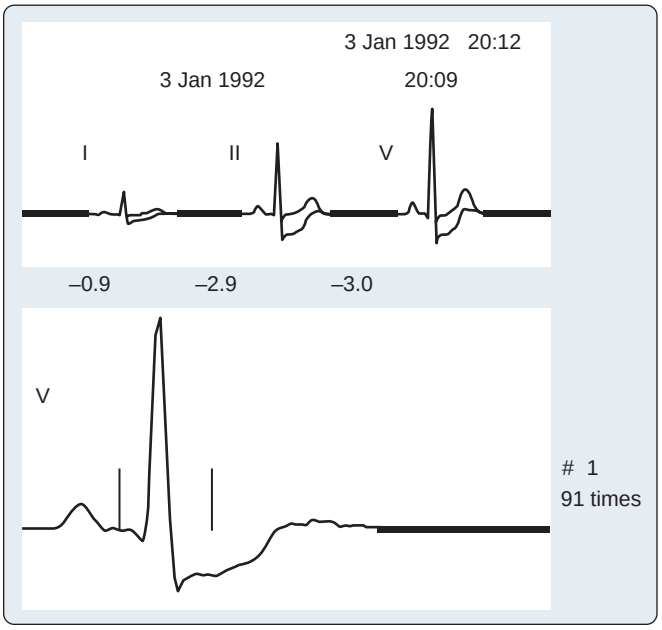

Fig. 12.5 The graphic output of the ST-segment adjustment window from a Marquette Electronics Series 7010 monitor (Milwaukee, WI) ST-segment analyzer. This software allows trending and display of three leads (ie, I, II, and any single V lead). In this window, the initial complex ("learned" when the program was activated) is displayed along with the current complex. Two complexes are superimposed with different intensities to facilitate comparison. ST-segment analysis is performed automatically at 80 ms after the J point, although the user can manually adjust this. The number of QRS complexes that are input to the monitor is displayed. *(From Reich DL, Mittnacht A, London M, Kaplan J. Monitoring of the heart and vascular system. In: Kaplan JA, Konstadt SN, Reich DL, eds.* Kaplan's Cardiac Anesthesia. *5th ed. Philadelphia: Saunders; 2006.)*

in a fashion similar to Einthoven's vector concepts, he postulated that it was located at the electrical center of the heart, representing the mean electrical potential of the body throughout the cardiac cycle. He described three additional limb leads (aVL, aVR, and aVF) (Fig. 12.7). These leads measured new vectors of activation, and in this way the hexaxial reference system for determination of the electrical axis was established. He subsequently introduced the six unipolar precordial V leads in 1935 (see Fig. 12.6).[31]

Six electrodes are placed on the chest in the following locations: V_1, fourth intercostal space at the right sternal border; V_2, fourth intercostal space at the left sternal border; V_3, midway between V_2 and V_4; V_4, fifth intercostal space in the midclavicular line; V_5, in the horizontal plane of V_4 at the anterior axillary line, or, if the anterior axillary line is ambiguous, midway between V_4 and V_6; and V_6, in the horizontal plane of V_4 at the midaxillary line[4] (see Fig. 12.6).

Clinical application of the unipolar limb leads was limited because of their significantly smaller amplitude relative to the bipolar limb leads from which they were derived. They were not clinically applied until Goldberger augmented their amplitude (by a factor of 1.5) by severing the connection between the central terminal and the lead extremity being studied (which he called augmented limb leads) in 1942. The limb leads, the precordial leads, and the augmented unipolar limb leads form what was accepted by the AHA as the conventional 12-lead ECG system.[32] Einthoven's law indicates that any one of the standard limb leads can be mathematically derived from the other 2 limb leads. Therefore, the "standard" 12-lead electrocardiogram actually contains 8 independent pieces of information: 2 measured potential differences from which the 4 remaining limb leads can be calculated and the 6 independent precordial leads.[4] In essence all leads are effectively "bipolar," and the differentiation between "bipolar" and "unipolar" in the description of the standard limb leads, the augmented limb leads, and the precordial leads is discouraged in the most recent statement by the AHA.[4]

Technical Aspects of Electrode Placement

Monitoring electrodes should preferentially be placed directly over bony prominences of the torso (eg, clavicular heads, iliac prominences) to minimize excursion of the electrode during respiration that could cause baseline wander. Electrode impedance must be optimized to avoid loss and alteration of the signal. By removing a portion of the stratum corneum (eg, gentle abrasion with a dry gauze pad that results in a minor amount of surface erythema works well), skin impedance can be reduced by a factor of 10 to 100. Optimal impedance is 5000 ohms or less. The electrode may be covered with a watertight dressing to prevent surgical scrub solutions from undermining electrode contact.

Intrinsic and Extrinsic Electrocardiographic Artifact

Intrinsic Sources

Skin Impedance

Motion artifact and "baseline wander" have several causes. Intrinsic to the body are electrical potentials generated by the skin.[33] Skin impedance has been shown to vary at different skin sites.

Electrodes

Direct current potentials are actually stored by the electrode itself (ie, offset potentials), and they vary with the type of electrode used. A striking example of an offset potential is the transient obliteration of the electrocardiogram that occurs immediately after electrical defibrillation. Poor electrode contact enhances pickup of alternating current power-line interference (60-Hz signals).

Motor Activity

Another major physiologic source of artifact is electromyographic noise produced by motor activity, either voluntary (ie, during treadmill testing or ambulatory ST-segment monitoring) or involuntary (ie, shivering or parkinsonian tremor). Electromyographic noise is similar in amplitude to the electrocardiogram, but it is generally of considerably higher frequency. Because it is a random signal, in contrast to the regular repetitive electrocardiogram, electromyographic noise is amenable to significant attenuation using routine DSP techniques (Fig. 12.8).[34]

Extrinsic Sources

Artifact also has extrinsic or nonphysiologic causes. An important cause is called common-mode rejection. The ECG signal is recorded as the difference in potential between two electrodes and is technically a differential signal. The body is not at absolute ground potential; this is why the right leg lead is used as a reference electrode.[24] This higher potential (over that of an absolute ground to earth) is called common-mode potential because it is common to both electrode inputs to the differential amplifier used to amplify the ECG signal. Common-mode potential must be rejected or it may alter the ECG signal.

Electrical Power-Line Interference

Electrical power-line interference (60 Hz) is a common environmental problem. Power lines and other electrical devices radiate energy that can enter the monitor by poor electrode contact or cracked or poorly shielded lead cables. Interference can also be induced electromagnetically as these signals radiate through the loop formed by the body, lead cables, and monitor.[33] This type of interference can be reduced by twisting the lead cables together (reducing the loop area) or by minimizing the distance between the lead cables. In current diagnostic ECG machines, A/D signal conversion occurs in an acquisition module close to the patient that effectively reduces the length of the lead cables and the amount of signal induction possible. A line frequency "notch" filter is often used to remove 60-Hz noise. Other means of mathematical manipulation and processing can also remove 60-Hz noise.[35]

Electrocautery

Electrocautery units generate radiofrequency currents at very high frequencies (800–2000 kHz) and high voltages (1 kV, which is 100 times greater than the ECG signal). Older units used a modulation frequency of 60 Hz, which spread substantial electrical noise into the QRS frequency range of the ECG signal. Newer units use a modulation frequency of 20 kHz, thus minimizing this problem[5]; however, case reports still exist of electrocautery as a cause of artifactual ST-segment changes in intraoperative electrocardiograms.[36,37] To minimize electrocautery artifact, the right leg reference electrode should be placed as close as possible to the return plate, and the ECG monitor should be plugged into a different power outlet from the electrosurgical unit.

Clinical Sources of Artifact

Clinical devices in physical contact with the patient, particularly through plastic tubing, may at times cause clinically significant ECG artifact.[38–41] Although the exact mechanism is uncertain, two leading explanations are either a piezoelectric effect secondary to mechanical deformation of the plastic or buildup of static electricity between two dissimilar materials, especially those materials in motion (as in the

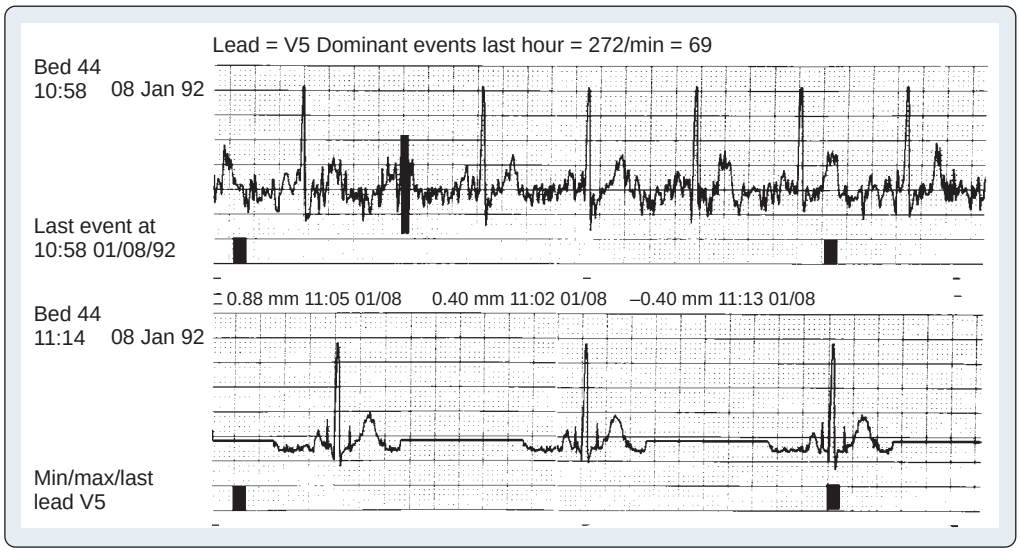

Fig. 12.8 Reduction of muscle artifact (simulated) by digital signal processing using signal averaging (PC2 Bedside Monitor, Spacelabs, Redmond, Wash). *(Top)* The initial learned complex (ie, dominant) on the left is followed by real-time complexes. *(Bottom)* Median complexes are smoothed by signal processing. Notice that the ST-segment position is isoelectric in the normal complex, but it does vary in accuracy with this degree of noise. The degree of noise reduction is proportional to the square root of the number of beats averaged. *(From Reich DL, Mittnacht A, London M, Kaplan J. Monitoring of the heart and vascular system. In: Kaplan JA, Konstadt SN, Reich DL, eds.* Kaplan's Cardiac Anesthesia. *5th ed. Philadelphia: Saunders; 2006.)*

case of cardiopulmonary bypass [CPB] tubing and the roller pump head described later). In this situation, the electricity generated in the pump flows into the patient through the tubing and is picked up by the electrodes. This artifact is not related to the electricity used to power the CPB pump because it has been reproduced by manually turning the pump heads.

Although ECG interference during CPB has been recognized for many years, Khambatta and colleagues[40] were the first to document it in the literature. It is manifested by marked irregularity of the baseline, similar to ventricular fibrillation, with a frequency of 1 to 4 Hz and a peak amplitude up to 5 mV. Uncorrected, it may make effective diagnosis of arrhythmias and conduction disturbances very difficult (Fig. 12.9), especially during the critical period of weaning from CPB, and it may also make accurate determination of asystolic arrest from the cardioplegia difficult. This artifact is more common in the winter than in the summer (56% vs 13% of patients), with low relative humidity (45–48% or less), and with room temperature lower than 18 to 20°C. Accumulation of static electricity is assumed to be the major etiologic factor, and Khambatta and colleagues recommended maintaining ambient temperature higher than 20°C. The current standard for operating room temperature is 20 to 24°C, in accordance with the American Society for Healthcare Engineering of the American Hospital Association.

ECG artifact often mimics arrhythmias, primarily atrial, because the baseline artifact may resemble flutter waves or atrial fibrillation. Kleinman and colleagues[41] (see the earlier discussion of pump artifact) reported the commonly observed "atrial flutter" artifact (see Fig. 12.9). Baseline artifact simulating flutter waves at 300/min occurred on an operating room monitor. The waves were observed to precisely track the pump head speed and to disappear when the pump was turned off. The artifact appears to have been caused by poor ECG electrode contact because these investigators the authors were able to produce it by undermining an ECG electrode with liquids. They pointed out that poor application of only one electrode could markedly impair the common-mode rejection capabilities of the ECG differential amplifier. This type of artifact has also been reported during noncardiac surgical procedures.[38] Other clinical devices associated with ECG interference, albeit rarely, include infusion pumps and blood warmers. Isolated

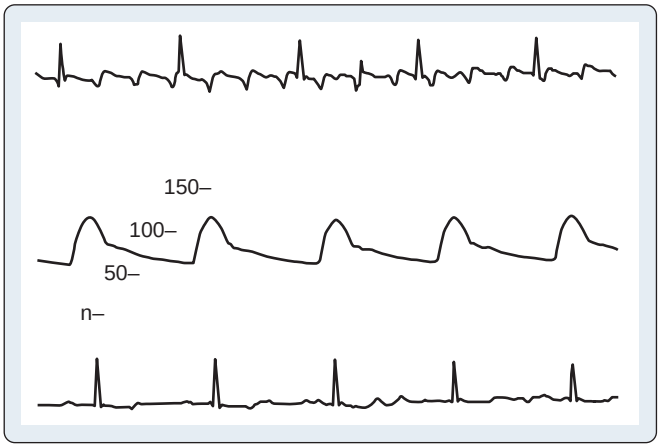

Fig. 12.9 *(Top)* Baseline artifact simulates atrial flutter in a cannulated patient. *(Middle)* This patient had stable arterial pressure just before institution of full cardiopulmonary bypass, similar to that described by Kleinman and associates.[41] *(Bottom)* The "pseudo-flutter waves" are corrected by application of the grounding cable. *(From London MJ, Kaplan JA. Advances in electrocardiographic monitoring. In: Kaplan JA, Reich DL, Konstadt SN, eds.* Cardiac Anesthesia. *4th ed. Philadelphia: Saunders; 1999.)*

power supply line isolation monitors have also been associated with 60-Hz interference. This can be diagnosed by removing the line isolation monitor fuses to see whether the artifact disappears.[42]

Frequency Response of Electrocardiographic Monitors: Monitoring and Diagnostic Modes

ECG signals must be amplified and filtered before display. To reproduce the component frequencies accurately, each must be amplified equally. The monitor must have a "flat amplitude response" over the wide range of frequencies present. Similarly, because the slight delay in a signal as it passes through a filter or amplifier may vary in duration with different

frequencies, all frequencies must be delayed equally. This is termed *linear phase response.* If the response is nonlinear, various components may appear temporally distorted *(phase shift)*. Given the importance of the electrocardiogram in diagnosing myocardial ischemia, it is important to realize that "significant" ST-segment depression or elevation can occur solely as a result of improper signal filtering in 12-lead ECG machines and bedside or ambulatory ST-segment monitors.[43–47] This artifact was a particular problem before the introduction of DSP. The AHA Committee on Electrocardiography Standardization addressed specific frequency requirements for monitoring in this setting.[6,28]

Nonlinear frequency response in the low-frequency range (0.5 Hz) can cause artifactual ST-segment depression, whereas phase delay in this range can cause ST-segment elevation.[6] The AHA recommended a bandwidth of 0.05 to 100 Hz (at 3 dB).[32] Although a completely linear response is desirable, with analog filters it is not generally possible. Because greater baseline noise is present when a 0.05-Hz cutoff is used, the 0.5Hz cutoff is often used to display a more stable signal. This is commonly referred to as the monitoring mode, and use of a 0.05-Hz low-frequency cutoff is known as the diagnostic mode.[48] The difference in ST-segment morphology at various low-frequency cutoffs is illustrated in Fig. 12.10. Because current monitors use signal averaging techniques that effectively eliminate most artifact even in the diagnostic mode, the clinician can usually (and should) avoid using the monitoring mode.

High-frequency response is less important clinically because the ST segment and T wave reside in the low-frequency spectrum. However, at the commonly used high-frequency cutoff of 40 Hz, the amplitude of the R and S waves may diminish significantly, thus making it difficult to diagnose ventricular hypertrophy.[44,49] Significant reduction in QRS amplitude may occur in the following circumstances: major decreases in left ventricular function, obesity, pericardial and pleural effusions, anasarca, and infiltrative or restrictive cardiac diseases.[50,51] Low QRS voltage is defined as peak-to-trough QRS amplitude of less than 5 mm in six limb leads and 10 mm or less in the precordial leads. Significant decrease in QRS voltage is more likely to be seen in the presence of a large pericardial effusion or fibrotic pericardial thickening. *Total electrical alternans* refers to the alternating high and low voltages of all ECG waveforms (P-QRS-T) between cardiac cycles within a given lead and is thought to result from swinging motion of the heart in a pericardial effusion at a frequency that is exactly one-half the heart rate. Total electrical alternans in addition to low voltage and widespread ST-segment elevation is pathognomic of significant pericardial effusion with cardiac tamponade.

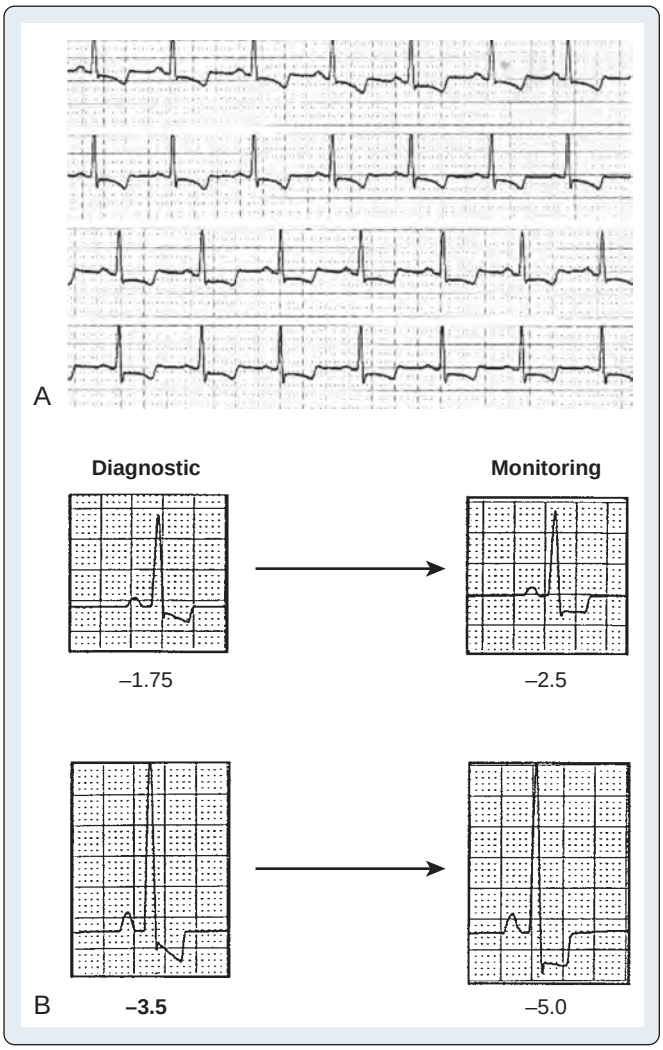

Fig. 12.10 (A) Monitoring versus diagnostic mode in *(top trace)* leads II and *(bottom trace)* V_5 in a patient undergoing coronary artery bypass grafting. Notice the straightening of the baseline with use of the monitoring mode, which is most notable in lead II. The degree of the PR and ST segments is exaggerated in both leads. (B) Effects of monitoring mode on ST-segment depth and morphology illustrated using a digital electrocardiographic simulator. A Spacelabs PC2 monitor (Redmond, WA) was switched from monitoring mode (0.5–40 Hz) to diagnostic mode (0.05–70 Hz). Notice the increase in the depth of ST-segment depression and the alteration of slope in both leads. *(From London MJ. Ischemia monitoring: ST segment analysis versus TEE. In: Kaplan JA, ed.* Cardiothoracic and Vascular Anesthesia Update. *Vol 3. Philadelphia: Saunders; 1993:1–20.)*

Electrocardiographic Changes With Myocardial Ischemia

Detection of Myocardial Ischemia

The ST segment is the most important portion of the QRS complex for evaluating ischemia.[52,53] It may come as a surprise that no gold standard criteria exist for the ECG diagnosis of myocardial ischemia. Many anesthesiologists, when evaluating an electrocardiogram for signs of ischemia, look for signs of repolarization or ST-segment abnormalities. Many other signs of myocardial ischemia may also be seen in the electrocardiogram, including T-wave inversion, QRS and T-wave axis alterations, R- or U-wave changes, or the development of previously undocumented arrhythmias or ventricular ectopy.[10] None of these, however, is as specific for ischemia as ST-segment depression or elevation. Depending on the location of the infarction, and the observed leads, the ST-segment changes are 84% to 100% specific and 12% to 66% sensitive for myocardial ischemia.[54]

The origin of the ST segment, at the J point, is easy to locate. However, J-point termination, which is generally accepted as the beginning of any change of slope of the T wave, is more difficult to determine. Physiologically normal persons may have no discernible ST segment because the T wave starts with a steady slope from the J point, especially at rapid heart rates. The TP segment has been used as the isoelectric baseline from which changes in the ST segment are evaluated, but with tachycardia, this segment is eliminated, and during exercise testing, the PR segment is used. The PR segment is used in all ST-segment analyzers.

Repolarization of the ventricle proceeds from the epicardium to the endocardium, opposite to the vector of depolarization. The ST segment reflects the midportion, or phase 2, of repolarization during little change in electrical potential occurs.[55] It is usually isoelectric. Ischemia causes a loss of intracellular potassium, resulting in a current of injury. The electrophysiologic mechanism accounting for ST-segment shifts (elevation or depression) remains controversial. The two major theories are based on a loss of resting potential as current flows from the uninjured to the injured area (ie, diastolic current) and on a true change in phase 2 potential as current flows from the injured to the uninjured area (ie, systolic current) (Fig. 12.11). With

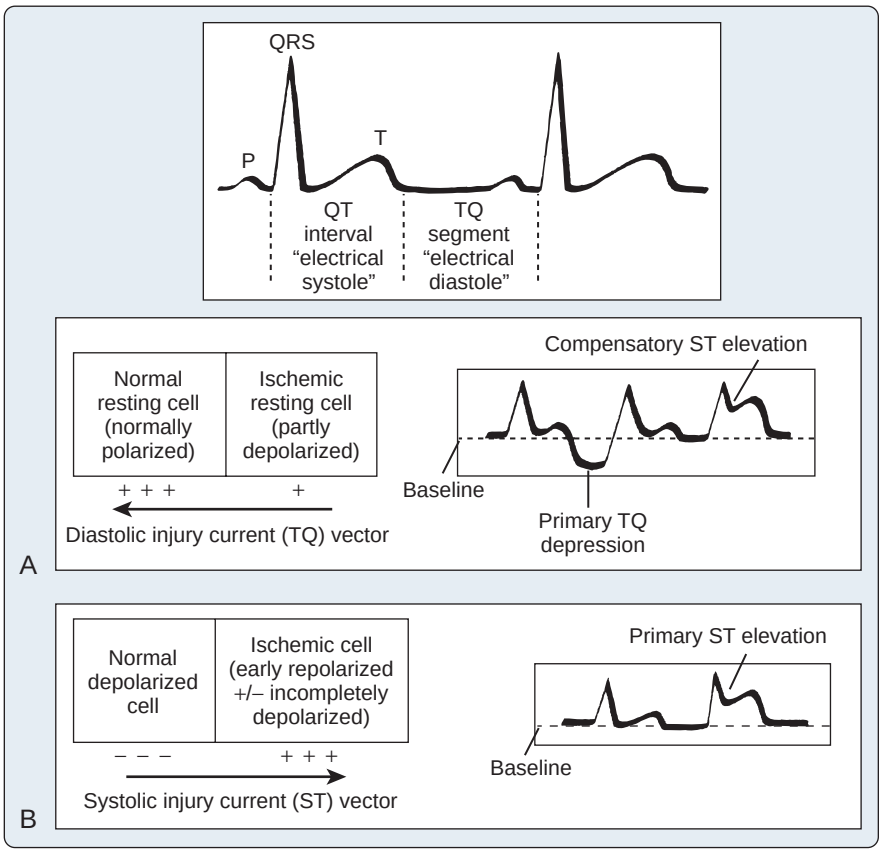

Fig. 12.11 Pathophysiology of ischemic ST-segment elevation. Two basic mechanisms have been advanced to explain the elevation seen with acute myocardial injury. (A) Diastolic current of injury. In this case (first QRS-T complex), the ST-segment vector is directed away from the relatively negative, partly depolarized, ischemic region during electrical diastole (TQ interval), and the result is primary TQ-interval depression. Conventional alternating current electrocardiograms compensate for the baseline shift, and an apparent ST-segment elevation (second QRS-T complex) results. (B) Systolic current of injury. In this case, the ischemic zone is relatively positive during electrical systole because the cells are repolarized early and the amplitude and upstroke velocity of their action potentials may be decreased. This injury current vector is oriented toward the electropositive zone, and the result is primary ST-segment elevation. *(From Mirvis DM, Goldberger AL. Electrocardiography. In: Bonow RO, Mann DL, Zipes DP, Libby P, eds.* Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine. *8th ed. Philadelphia: Saunders; 2008:174.)*

subendocardial injury, the ST segment is depressed in the surface leads. With epicardial or transmural injury, the ST segment is elevated (Fig. 12.12). When a lead is placed directly on the endocardium, the opposite patterns are recorded.

Although myocardial ischemia may manifest in PR-segment, QRS complex, ST-segment, or T-wave changes, the earliest ECG signs of ischemia are typically T-wave and ST-segment changes. Acute increases in T-wave amplitude, with prominent symmetric T waves in at least two contiguous leads, are early signs that may precede the elevation of the ST segment. Transient Q waves may be observed during an episode of acute ischemia or (rarely) during acute myocardial infarction (MI) with successful reperfusion.[56] With myocardial ischemia, repolarization is affected, resulting in downsloping or horizontal ST-segment depression. Various local effects and differences in vectors during repolarization result in different ST-segment morphologic features that are recorded by the different leads. It is generally accepted that ST-segment changes in multiple leads are associated with more severe degrees of CAD.

The criteria for MI are divided into two categories: ST-segment elevation MI (STEMI), and ST-segment depression/T-wave change MI (NSTEMI). The J point is located at the juncture of the QRS complex and the ST segment, and it is used to measure the magnitude of the ST-segment deflection as compared with the baseline of the ECG. A new J-point elevation of 0.1 mV or greater is required in all leads except V_2 and V_3 to meet the criteria for STEMI. J-point elevations of up to 0.25 mV may be seen in leads V_2 and V_3 in healthy men younger than 40 years of age; however, this finding decreases with age and is less prominent in women. For this reason, a range of J-point elevation criteria for MI are defined for V_2 and V_3 leads: 0.2 mV or greater for men 40 years old and older, 0.25 mV or greater for men younger than 40 years of age, and 0.15 mV or greater for women.[56] The J-point elevations must be seen in two or more contiguous leads for the satisfaction of ST-segment elevation criteria.[56] New horizontal or downsloping ST-segment depressions of 0.05 mV or greater or T-wave inversion of 0.1 mV or greater in two contiguous leads with an R-wave–to–S-wave ratio greater than 1 satisfy the criteria for NSTEMI. However, ST-segment elevations are more specific than ST-segment depressions and/or T-wave inversions for localizing the site of ischemia.[56] ST-segment elevation generally suggests greater degrees of myocardial damage than ST-segment depression or T-wave changes.[57] Previously inverted T waves may pseudonormalize during episodes of acute myocardial ischemia[56] (Appendix 12.1).

Nonspecific ST-segment depression can be related to drug use, particularly digoxin.[58] Interpretation of ST-segment changes in patients with left ventricular hypertrophy is particularly controversial given the tall R-wave baseline, J-point depression, and steep slope of the

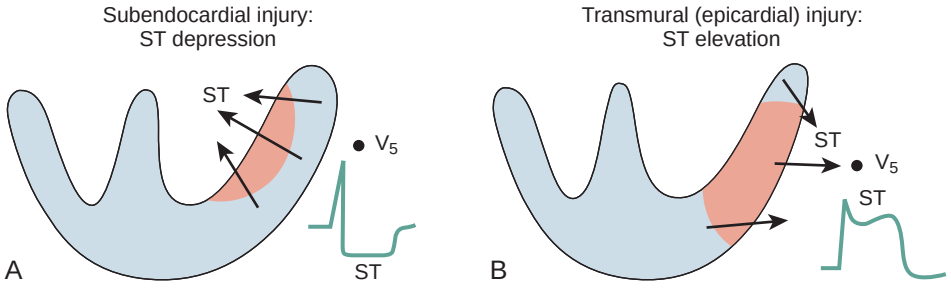

Fig. 12.12 Current of injury patterns with acute ischemia. (A) With predominant subendocardial ischemia the resultant ST-segment vector is directed toward the inner layer of the affected ventricle and the ventricular cavity. Overlying leads therefore record ST-segment depression. (B) With ischemia involving the outer ventricular layer (transmural or epicardial injury), the ST-segment vector is directed outward. Overlying leads record ST-segment elevation. Reciprocal ST-segment depression can appear in contralateral leads. *(From Mirvis DM, Goldberger AL. Electrocardiography. In: Bonow RO, Mann DL, Zipes DP, Libby P, eds.* Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine. *8th ed. Philadelphia: Saunders; 2008:174.)*

ST segment. Although some studies excluded such patients, others (including those using other modalities or epidemiologic studies) observed that left ventricular hypertrophy is a highly significant predictor of adverse cardiac outcome.[59] Occasionally, other conditions cause ECG changes that may confound diagnosing myocardial ischemia exclusively by electrocardiogram. For example, pulmonary embolism, intracranial bleeding, electrolyte abnormalities, hypothermia, and pericarditis may also result in ST-segment or T-wave abnormalities. The diagnosis of ischemia is more difficult in the presence of left bundle branch block and may require comparison with a previous electrocardiogram.[56] In contrast, patients with right bundle branch block often have ST-segment and T-wave abnormalities in leads $V_1$to V_3 that also confound the diagnosis of new ischemia. Ultimately, clinical suspicion should guide interpretation of the electrocardiogram.

The criteria for myocardial ischemia with ST-segment changes described previously are used in conjunction with clinical symptoms and confirmation with elevation of biomarkers to diagnose acute coronary syndromes.[60] These changes usually result from transmural ischemia, but they may potentially represent a reciprocal change in a lead oriented opposite to the primary vector with subendocardial ischemia (as may be seen in the reverse situation).[61,62] Perioperative ambulatory monitoring studies have also included more than 0.2 mV in any single lead as a criterion, but ST-segment elevation is rarely reported in the setting of noncardiac surgical procedures. It is commonly observed, however, during weaning from CPB in cardiac operations and during CABG procedures (on and off pump) with interruption of coronary flow in a native or graft vessel. ST-segment elevation in a lead with a Q wave should not be analyzed for acute ischemia, although it may indicate the presence of a ventricular aneurysm.

Although repolarization changes (eg, ST-T wave) are the focus of ischemia detection, computerized ECG analysis using signal averaging techniques has documented changes in depolarization with ischemia manifested by a reduction in high-frequency components of the QRS complex (150–250 Hz). Such changes are not visible on the standard electrocardiogram because they are in the range of only 10 to 20 mV and are measured quantitatively using the root mean square value (calculated by squaring the amplitude of each sample and determining the means of the squares and then the square root of that mean value). Absolute changes in the root mean square value greater than 0.6 mV or relative changes of more than 20% are considered clinically significant. This effect likely reflects slowing of conduction velocity in the ischemic region.[63]

One study documented higher sensitivity of this approach compared with 12-lead ST-segment analysis in the detection of acute coronary occlusion during percutaneous transluminal coronary angioplasty.[64] The overall sensitivity was 88%, compared with 71% using ST-segment elevation criteria or 79% by combining ST-segment elevation and depression. More recent studies suggested that high-frequency QRS analysis can be used in quantification of myocardial areas at risk of ischemia.[65]

Anatomic Localization of Ischemia With the Electrocardiogram

As noted earlier, ST-segment depression is a common manifestation of subendocardial ischemia. From a practical clinical standpoint, it has a single major strength and limitation. Its strength is that it is almost always present in one or more of the anterolateral precordial leads (V_4–V_6).[66] However, it fails to "localize" the offending coronary lesion and has little relation to underlying segmental asynergy.[67,68]

In contrast, ST-segment elevation correlates well with segmental asynergy and localizes the offending lesion relatively well.[67,69] Reciprocal ST-segment depression often is present in one or more of the other 12 leads. In patients with angiographically documented single-vessel disease, ST-segment elevation (as well as Q waves or inverted T waves) in leads I, aVL, or V_1 through V_4 is closely correlated with disease of the left anterior descending coronary artery, whereas similar findings in leads, I, III, and aVF indicate disease of the right coronary or left circumflex arteries (surprisingly, the latter two cannot be differentiated by ECG criteria).[69] A multivariate analysis suggested that ST-segment elevation, abnormal Q waves, and inverted T waves in leads I and aVL (with normal V_1 and V_6) can be used to differentiate isolated first diagonal branch occlusion from the more ominous proximal left anterior descending coronary artery occlusion.[70]

Clinical Lead Systems for Detecting Ischemia

Early clinical reports of intraoperative monitoring using the V_5 lead in high-risk patients were based on observations during exercise testing, in which bipolar configurations of V_5 demonstrated high sensitivity for myocardial ischemia detection (up to 90%). Subsequent studies using 12-lead monitoring (torso mounted for stability during exercise) confirmed the sensitivity of the lateral precordial leads.[71,72] Some studies, however, reported higher sensitivity for leads V_4 or V_6 compared with V_5, followed by the inferior leads (in which most false-positive responses were reported).[66,73–79]

The exact nature of perioperative MI (PMI) in noncardiac surgical procedures remains uncertain and is a subject of debate and controversy. The interaction between morphologic and functional factors is unpredictable. Some older pathologic and angiographic studies suggested that the cause of PMI resembles that in the nonsurgical setting (ie, plaque rupture in 50% of cases). However, newer analysis suggested that myocardial oxygen supply/demand imbalance predominates in the first 3 to 4 postoperative days, and patients suffer from demand

ischemia and injury. In PMI, the location and severity of underlying coronary artery stenosis do not necessarily predict the infarct territory. The high incidence of histologically confirmed transmural infarctions seems to be contradictory to the ECG finding of almost exclusively non–Q-wave PMIs. Conversely, the presence of subendocardial PMI is consistent with a myocardial oxygen supply/demand mismatch as the main trigger of myocardial injury.[80,81] Given the relatively low sensitivity and specificity of the electrocardiogram, echocardiographic imaging is now routinely used in addition to the electrocardiogram in cardiology evaluations.

With the widespread growth of percutaneous coronary interventions for acute MI and unstable angina, some investigators have reported the use of continuous ECG monitoring (3 or 12 leads) in this setting. These observations have extended the classic teaching on localization of sites of coronary artery occlusion. Horacek and Wagner[82] reviewed the complexities and controversies regarding vessel-specific ECG responses to acute myocardial ischemia in detail. In general, ST-segment elevation in leads V_2 and V_3 is most sensitive for occlusion of the left anterior descending coronary artery, and leads III and aVF are most sensitive for the right coronary artery. In contrast, circumflex artery occlusion results in variable responses, with primary elevation in the posterior precordial leads V_7 through V_9 (which are rarely monitored clinically) and reciprocal ST-segment depression in the standard precordial leads (V_2 or V_3).[83,84] For transmural ischemia, sensitivity is highest in the anterior rather than the lateral precordial leads. An international multidisciplinary working group specifically recommended continuous monitoring of leads III, V_3, and V_5 for all patients with acute coronary syndromes.[85]

Intraoperative Lead Systems

Detection of perioperative myocardial ischemia is an integral part of clinical monitoring and guides therapy. Many studies demonstrated associations of perioperative ischemia with adverse cardiac outcomes in adults undergoing a variety of cardiac and noncardiac surgical procedures, particularly major vascular operations.[86–91] Perhaps the greater challenge is interpreting minor ST-segment changes in the context of the overall risk profile of the patient to avoid inappropriate performance of costly diagnostic tests. Studies documented that transient myocardial ischemia occurs in the absence of significant CAD in unexpected patients, such as parturient women, particularly with significant hemodynamic stress or hemorrhage.[92] Although the precise cause of such changes is uncertain, significant troponin release has been documented in these patients, thus confirming the suspicion that these ECG changes are true ischemic responses (probably related to subendocardial ischemia secondary to global hypoperfusion).

How accurately the clinician places ECG leads on the patient's torso is probably the single most important factor influencing clinical utility of the electrocardiogram. Placement of the limb leads almost anywhere on the torso at or near the origin of the arms allows accurate rendition of lead II because both electrodes are farther than 12 cm from the heart (a distance considered to be the electrical infinity value beyond which amplitude of the QRS complex is unchanged).[93]

The cardiac anesthesiologist encounters a variety of ECG changes consistent with or pathognomonic for myocardial ischemia or infarction at many phases of the perioperative period in patients undergoing cardiac operations. In the majority of these patients (ie, those with known CAD), the sensitivity and specificity of the major signs described are high, and few false-positive or false-negative changes are encountered. However, the abnormal physiology of CPB, including acute changes in temperature, electrolyte concentrations, and catecholamine levels can significantly influence sensitivity and specificity. In addition, patients undergoing valve replacement, even those without coronary artery lesions, can develop significant subendocardial and transmural ischemia (ie, coronary artery embolus of valve calcification, vegetations, or air). Even neonates can develop myocardial ischemia[94](Fig. 12.13).

Detecting and recognizing the clinical significance of various ECG signs of ischemia or infarction and collaborating the findings with transesophageal echocardiography can enhance patient care in the acute setting, as in emergency treatment of coronary artery spasm or air embolus, or by alerting the surgeon that myocardial

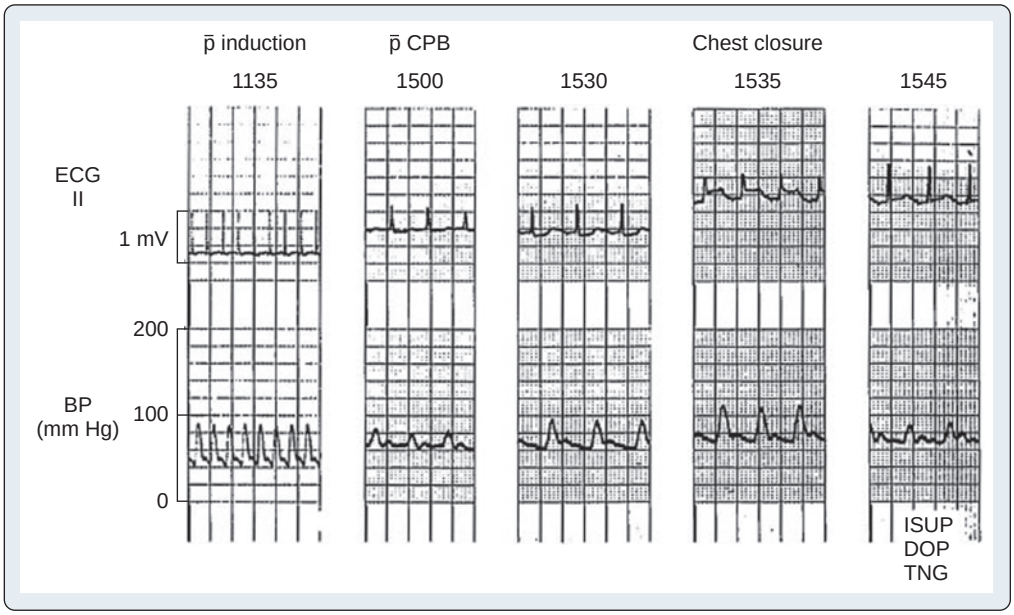

Fig. 12.13 In a 2-day-old, 3.5-kg male infant undergoing a Senning procedure, early ST-segment changes in lead II first noted immediately after cardiopulmonary bypass) (15:00 h) and 30 min later (15:30 h). Significant ST-segment elevation during chest closure (15:35 h) improved after administration of trinitroglycerin *(TNG)*, isoproterenol *(ISUP)*, and dopamine *(DOP)* at 15:45 h. *BP*, Blood pressure; *ECG*, electrocardiogram; p̄, after. *(Reproduced with permission from Bell C, Rimar S, Barash P. Fig. 12.15 Histogram showing the incidence in which prolonged ischemia was first noted by each lead at the onset of ischemia in all 38 longest ischemic events and in the 12 ischemic events that progressed to myocardial infarction. *(Reproduced with permission from Landesberg G, Mosseri M, Wolf Y, et al. Perioperative myocardial ischemia and infarction: identification by continuous 12-lead electrocardiogram with online ST-segment monitoring.* Anesthesiology. *2002;96:264–270.)*

revascularization may have been inadequate. This may lead to reexploration of a saphenous vein or internal mammary artery anastomosis, especially if the transesophageal echocardiographic data support the diagnosis of ischemia.

The early reports of Dalton[95] and Kaplan and King,[96] recommending routine intraoperative monitoring of V_5 in high-risk patients, cited exercise tolerance tests as the source of their recommendations. Subsequently, the recommended leads for intraoperative monitoring, based on several clinical studies, did not differ substantially from those used during exercise testing, although considerable controversy on the optimal leads persists in both clinical settings. The use of continuous ECG monitoring in the coronary care unit has received increasing attention.[97] A clinical study using continuous, computerized 12-lead ECG analysis in a mixed cohort (for vascular and other noncardiac procedures) by London and associates[98] reported that almost 90% of changes involved ST-segment depression alone (75% in V_5 and 61% in V_4). In approximately 70% of patients, significant changes were observed in multiple leads. The sensitivity of each of the 12 leads in that study is shown in Fig. 12.14. When considered in combination (as occurs clinically), the use of leads V_4 and V_5 increased sensitivity to 90%, whereas sensitivity for the standard clinical combination of leads II and V_5 was only 80%. Use of leads V_2 through V_5 and lead II captured all episodes (Table 12.2).

A larger clinical study by Landesberg and colleagues[99] of patients undergoing vascular operations using a longer period of monitoring (up to 72 hours) with more specific criteria for ischemia (>10-minute duration of episode) extended these observations. These investigators reported that V_3 was most sensitive lead for ischemia (87%) followed by V_4 (79%), whereas V_5 alone was only 66% sensitive (Fig. 12.15).[99] In the subgroup of patients whose prolonged ischemic episodes ultimately culminated in infarction, V_4 was most sensitive lead (83%). In this study, all MIs were non–Q-wave events detected by troponin elevation. The use of two precordial leads detected 97% to 100% of changes. Based on analysis of the resting isoelectric levels of each of the 12 leads (a unique component of this study), it was recommended that V_4 was the best single choice for monitoring a single precordial lead because it was most likely to be isoelectric relative to the resting 12-lead preoperative electrocardiogram. In contrast, the baseline ST-segment was more likely above isoelectric in V_1 through V_3 and below isoelectric in V_5 and V_6. Surprisingly, no episodes of ST-segment elevation occurred in this study, as opposed to 12% in the earlier study of London and associates,[98] in which such changes were detected in inferior and anteroseptal precordial leads.

Martinez and colleagues[100] evaluated a cohort of vascular surgical patients monitored in the intensive care unit for the first postoperative days with continuous 12-lead ECG monitoring using a threshold of 20 minutes for an ischemic episode. Eleven percent of 149 patients met the criteria, with ST-segment depression in 71% and ST-segment elevation alone in 18% (12% had both). Most changes were detected in V_2 (53%) and V_3 (65%). Using the standard two-lead system (II and V_5), only 41% of episodes would have been detected. Although these studies clearly support the value of precordial monitoring in patients at risk for subendocardial ischemia, clinicians must be vigilant for the rare patient with an acute Q-wave infarction (most commonly in the inferior leads). The studies previously cited were all conducted in patients undergoing noncardiac operations because it is not practical to conduct such studies in patients with open chests or extensive surgical dressings in the precordial region. However, no reason exists to assume that any significant differences would have been observed in the cardiac surgical patient. Sudden episodes of acute transmural ischemia (associated with ST-segment elevation) are much more likely in this setting from acute ischemia or infarction (eg, thrombotic occlusion) or from surgically induced reductions in coronary blood flow.

Abnormalities in T-wave morphology are probably the most common perioperative ECG abnormalities in the general surgical population. Breslow and associates[101] noted new T-wave abnormalities within 1 hour postoperatively in 18% of an unselected surgical population of 394 patients (excluding cardiac and neurosurgical procedures). Approximately two-thirds of the changes were limited to T-wave flattening, and the remainder had new inversions. The incidence was no different between patients with known CAD and those without it. Out of a battery of variables, the only one statistically associated with T-wave abnormalities was intraabdominal operation. The ECG changes were not associated with any clinical morbidity. This study illustrates the known relationship of T-wave changes with a variety of autonomic stimuli, including changes in serum glucose, elevated catecholamines, acute hyperventilation, and upper gastrointestinal disease. Similar analyses in patients undergoing cardiac surgical procedures are not available, and the specificity of the response would be expected to be much lower.

Electrocardiographic Changes With Pacemakers, Respirations, Electrolytes, and Medications

Use of the inferior leads (II, III, aVF) allows superior discrimination of P-wave morphology and facilitates the visual diagnosis of arrhythmias and conduction disorders. Although esophageal (and even intracardiac) leads allow the greatest sensitivity in detecting P waves, these leads are rarely used clinically. Nevertheless, they should be kept in mind for difficult diagnoses. With the increasing use of implantable defibrillators and automatic external defibrillators to treat ventricular fibrillation and ventricular tachycardia, considerable interest exists in the refinement of arrhythmia detection algorithms and their validation.[102] As expected, the accuracy of these devices for detecting ventricular arrhythmias is high, but it is much lower for detecting atrial arrhythmias. In the settings of critical care and ambulatory monitoring, various artifacts are common causes of false-positive responses.[102] Detection of pacemaker spikes may be complicated by very-low-amplitude signals related to bipolar pacing leads, amplitude varying with respiration, and total-body fluid accumulation.[102,103] Most critical care and ambulatory monitors incorporate pacemaker spike enhancement for small high-frequency signals (typically 5–500 mV with 0.5- to 2-ms pulse duration) to facilitate recognition. However, this can cause artifact if high-frequency noise is present within the lead system.

A promising application of the electrocardiogram is to correlate respiratory variation in wave amplitude with patients' volume responsiveness. The R wave, especially in lead II (RII), shows consistent respiratory amplitude variation during positive-pressure mechanical ventilation. This variation is likely caused by the "Brody effect," a theoretical analysis of left ventricular volume and electrical conductance.[104] RII-wave amplitude variation may be used as a dynamic index of volume responsiveness in a mechanically ventilated patient, similar to the use of arterial pulse contour analysis and esophageal Doppler monitoring to derive pulse-pressure and stroke volume variation as dynamic measures of fluid responsiveness.[105–107] Real-time, intraoperative RII-wave amplitude variation has the potential to become a truly noninvasive monitor for fluid responsiveness; however, at present, no commercially available intraoperative monitoring systems provide ECG R-wave amplitude variation measures.

Electrocardiographic Changes Resulting From Electrolyte Disorders

Cardiac myocytes exhibit a long action potential (200–400 ms) compared with neurons and skeletal muscle (1–5 ms). Multiple different channels are involved in cardiac muscle depolarization and repolarization. Sodium and calcium channels are the primary carriers of depolarizing current in both atria and ventricles. Inactivation of these currents and activation of potassium channels are predominantly involved in repolarizing the cardiac cells, thereby reestablishing the negative resting membrane potential. Thus it is not surprising that perturbations in the plasma concentrations of potassium and calcium ions lead to changes in the finely tuned cardiac electrical activity and the surface electrocardiogram. They typically cause changes in repolarization (ST-T-U waves) and can also lead to QRS complex prolongation.[108]

Hyperkalemia

Hyperkalemia is not an uncommon occurrence in patients undergoing cardiac surgical procedures with CPB. Hyperkalemia affects repolarization of cardiac cells. Although progressive changes in the surface electrocardiogram with increasing levels of potassium have been described, the correlation between serum potassium levels and ECG changes is not strong.[109] Typically, ECG changes start with narrowing and peaking of the T waves. Further elevation of extracellular potassium leads to prolongation of the QRS complex. The reason is delayed AV conduction, and an AV block may appear. These changes are typically followed by prolongation of the PR interval, flattening of the P waves, and loss of the P wave because the high potassium levels delay the spread of the cardiac activating impulse through the myocardium. Further increase in plasma potassium levels cause sine waves, which can progress to asystole or ventricular fibrillation. Hyperkalemia may also reduce the myocardial response to artificial pacemaker stimulation.

Hypokalemia

Because potassium channels and ions are significantly involved in cardiac repolarization, it is not surprising that hypokalemia prolongs ventricular repolarization. This results in characteristic reversal in the relative amplitudes of the T and U waves. T-wave flattening or inversion is noted, whereas U waves become more prominent. The U-wave prominence is caused by the prolongation of the recovery phase of the cardiac action potential. This can lead to the life-threatening torsades de pointes type of ventricular arrhythmia. Slight depression of the ST segment may also occur, as well as increased amplitude and width of the P waves with prolongation of the PR interval.

Hypocalcemia and Hypercalcemia

The ventricular recovery time, as represented on the electrocardiogram by the QTc interval, is altered by the extremes of serum calcium. Hypocalcemia can cause a prolonged QTc interval (ST portion), whereas hypercalcemia shortens the QTc interval. In hypocalcemia, the prolonged QT interval may be accompanied by terminal T-wave inversions. In extreme hypercalcemia, an increase in QRS complex, biphasic T waves, and Osborn waves have been described.

Medications

Many antiarrhythmic medications are used in the perioperative period in patients undergoing cardiac surgical procedures. Detailed discussion of each of these drugs is beyond the scope of this chapter (see Chapter 10). Generally, drugs that increase the duration of the cardiac action potential prolong the QT interval. These include class Ia and Ic antiarrhythmic drugs (eg, quinidine, procainamide), phenothiazines, antidepressants, haloperidol, and atypical antipsychotic agents. Intravenous amiodarone, commonly used in the management of perioperative arrhythmias, also causes QT-interval prolongation. Other class III antiarrhythmic drugs (eg, sotalol) cause QT-interval prolongation as well. Unlike class Ia and III antiarrhythmic drugs, digitalis glycosides shorten the QT interval and often cause "scooping" of the ST-T wave complex.

12.1

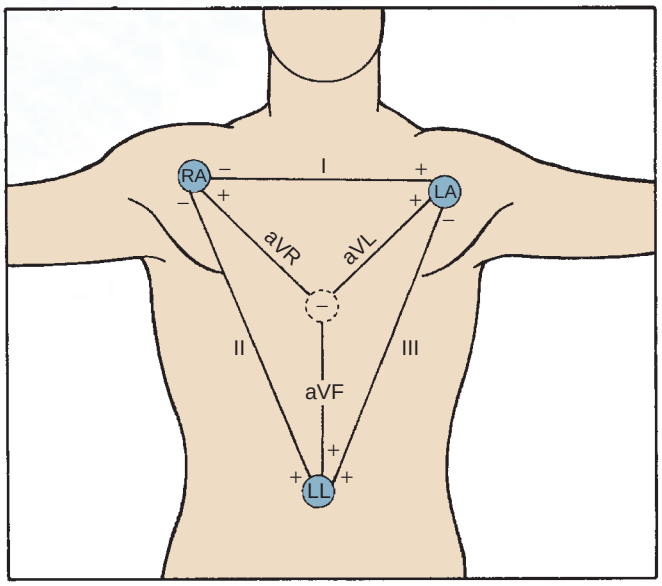
Electrocardiogram Atlas: A Summary of Important Changes on the Electrocardiogram

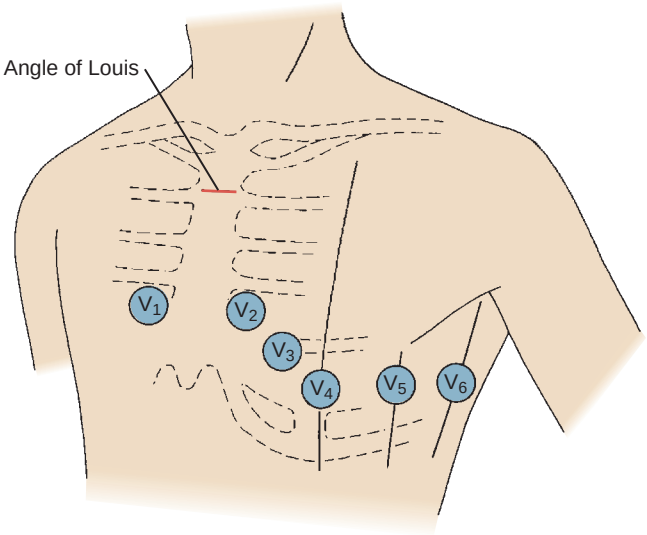
GINA C. BADESCU, MD | BENJAMIN SHERMAN, MD | JAMES R. ZAIDAN, MD, MBA | PAUL G. BARASH, MD

Lead Placement

	Electrode	
Lead Placement	*Positive*	*Negative*
Bipolar Leads		
I	LA	RA
II	LL	RA
III	LL	LA
Augmented Unipolar Leads		
aVR	RA	LA, LL
aVL	LA	RA, LL
aVF	LL	RA, LA
Precordial Leads		
V_1	4 ICS–RSB	
V_2	4 ICS–LSB	
V_3	Midway between V_2 and V_4	
V_4	5 ICS–MCL	
V_5	5 ICS–AAL	
V_6	5 ICS–MAL	

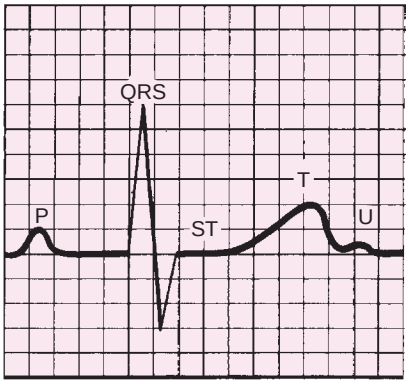
AAL, Interaxillary line; *ICS,* intercostal space; *LA,* left arm; *LL,* left leg; *LSB,* left sternal border; *MAL,* midaxillary line; *MCL,* midclavicular line; *RA,* right arm; *RSB,* right sternal border.

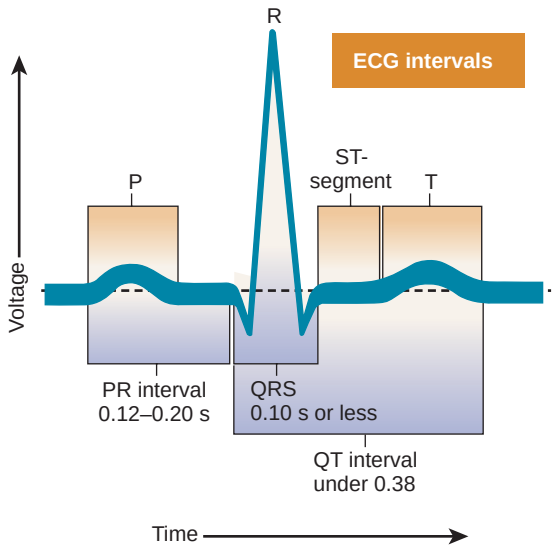




Normal Electrocardiogram: Cardiac Cycle

The normal electrocardiogram is composed of waves (P, QRS, T, and U) and intervals (PR, QRS, ST, and QT).





Atrial Fibrillation

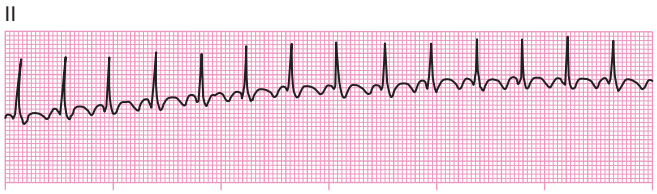
Rate: Variable (~150–200 beats/min)
Rhythm: Irregular
PR interval: No P wave; PR interval not discernible
QT interval: QRS normal

Note: This must be differentiated from atrial flutter: (1) absence of flutter waves and presence of fibrillatory line; (2) flutter usually associated with higher ventricular rates (>150 beats/min). Loss of atrial contraction reduces cardiac output (10–20%). Mural atrial thrombi may develop. It is considered controlled if the ventricular rate is <100 beats/min.

Atrial Flutter

Rate: Rapid, atrial usually regular (250–350 beats/min); ventricular usually regular (<100 beats/min)
Rhythm: Atrial and ventricular regular
PR interval: Flutter (F) waves saw-toothed; PR interval cannot be measured
QT interval: QRS usually normal; ST segment and T waves not identifiable

Note: Carotid massage slows the ventricular response, thus simplifying recognition of the F waves.



Atrioventricular Block

First-Degree

Rate: 60–100 beats/min
Rhythm: Regular
PR interval: Prolonged (>0.20 second) and constant
QT interval: Normal

Note: It is usually clinically insignificant; it may be an early harbinger of drug toxicity.

Second-Degree: Mobitz Type I/Wenckebach Block

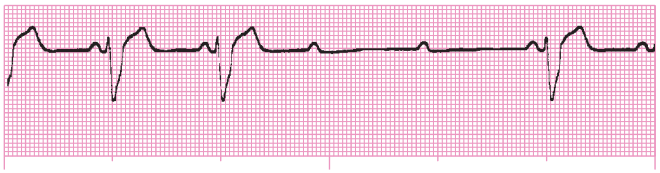
Rate: 60–100 beats/min
Rhythm: Atrial regular; ventricular irregular
PR interval: P-wave normal; PR interval progressively lengthens with each cycle until QRS complex is dropped (dropped beat); PR interval following dropped beat is shorter than normal.
QT interval: QRS complex normal but dropped periodically

Note: It is commonly seen (1) in trained athletes and (2) with drug toxicity.

Second-Degree: Mobitz Type II Block

Rate: <100 beats/min
Rhythm: Atrial regular; ventricular regular or irregular
PR interval: P waves normal, but some not followed by QRS complex
QT interval: Normal but may have widened QRS complex if block is at level of bundle branch. ST segment and T wave may be abnormal, depending on location of block

Note: In contrast to Mobitz type I block, the PR and RR intervals are constant and the dropped QRS occurs without warning. The wider the QRS complex (block lower in the conduction system), the greater is the amount of myocardial damage.



Third-Degree: Complete Heart Block

Rate: <45 beats/min
Rhythm: Atrial regular; ventricular regular; no relationship between P wave and QRS complex
PR interval: Variable because atria and ventricles beat independently
QT interval: QRS morphology variable, depending on the origin of the ventricular beat in the intrinsic pacemaker system (atrioventricular [AV] junctional vs ventricular pacemaker); ST segment and T wave normal

Note: AV block represents complete failure of conduction from atria to ventricles (no P wave is conducted to the ventricle). The atrial rate is faster than the ventricular rate. P waves have no relation to QRS complexes (eg, they are electrically disconnected). In contrast, with AV dissociation, the P wave is conducted through the AV node, and the atrial and ventricular rates are similar. Immediate treatment with atropine or isoproterenol is required if cardiac output is reduced. Consideration should be given to insertion of a pacemaker. This is seen as a complication of mitral valve replacement.

Atrioventricular Dissociation

Rate: Variable
Rhythm: Atrial regular; ventricular regular; ventricular rate faster than atrial rate; no relation between P wave and QRS complex
PR interval: Variable because atria and ventricles beat independently
QT interval: QRS morphology dependent on location of ventricular pacemaker; ST segment and T wave abnormal

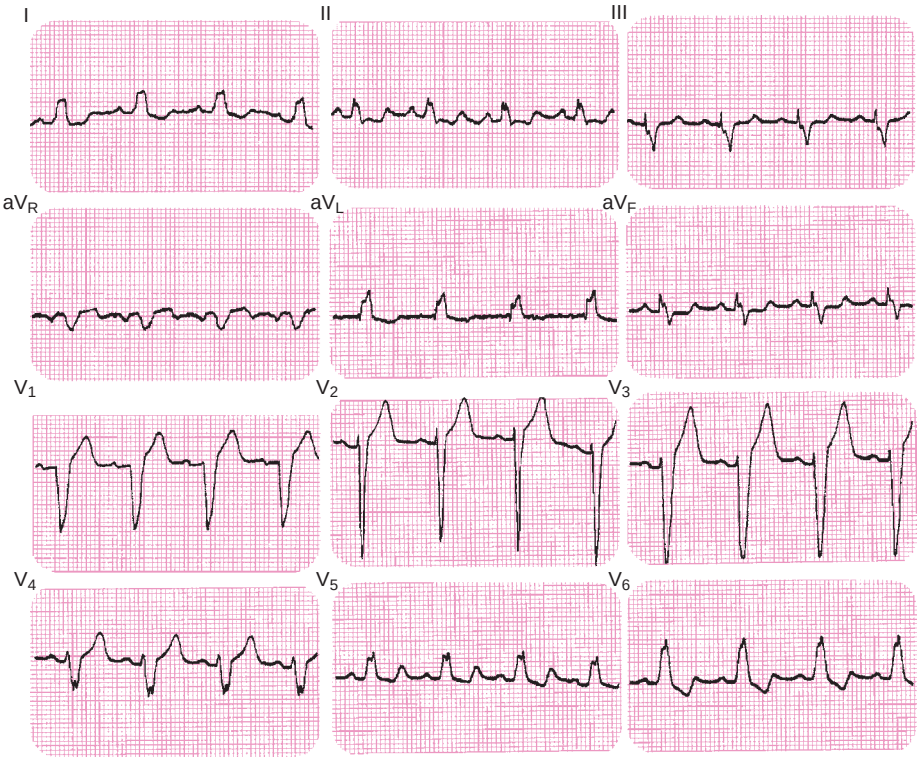
Note: In AV dissociation, the atria and ventricles beat independently. The P wave is conducted through the AV node, and the atrial and ventricular rate are similar. In contrast, AV block represents complete failure of conduction from atria to ventricles (no P wave is conducted to the ventricle). The atrial rate is faster than the ventricular rate. P waves have no relation to QRS complexes (eg, they are electrically disconnected). Digitalis toxicity can manifest as AV dissociation.

Bundle Branch Block

Left Bundle Branch Block

Rate: <100 beats/min
Rhythm: Regular
PR interval: Normal
QT interval: Complete left bundle branch block (LBBB; QRS >0.12 second); incomplete LBBB (QRS = 0.10–0.12 second); lead V_1 negative RS complex; I, aVL, V_6 wide R wave without Q or S component; ST-segment and T-wave defection opposite direction of the R wave

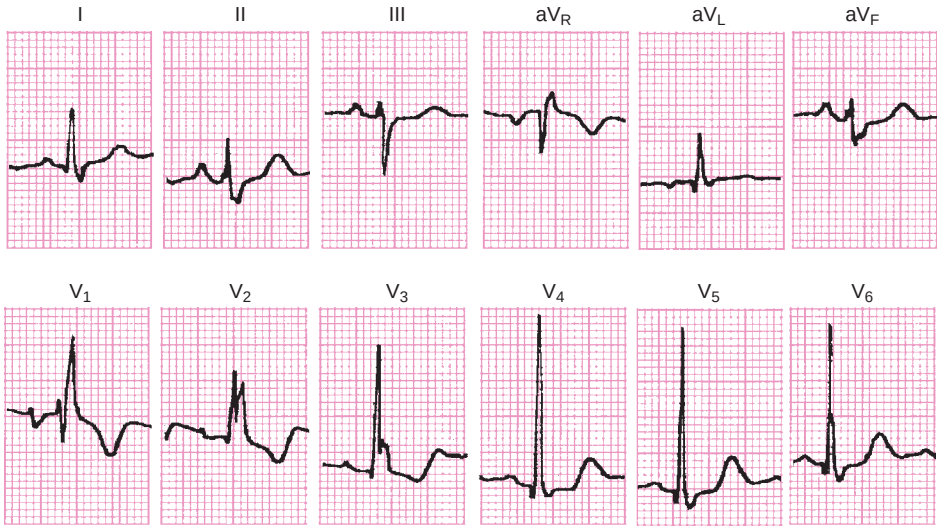
Note: LBBB does not occur in healthy patients and usually indicates serious heart disease with a poorer prognosis. In patients with LBBB, insertion of a pulmonary artery catheter may lead to complete heart block.



Right Bundle Branch Block

Rate: <100 beats/min
Rhythm: Regular
PR interval: Normal
QT interval: Complete right bundle branch block (RBBB; QRS >0.12 second); incomplete RBBB (QRS = 0.10–0.12 second); varying patterns of QRS complex; rSR (V_1); RS, wide R with M pattern; ST-segment and T-wave opposite direction of the R wave

Note: In the presence of RBBB, Q waves may be seen with a myocardial infarction (MI).

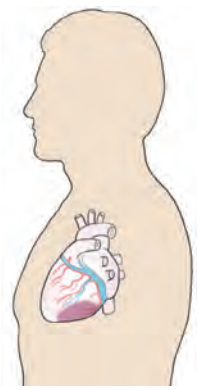


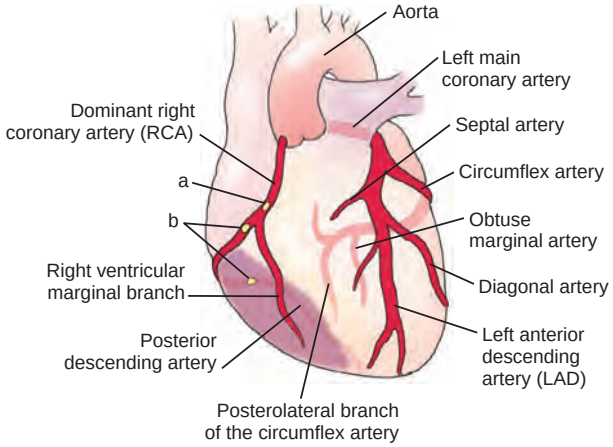
Coronary Artery Disease

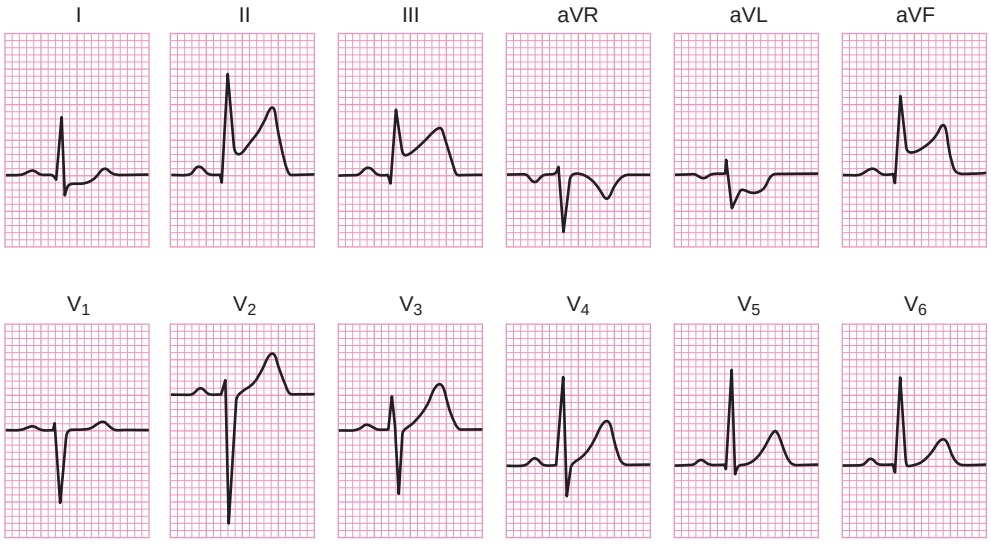
Transmural Myocardial Infarction

Q waves seen on the electrocardiogram, useful in confirming diagnosis, are associated with poorer prognosis and more significant hemodynamic impairment. Arrhythmias frequently complicate the course. Small Q waves may be a normal variant. For MI, Q waves last longer than 0.04 second, and depth exceeds one-third of the R wave (inferior wall MI). For inferior wall MI, differentiate it from right ventricular hypertrophy by axis deviation.

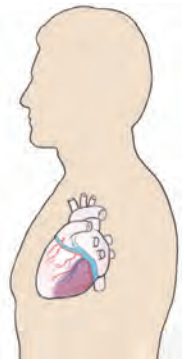
Anatomic Site	Leads	ECG Changes	Coronary Artery
Inferior	II, III, AVF	Q, ↑ST, ↑T	Right

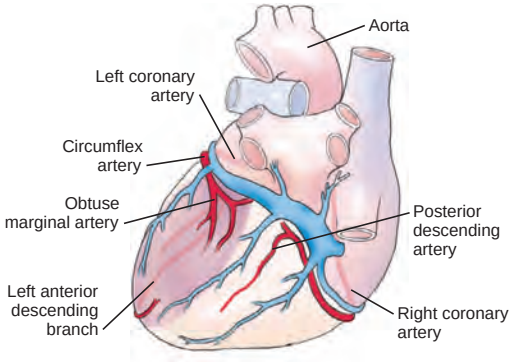


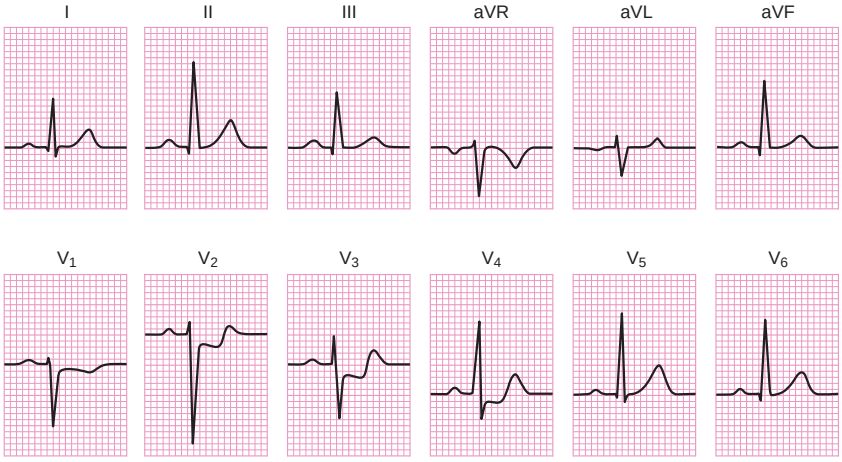




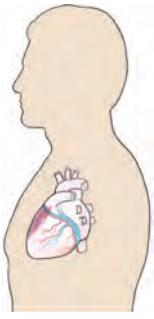
Anatomic Site	Leads	ECG Changes	Coronary Artery
Posterior	V_1–V_2	↑R, ↓ST, ↓T	Left circumflex

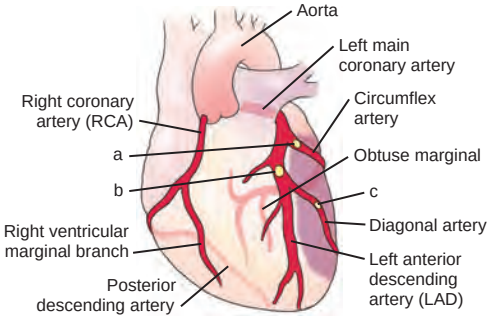


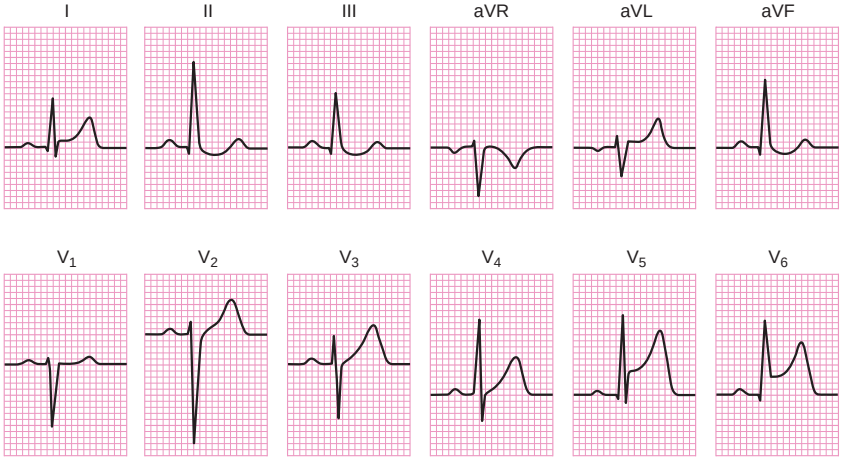




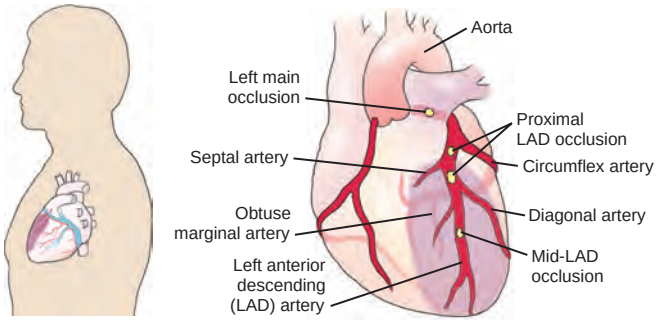
Anatomic Site	Leads	ECG Changes	Coronary Artery
Lateral	I, aVL, V_5, V_6	Q, ↑ST, ↑T	Left circumflex

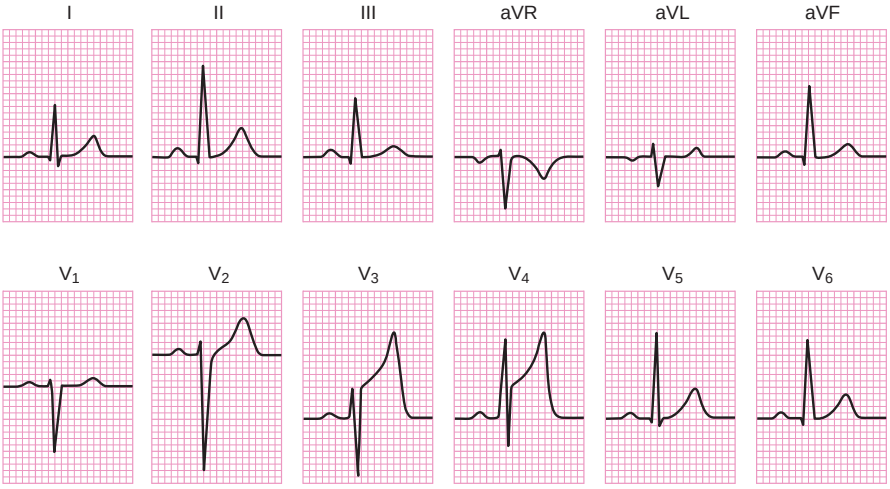




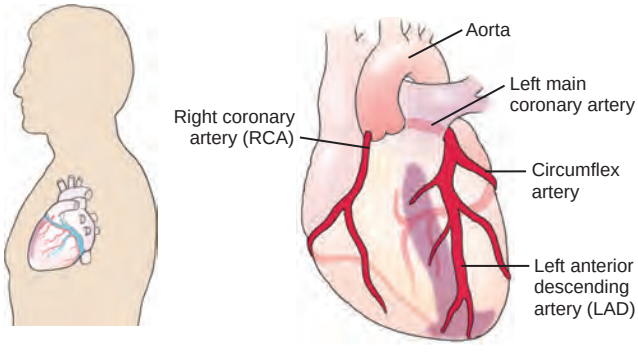


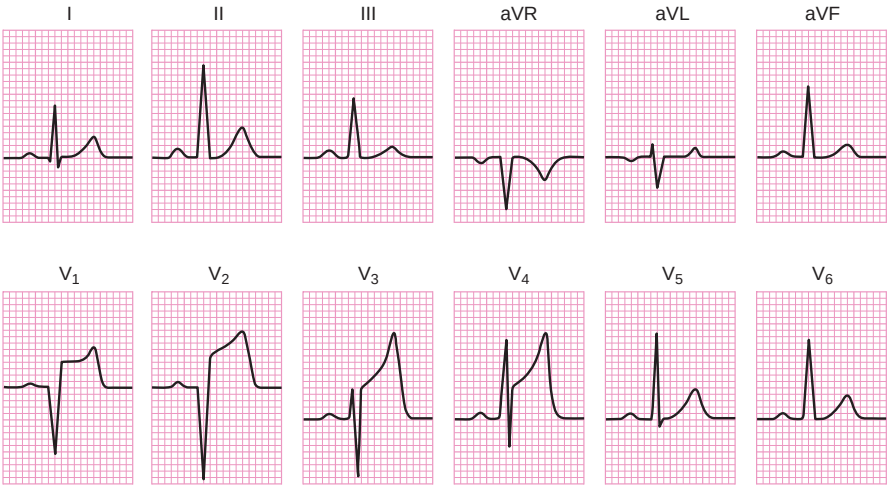
Anatomic Site	Leads	ECG Changes	Coronary Artery
Anterior	I, aVL, V_1–V_4	Q, ↑ST, ↑T	Left anterior descending





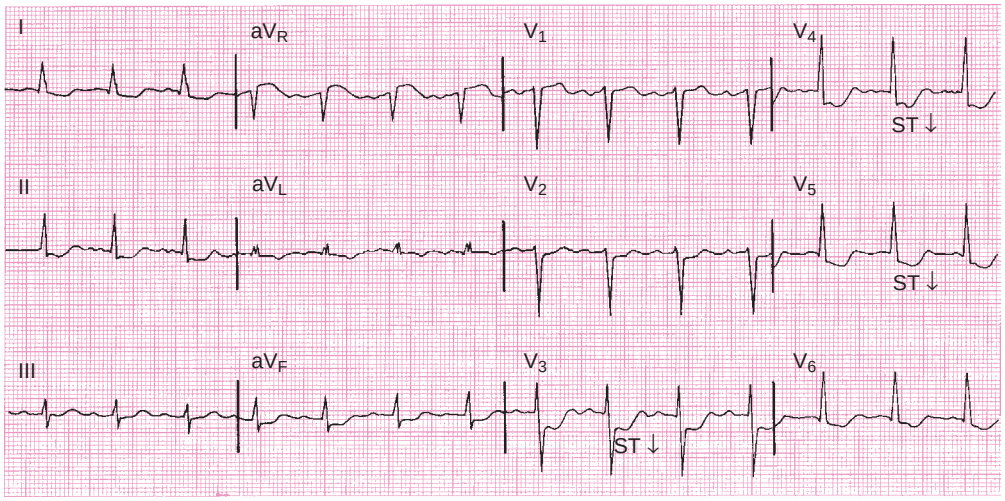
Anatomic Site	Leads	ECG Changes	Coronary Artery
Anteroseptal	V_1–V_4	Q, ↑ST, ↑T	Left anterior descending





Subendocardial Myocardial Infarction

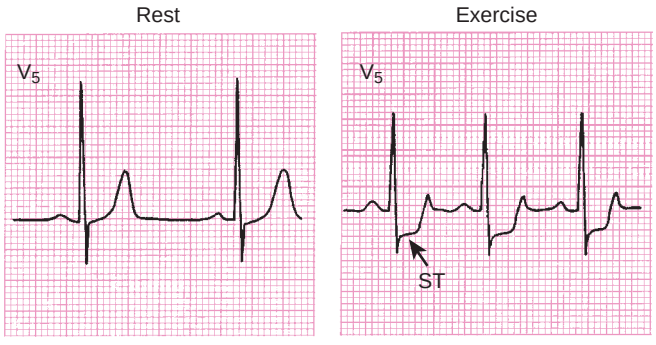
Persistent ST-segment depression or T-wave inversion occurs in the absence of a Q wave. This usually requires additional laboratory data (eg, isoenzymes) to confirm the diagnosis. The anatomic site of the coronary lesion is similar to that of transmural MI electrocardiographically.

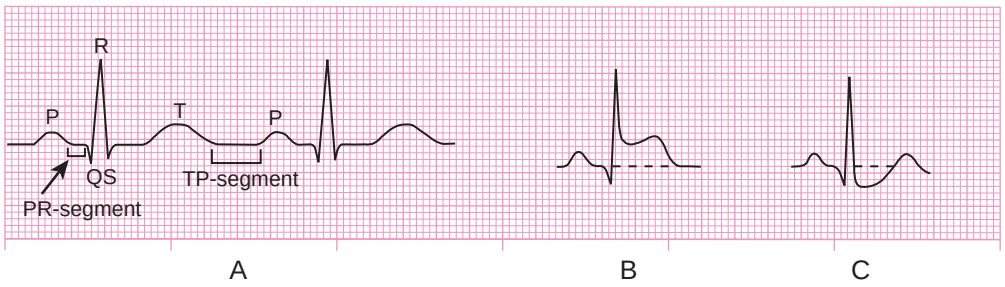


Myocardial Ischemia

Rate: Variable
Rhythm: Usually regular, but may show atrial and/or ventricular arrhythmias
PR interval: Normal
QT interval: ST segment depressed; J-point depression; T-wave inversion; conduction disturbances; coronary vasospasm (Prinzmetal) ST-segment elevation; (A) TP and PR intervals baseline for ST-segment deviation, (B) ST-segment elevation, (C) ST-segment depression

Note: Intraoperative ischemia usually is seen in the presence of "normal" vital signs (eg, ±20% of preinduction values).

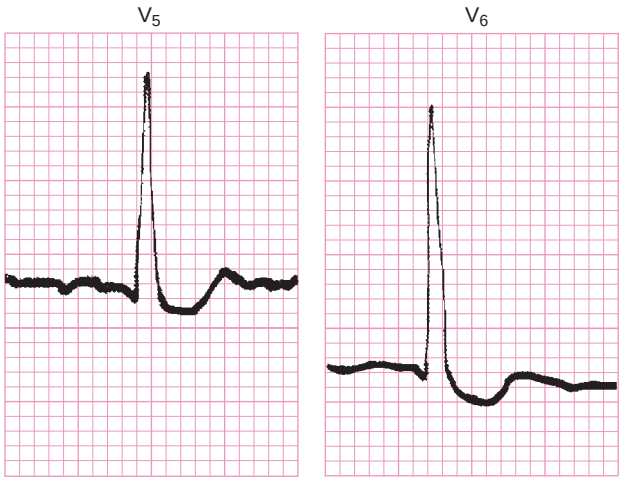




Digitalis Effect

Rate: <100 beats/min
Rhythm: Regular
PR interval: Normal or prolonged
QT interval: ST-segment sloping ("digitalis effect")

Note: Digitalis toxicity can be the cause of many common arrhythmias (eg, premature ventricular contractions, second-degree heart block). Verapamil, quinidine, and amiodarone cause an increase in serum digitalis concentration.

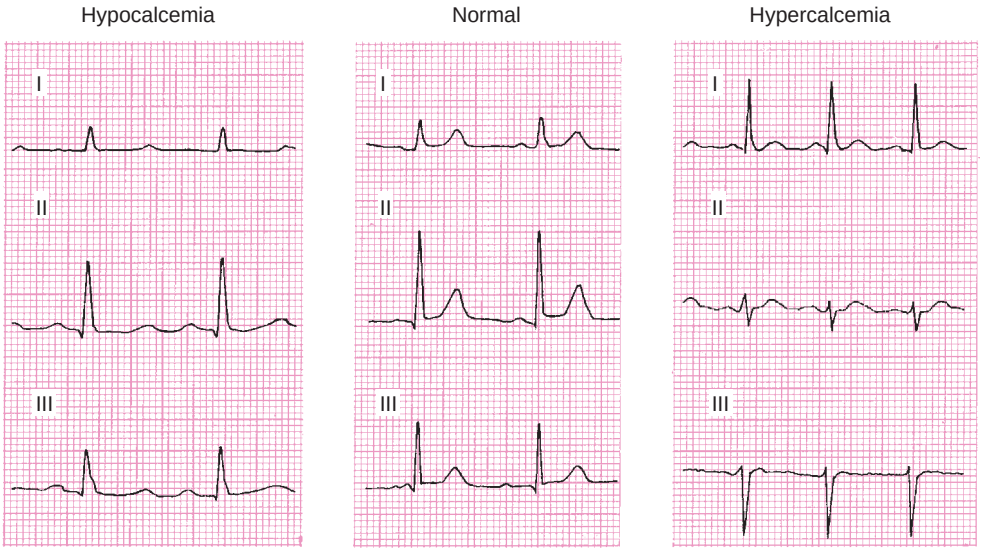


Electrolyte Disturbances

	↓Calcium	↑Calcium	↓Potassium	↑Potassium
Rate	<100 beats/min	<100 beats/min	<100 beats/min	<100 beats/min
Rhythm	Regular	Regular	Regular	Regular
PR interval	Normal	Normal/increased	Normal	Normal
QT interval	Increased	Decreased	Normal	Increased
Other			T wave flat U wave	T wave peaked

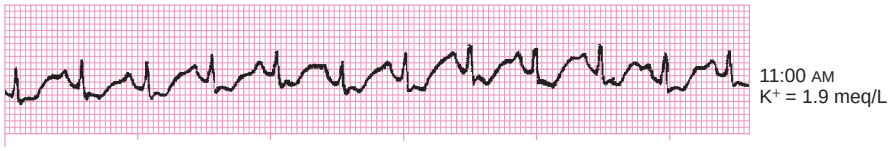
Note: Electrocardiographic (ECG) changes usually do not correlate with serum calcium. Hypocalcemia rarely causes arrhythmias in the absence of hypokalemia. In contrast, abnormalities in serum potassium concentration can be diagnosed by electrocardiogram. Similarly, in the clinical range, magnesium concentrations rarely are associated with unique ECG patterns. The presence of a "u" wave (>1.5 mm in height) also is seen in left main coronary artery disease, certain medications, and long QT syndrome.

Calcium



Potassium

Hypokalemia (K^+ = 1.9 mEq/L)

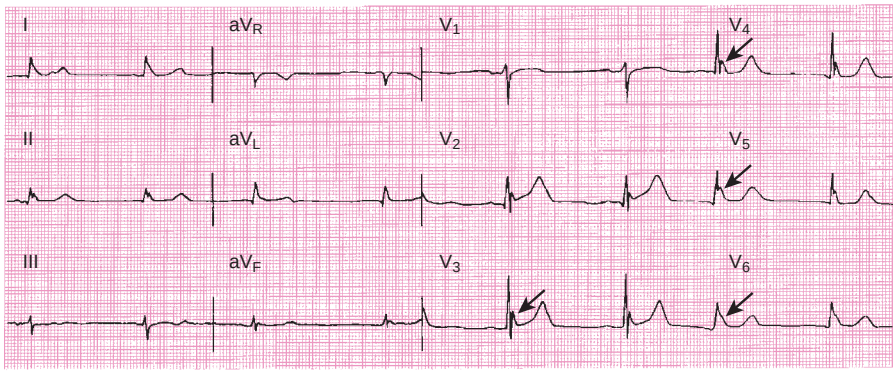


Hyperkalemia (K^+ = 7.9 mEq/L)

Hypothermia

Rate: <60 beats/min
Rhythm: Sinus
PR interval: Prolonged
QT interval: Prolonged

Note: This is seen at temperatures less than 33°C with ST-segment elevation (J point or Osborn wave). Tremor caused by shivering or Parkinson disease may interfere with ECG interpretation and may be confused with atrial flutter. This may represent a normal variant of early ventricular repolarization. (The *arrow* indicates a J point or Osborn waves.)



Multifocal Atrial Tachycardia

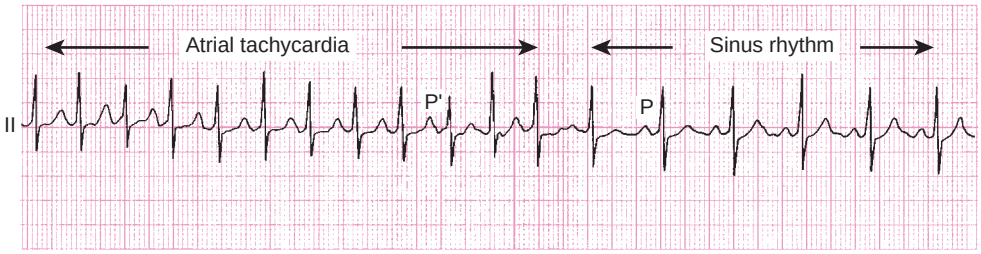
Rate: 100–200 beats/min
Rhythm: Irregular
PR interval: Consecutive P waves are of varying shape
QT interval: Normal

Note: This is seen in patients with severe lung disease. Carotid massage has no effect. At heart rates lower than 100 beats/min, it may appear as wandering atrial pacemaker. It may be mistaken for atrial fibrillation. Treatment is of the causative disease process.

Paroxysmal Atrial Tachycardia

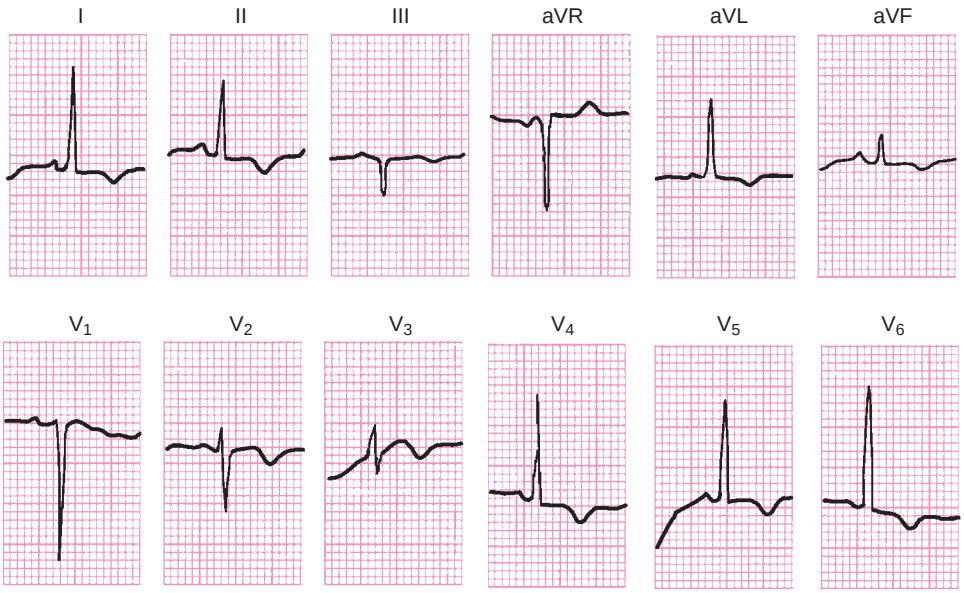
Rate: 150–250 beats/min
Rhythm: Regular
PR interval: Difficult to distinguish because of tachycardia obscuring P wave; P wave may precede, be included in, or follow QRS complex
QT interval: Normal, but ST segment and T wave may be difficult to distinguish

Note: Therapy depends on the degree of hemodynamic compromise. Carotid sinus massage may terminate the rhythm or decrease heart rate. In contrast to management of paroxysmal atrial tachycardia (PAT) in awake patients, synchronized cardioversion rather than pharmacologic treatment is preferred in hemodynamically unstable anesthetized patients.



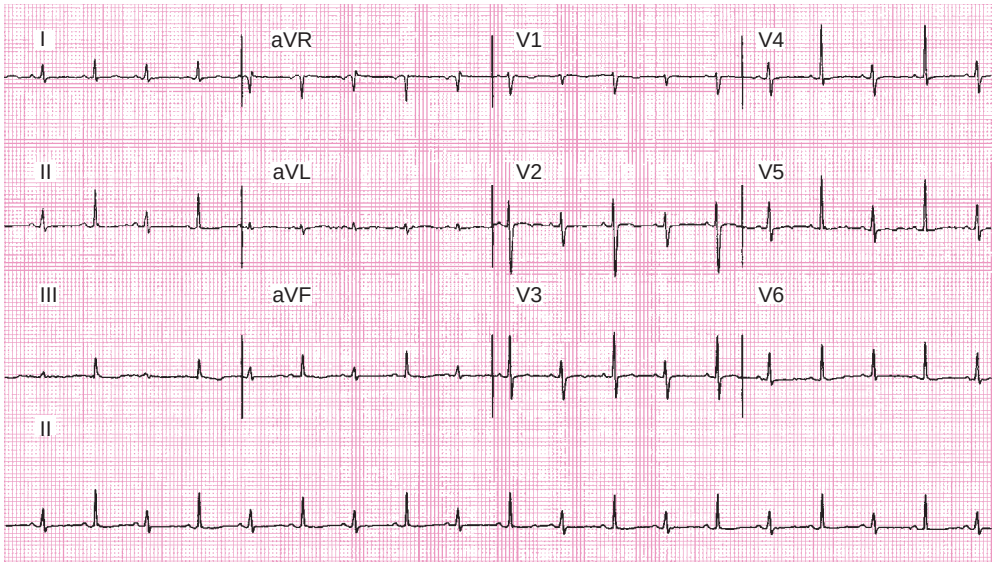
Pericarditis

Rate: Variable
Rhythm: Variable
PR interval: Normal
QT interval: Diffuse ST- and T-wave changes with no Q wave and seen in more leads than an MI



Pericardial Tamponade

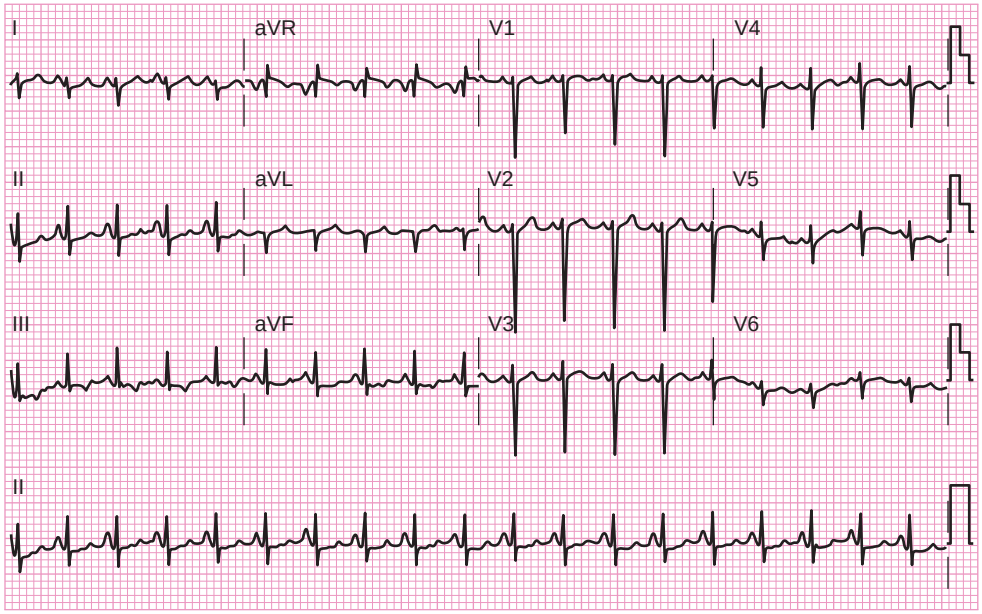
Rate: Variable
Rhythm: Variable
PR interval: Low-voltage P wave
QT interval: Seen as electrical alternans with low-voltage complexes and varying amplitude of P, QRS, and T waves with each heartbeat



Pneumothorax

Rate: Variable
Rhythm: Variable
PR interval: Normal
QT interval: Normal

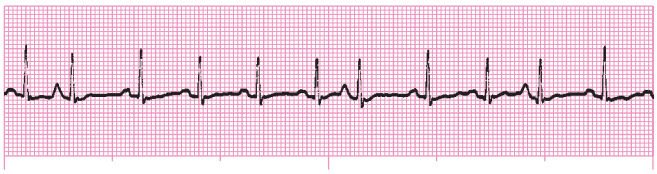
Note: Common ECG abnormalities include right-axis deviation, decreased QRS amplitude, and inverted T waves in leads V_1 to V_6. Differentiate from pulmonary embolus. It may manifest as electrical alternans; thus, pericardial effusion should be ruled out.



Premature Atrial Contraction

Rate: <100 beats/min
Rhythm: Irregular
PR interval: P waves may be lost in preceding T waves; PR interval variable
QT interval: QRS normal configuration; ST segment and T wave normal

Note: Nonconducted premature atrial contraction (PAC) appearance is similar to that of sinus arrest; T waves with PAC may be distorted by inclusion of a P wave in the T wave.



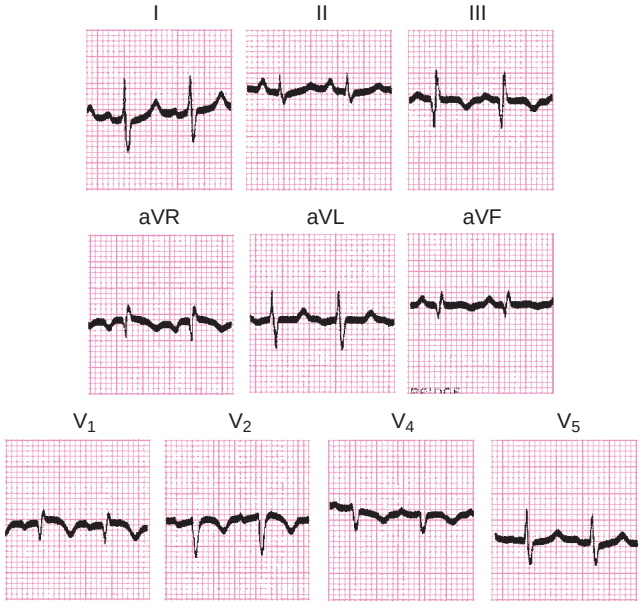
Premature Ventricular Contraction

Rate: Usually <100 beats/min
Rhythm: Irregular
PR interval: P wave and PR interval absent; retrograde conduction of P wave can be seen
QT interval: Wide QRS (>0.12 second); ST segment cannot be evaluated (eg, ischemia); T wave opposite direction of QRS with compensatory pause; fourth and eighth beats premature ventricular contractions

Pulmonary Embolus

Rate: >100 beats/min
Rhythm: Sinus
PR interval: P-pulmonale waveform
QT interval: Q waves in leads III and AV_F

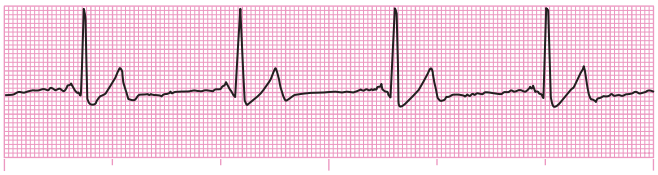
Note: Classic ECG signs of $S_1Q_3T_3$ with T-wave inversion are also seen in leads V_1 to V_4 and right ventricular strain (ST-segment depression in $V_{1–4}$). It may manifest with atrial fibrillation or flutter.



Sinus Bradycardia

Rate: <60 beats/min
Rhythm: Sinus
PR interval: Normal
QT interval: Normal

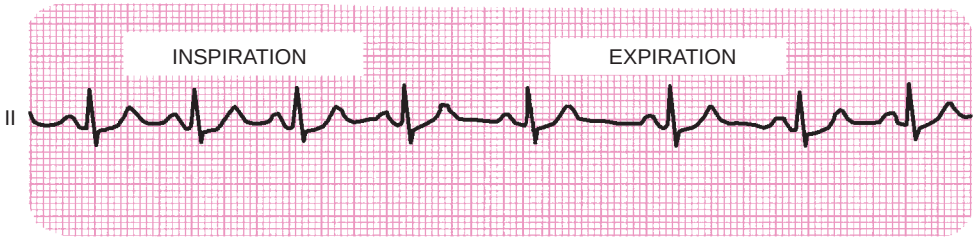
Note: This is seen in trained athletes as a normal variant.



Sinus Arrhythmia

Rate: 60–100 beats/min
Rhythm: Sinus
PR interval: Normal
QT interval: R-R interval variable

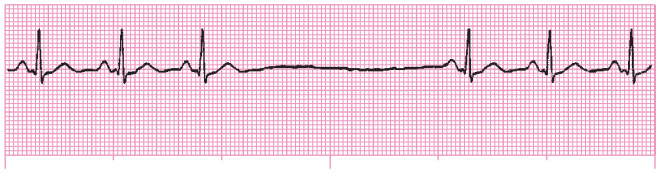
Note: Heart rate increases with inhalation and decreases with exhalation are ±10% to 20% (respiratory). Nonrespiratory sinus arrhythmia is seen in older adults with heart disease. It is also seen with increased intracranial pressure.



Sinus Arrest

Rate: <60 beats/min
Rhythm: Varies
PR interval: Variable
QT interval: Variable

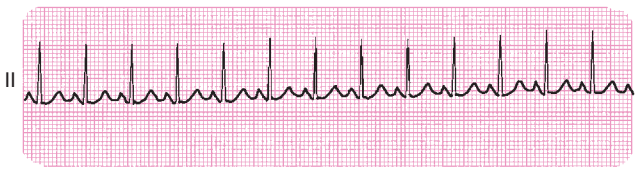
Note: Rhythm depends on the cardiac pacemaker's firing in the absence of sinoatrial stimulus (atrial pacemaker, 60–75 beats/min; junctional, 40–60 beats/min; ventricular, 30–45 beats/min). Junctional rhythm is most common. Occasional P waves may be seen (retrograde P wave).



Sinus Tachycardia

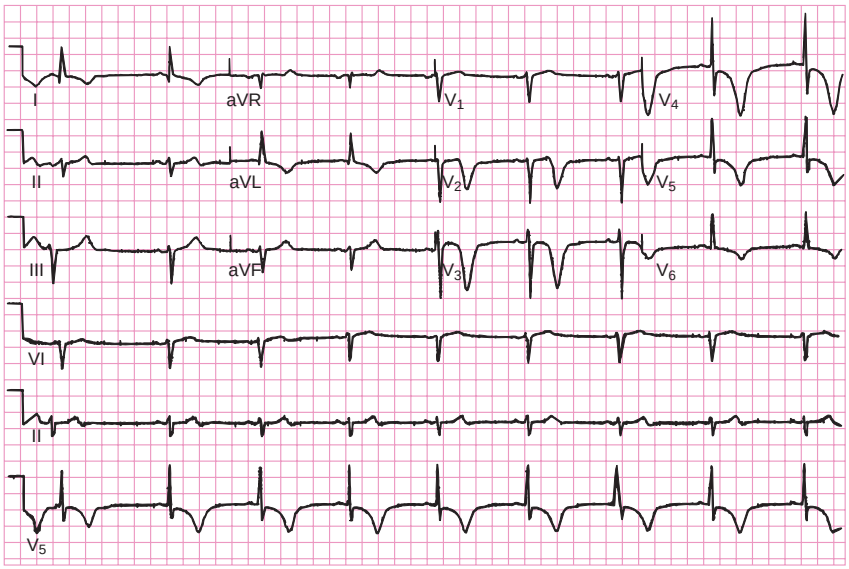
Rate: 100–160 beats/min
Rhythm: Regular
PR interval: Normal; P wave may be difficult to see
QT interval: Normal

Note: This should be differentiated from PAT. With PAT, carotid massage terminates the arrhythmia. Sinus tachycardia may respond to vagal maneuvers but reappears as soon as vagal stimulus is removed.



Subarachnoid Hemorrhage

Rate: <60 beats/min
Rhythm: Sinus
PR interval: Normal
QT interval: T-wave inversion deep and wide, prominent U waves; sinus arrhythmias; Q waves may be seen and may mimic acute coronary syndrome

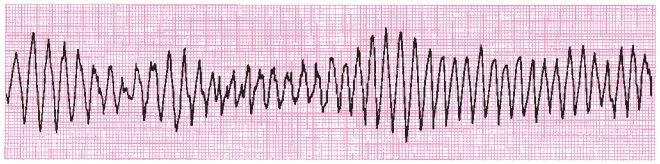


Torsades de Pointes

Rate: 150–250 beats/min
Rhythm: No atrial component seen; ventricular rhythm regular or irregular
PR interval: P wave buried in QRS complex
QT interval: QRS complexes usually wide and with phasic variation twisting around a central axis (a few complexes point upward, then a few point downward); ST segments and T waves difficult to discern

Note: This type of ventricular tachycardia is associated with a prolonged QT interval. It is seen with electrolyte disturbances (eg, hypokalemia, hypocalcemia, and hypomagnesemia) and bradycardia. Administering standard antiarrhythmic agents (eg, lidocaine, procainamide) may worsen torsades de pointes. Prevention includes treatment of the electrolyte disturbance. Treatment includes shortening of the QT interval, pharmacologically or by pacing; unstable polymorphic VT is treated with immediate defibrillation.

Torsades de Pointes: Sustained

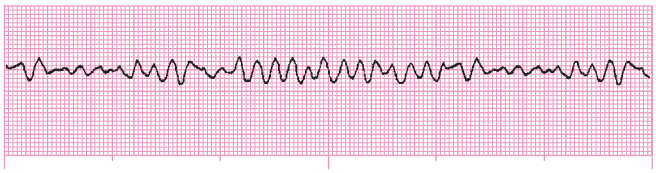


Ventricular Fibrillation

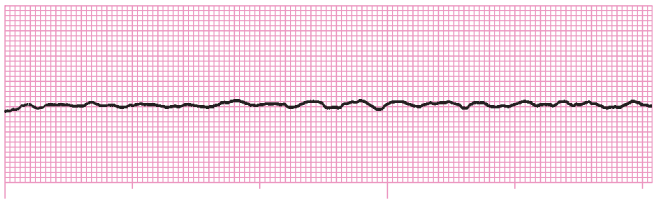
Rate: Absent
Rhythm: None
PR interval: Absent
QT interval: Absent

Note: "Pseudoventricular fibrillation" may be the result of a monitor malfunction (eg, ECG lead disconnect). Always check for the carotid pulse before instituting therapy.

Coarse Ventricular Fibrillation



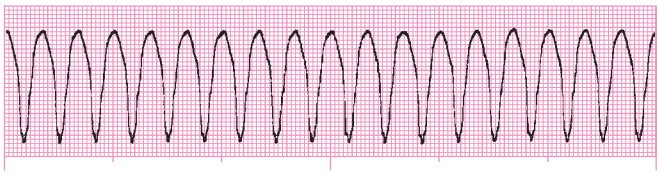
Fine Ventricular Fibrillation



Ventricular Tachycardia

Rate: 100–250 beats/min
Rhythm: No atrial component seen; ventricular rhythm irregular or regular
PR interval: Absent; retrograde P wave may be seen in QRS complex
QT interval: Wide, bizarre QRS complex; ST segment and T wave difficult to determine

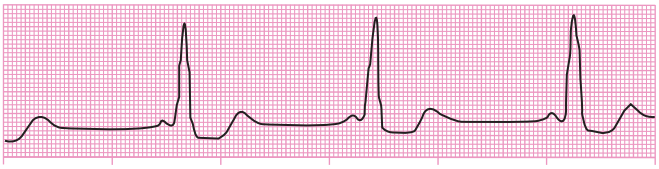
Note: In the presence of hemodynamic compromise, immediate direct current synchronized cardioversion is required. If the patient is stable, with short bursts of ventricular tachycardia, pharmacologic management is preferred. This should be differentiated from supraventricular tachycardia with aberrancy (SVT-A). A compensatory pause and AV dissociation suggest a premature ventricular contraction. P waves and SR′ (V_1) and slowing to vagal stimulus also suggest SVT-A.



Wolff-Parkinson-White Syndrome

Rate: <100 beats/min
Rhythm: Regular
PR interval: P wave normal; PR interval short (<0.12 second)
QT interval: Duration (>0.10 second) with slurred QRS complex; type A has delta wave, RBBB, with upright QRS complex V_1; type B has delta wave and downward QRS-V_1; ST segment and T wave usually normal

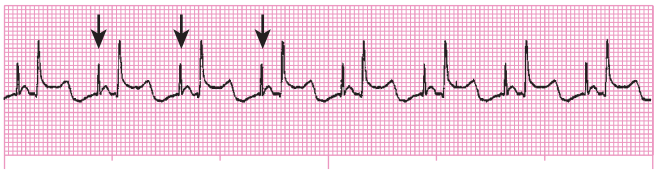
Note: Digoxin should be avoided in the presence of Wolff-Parkinson-White syndrome because it increases conduction through the accessory bypass tract (bundle of Kent) and decreases AV node conduction; consequently, ventricular fibrillation can occur.



Pacing

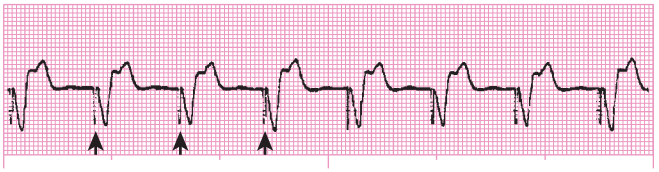
Atrial Pacing

Atrial pacing as demonstrated in this figure is used when the atrial impulse can proceed through the AV node. Examples are sinus bradycardia and junctional rhythms associated with clinically significant decreases in blood pressure. (The *arrows* are the pacemaker spike.)



Ventricular Pacing

In this tracing, ventricular pacing is evident by absence of an atrial wave (P wave) and the pacemaker spike preceding the QRS complex. Ventricular pacing is used in the presence of bradycardia secondary to AV block or atrial fibrillation. (The *arrows* are the pacemaker spike.)



DDD Pacing

The DDD pacemaker (generator), one of the most commonly used, paces and senses both the atrium and the ventricle. Each atrial and ventricular complex is preceded by a pacemaker spike.

Monitoring of the Heart and Vascular System

ALEXANDER J.C. MITTNACHT, MD | DAVID L. REICH, MD | MICHAEL SANDER, MD | JOEL A. KAPLAN, MD, CPE, FACC

KEY POINTS

1. Patients with severe cardiovascular disease and those undergoing surgery associated with rapid hemodynamic changes should be adequately monitored at all times.
2. Standard monitoring for cardiac surgery patients includes invasive blood pressure, electrocardiography, central venous pressure, urine output, temperature, capnometry, pulse oximetry, and intermittent blood gas analysis.
3. Additional monitoring is based on specific patient, surgical, and environmental factors. In the absence of evidence that advanced monitoring improves outcome, potential benefits have to be weighed against potential risks on an individual basis.
4. The Society of Cardiovascular Anesthesiologists and the American Society of Echocardiography have published recommendations for intraoperative transesophageal echocardiography (TEE) (see Chapters 14 through 17). TEE is recommended for all patients undergoing cardiac surgery, unless contraindications to probe insertion apply.
5. Transthoracic echocardiography is a less invasive alternative to TEE in the perioperative setting.
6. Ultrasound-guided vascular access is now routinely practiced in many institutions.
7. The use of pulmonary artery catheters (PACs) has been steadily declining. Guidelines for PAC use have been published but not specifically for the cardiac surgery setting. Many practitioners still use PACs to guide treatment in patients with low cardiac output or pulmonary arterial hypertension.
8. The role of noninvasive neuromonitoring is expanding, including regional oxygen saturation (cerebral oximetry) and processed electroencephalography (such as bispectral index) (see Chapter 18).
9. The use of additional highly invasive monitoring techniques, such as left atrial or coronary sinus pressures and cerebrospinal fluid pressures, are restricted to very specific indications.
10. Minimally invasive and noninvasive techniques for hemodynamic assessment continue to be developed, with increasing functionality and accuracy. Their role in the care of cardiac surgery patients requires further evaluation.

Hemodynamic Monitoring

The availability of monitoring devices is increasing continually. These devices range from those that are completely noninvasive to those that are highly invasive, such as the pulmonary artery catheter (PAC). Limitations to less invasive monitoring technologies often apply, and interventions based on information gained from noninvasive monitoring carry intrinsic risks, such as when blood is transfused to a patient with low cerebral oximetry readings. To make the best use of any monitoring technology, the potential benefits to be gained from the information must outweigh the potential complications. This risk-benefit ratio is highly variable and must be evaluated for each clinical scenario individually.

In many patients with significant cardiovascular morbidity undergoing cardiac or major noncardiac surgery, the benefits obtained are often believed to outweigh the risks, explaining the widespread use of invasive monitoring. Although outcome changes are difficult to prove, the assumption that appropriate hemodynamic monitoring should reduce the incidence of major cardiovascular complications is reasonable. This is based on the presumption that the data obtained from these monitors are interpreted correctly and that therapeutic interventions known to improve outcomes are implemented in a timely fashion.

Standard monitoring for all patients undergoing surgery has been defined by the American Society of Anesthesiologists (ASA) practice guidelines.[1] In patients undergoing cardiac or major noncardiac surgery with expected large fluid shifts or hemodynamic instability, invasive blood pressure (BP) monitoring is nearly universally employed, which also enables frequent arterial blood sampling. Transesophageal echocardiography (TEE), a less invasive technology, provides extensive hemodynamic data and other diagnostic information and is described in detail in Chapters 14 through 17. The Society of Cardiovascular Anesthesiologists and the American Society of Echocardiography have published recommendations for intraoperative TEE use.[2] Unless contraindications to probe insertion apply, TEE is now recommended for all patients undergoing cardiac surgery. The role of noninvasive brain monitoring is expanding, including regional oxygen saturation (cerebral oximetry) and processed electroencephalography (such as bispectral index). In the absence of guidelines specifying their role, institutional practices often include some form of neuromonitoring in patients undergoing cardiac surgery. Box 13.1 summarizes monitoring typically used in cardiac and major noncardiac surgeries.

The next tier of monitoring is typically more invasive, including PACs with thermodilution cardiac output (CO) and other CO monitors, spinal fluid pressure for thoracic aorta surgery (see Chapter 23), and rarely, left atrial pressure (LAP) monitoring. The interpretation of these complex data requires an astute clinician who is aware of the patient's overall condition and the limitations of the monitors. Additionally, with the expansion of less invasive surgical techniques,

BOX 13.1 STANDARD MONITORING FOR CARDIAC SURGICAL PATIENTS

- (Invasive) blood pressure
- Electrocardiogram
- Pulse oximetry
- Capnometry
- Temperature
- Central venous pressure
- Transesophageal echocardiography
- Urine output
- Intermittent arterial blood sampling for blood gas and laboratory analyses
- Neuromonitoring (cerebral oximetry, processed electroencephalography)

BOX 13.2 EXTENDED MONITORING FOR PATIENTS BASED ON CASE-SPECIFIC FACTORS

- Retrograde cardioplegia pressure
- Pulmonary artery catheter
- Cardiac output measurements
- Left atrial pressure
- Cerebrospinal fluid (intrathecal) pressure

the anesthesiologist is getting more involved in guiding cardiopulmonary bypass (CPB) cannulation and adequacy of cardioprotection techniques. This includes retrograde cardioplegia cannula positioning in the coronary sinus (CS) and pressure monitoring. Advanced monitoring is summarized in Box 13.2.

Arterial Pressure Monitoring

Anesthesia for cardiac and major noncardiac surgeries is frequently complicated by rapid and sudden changes in BP. Sudden losses of large amounts of blood, direct compression of the heart, impaired venous return attributable to retraction and cannulation of the vena cavae and aorta, arrhythmias, and manipulations that may impair right ventricular outflow and pulmonary venous return all contribute to hemodynamic instability. Therefore a safe and reliable method of measuring acute changes in BP is indispensable. Numerous methods of noninvasive BP measurement are clinically available and are discussed later in this chapter. Despite significant technologic advancements, none of these noninvasive devices so far have proven to be suitable for cardiac surgery. Thus direct intraarterial monitoring remains the gold standard, providing a continuous, beat-to-beat indication of the arterial pressure and waveform and allowing frequent sampling of arterial blood for laboratory analyses.

General Principles

The arterial pressure waveform ideally is measured in the ascending aorta. The pressure measured in the more peripheral arteries is different from the central aortic pressure, because the arterial waveform becomes progressively more distorted as the signal is transmitted down the arterial system. The high-frequency components, such as the dicrotic notch, disappear, the systolic peak increases, the diastolic trough decreases, and a transmission delay occurs. These changes are caused by decreased arterial compliance in the periphery and reflection and resonance of pressure waves in the arterial tree.[3] This effect is most pronounced in the dorsalis pedis artery, in which the systolic blood pressure (SBP) may be 10 to 20 mm Hg higher and the diastolic blood pressure (DBP) 10 to 20 mm Hg lower than in the central aorta

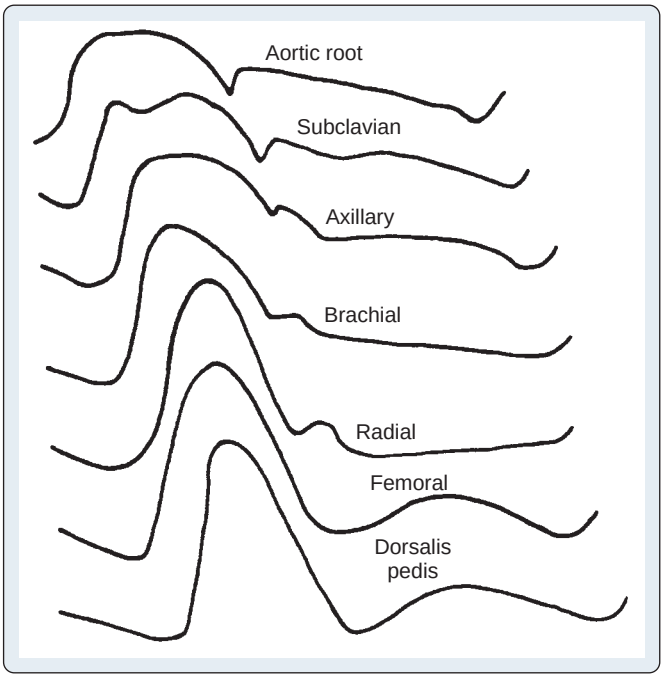

Fig. 13.1 The waveform of the arterial pressure changes significantly according to the site of the intraarterial catheter. These changes are shown as a progression from central monitoring *(top)* through peripheral monitoring *(bottom)*. These changes are thought to be caused by forward wave propagation and wave reflection. In the periphery, systolic pressure is higher, diastolic pressure is lower, and mean pressure is minimally lower. *(Modified from Bedford RF. Invasive blood pressure monitoring. In: Blitt CD, ed.* Monitoring in Anesthesia and Critical Care. *New York: Churchill Livingstone; 1985:505.)*

(Fig. 13.1).[4] Despite this distortion, the mean arterial pressure (MAP) measured in the peripheral arteries should be similar to the central aortic pressure under normal circumstances. After separation from CPB, however, MAP measured in a peripheral artery can be significantly lower than central aortic pressure for periods of time.[5,6]

The magnitude of BP is directly related to CO and systemic vascular resistance (SVR). This is conceptually similar to Ohm's law of electricity (voltage = current × resistance), in which BP is analogous to voltage, CO to current flow, and SVR to resistance. An increase in BP may reflect an increase in CO or SVR, or both.

MAP is probably the most useful parameter when assessing overall end-organ perfusion. MAP is measured directly by integrating the arterial waveform tracing over time or using the formula: MAP = (SBP + [2 × DBP]) ÷ 3. Perfusion of the heart differs from most other organs, with coronary perfusion of the left ventricle mostly occurring during diastole. Coronary blood flow to the normal right ventricle (RV) is maintained during systole and diastole. However, in patients with right ventricular hypertrophy or pulmonary arterial hypertension, perfusion of the RV becomes significantly decreased during right ventricular systole and more dependent on the diastolic phase of the cardiac cycle and diastolic perfusion pressure.[7,8]

Additional information can be gained from an arterial waveform tracing that supplements timely BP measurements.[9] For example, the slope of the arterial upstroke correlates with the derivative of pressure measured over time (dP/dt) and gives an indirect estimate of myocardial contractility. This information is not always reliable, because an increase in SVR alone will also result in an increase in the slope of the upstroke. The arterial pulse contour can be used to estimate stroke volume (SV) and CO. Large SBP variations during the respiratory cycle in the mechanically ventilated patient suggest hypovolemia.[10–12] A reduced pulse pressure and small area under the arterial pressure curve can indicate low CO; however, technical errors in pressure

transducing and associated cardiac pathologic conditions complicate these interpretations.

Components of a Pressure Measurement System

Pressure waves in the arterial (or venous) tree represent the transmission of forces generated in the cardiac chambers. Measurement of these forces requires their transmission to a device that converts mechanical energy into electronic signals. The components of a system for intravascular pressure measurement include an intravascular catheter, fluid-filled tubing and connections, an electromechanical transducer, an electronic analyzer, and electronic storage and display systems. For arterial pressure measurements, short, narrow catheters are recommended (20 gauge or smaller), because they have favorable dynamic response characteristics and are less thrombogenic than larger catheters.[13] An artifact associated with intraarterial catheters has been designated *end-pressure artifact*.[14] When flowing blood comes to a sudden halt at the tip of the catheter, it is estimated that an added pressure of 2 to 10 mm Hg results. Conversely, clot formation on the catheter tip will dampen the system and narrow the pulse pressure. The coupling system usually consists of pressure tubing, stopcocks, and a continuous flushing device. This is the major source of distortion of arterial pressure tracings. The arterial catheter should be kept patent with a continuous infusion of normal saline solution (1 to 3 mL/hr). Heparin is no longer routinely recommended as an additive to flush solutions, attributable to the risk of heparin-induced thrombocytopenia in susceptible patients. The function of pressure transducers is to convert mechanical forces into electrical current or voltage, which is accomplished by incorporating a variable resistor into a Wheatstone bridge–type electrical circuit. The resistor changes electrical resistance according to the mechanical forces transmitted via a fluid column. To avoid direct contact, the resistor is separated from the fluid column and blood by a diaphragm into which the resistive elements have been etched. The manufacturers have adopted an output standard of 5 μV per volt excitation per 1 mm Hg so that, theoretically, any transducer can be used with any monitor.[15] Modern disposable transducers are already calibrated and pass manufacturing standards, thus eliminating many of the difficulties that used to require frequent recalibration because of drifting of the zero point. Nevertheless, drifting of the zero point still occurs and may be attributed to the transducer-to-cable-to-monitor input connection. Unrecognized drifting of the zero point is a serious problem, possibly resulting in unwarranted and potentially harmful interventions. The major practical problem remaining with transducer systems, however, is improper levelling of the transducer height relative to the patient. For accurate pressure readings, and especially for accurately determining pressure values in the low pressure system, exact leveling of the transducer height with the heart must be achieved. Careful leveling with the midaxillary line is the most common method. Alternatively, fluid-filled pressure tubing passed from the surgical field is connected to a transducer, with the height of the transducer adjusted until the pressure reads zero. It is important to recall that electronically zeroing the transducer system is a distinct task from accurate leveling of the transducer unit. This problem is of less clinical relevance for arterial BP measurements yet still results in errors that could adversely affect care.

Characteristics of a Pressure Measurement System

The dynamic response of a pressure measurement system is characterized by its natural frequency and its damping.[16] These concepts are best understood by snapping the end of a transducer-tubing assembly with a finger. The waveform on the monitor demonstrates rapid oscillations above and below the baseline (the natural frequency), which quickly decays to a straight line attributable to friction in the system (damping). The peaks and troughs of an arterial pressure waveform will be amplified if the transducer-tubing-catheter assembly has a natural frequency that lies close to the frequencies of the underlying sine waves of an arterial pressure waveform (typically less than 20 Hz).

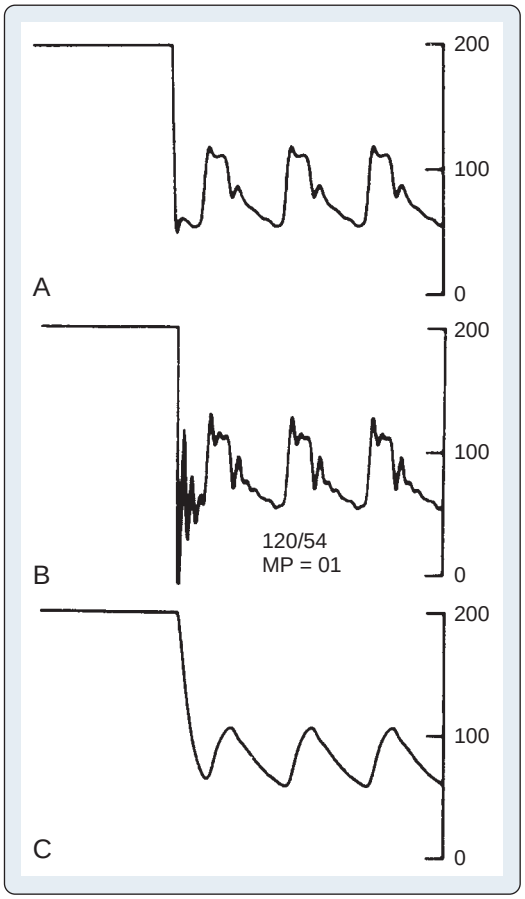

Fig. 13.2 The fast-flush test demonstrates the harmonic characteristics of a pressure monitoring system (ie, transducer, fluid-filled tubing, and intraarterial catheter). In an optimally damped system *(A)*, the pressure waveform returns to baseline after only one oscillation. In an underdamped system *(B)*, the pressure waveform oscillates above and below the baseline several times. In an overdamped system *(C)*, the pressure waveform returns to the baseline slowly with no oscillations. *(A–C, Adapted from Gibbs NC, Gardner RM. Dynamics of invasive pressure monitoring systems: clinical and laboratory evaluation.* Heart Lung. *1988;17:43–51.)*

This is commonly known as *ringing* or *resonance* of the system (Fig. 13.2). For an arterial pressure monitoring system to remain accurate at a higher heart rate (HR), its natural frequency should be higher. It is recommended that the natural frequency of the pressure transducing system is at least eight times higher than the frequency of the measured sine wave. Thus for an HR up to 180 beats per minute, the resulting minimum natural frequency requirement would be 24 Hz (ie, [180 × 8] ÷ 60 seconds).[17] The dynamic response of the bare transducers without the tubing is usually considerably higher, in the 200 to 500 Hz range. However, adding transducer tubing and three-way stopcocks significantly lowers the natural frequency. In general, longer transducer tubing decreases the natural frequency of the system and tends to amplify the height of the SBP (peak) and the depth of the DBP (trough) values.[16,18] Boutros and Albert[19] demonstrated that by changing the length of low-compliance (rigid) tubing from 6 inches to 5 feet, the natural frequency decreased from 34 to 7 Hz. As a result of the reduced natural frequency of the pressure transducing system, the SBP measured with the longer tubing exceeded reference pressures by 17.3%. Conversely, reducing the length of the tubing or a larger size cannula will increase the natural frequency.

Damping is the tendency of factors such as friction, compliant (soft) tubing, and air bubbles to absorb energy and decrease the amplitude of peaks and troughs in the waveform. The optimal degree of damping

is that which counterbalances the distorting effects of transducer-tubing systems with lower natural frequencies, which is very difficult to achieve. The damping of a clinical pressure measurement system can be assessed by observing the response to a rapid high-pressure flush of the transducer-tubing-catheter system (see Fig. 13.2). In a system with a low damping coefficient, a fast-flush test results in several oscillations above and below the baseline before the pressure becomes constant. In an adequately damped system, the baseline is reached after one oscillation, whereas in an overdamped system, the baseline is reached after a delay and without oscillations.[20–23] Overdamping causes a falsely lower SBP reading and a higher DBP reading, with the mean arterial BP mostly unaffected, unless a significant distortion occurs (eg, from clot formation). Underdamping of a system results in the opposite effects on BP readings. These may be a major source of error, causing an underreading of the SBP and overreading of DBP, although the MAP is relatively unaffected.

The formulas for calculating the natural frequency and damping coefficient are as follows:

$$\text{Natural frequency: } f_n = \frac{d}{8}\sqrt{\frac{3}{\pi L \rho V_d}}$$

$$\text{Damping coefficient: } \zeta = \frac{16\eta}{d^3}\sqrt{\frac{3LV_d}{\pi\rho}}$$

where d = tubing diameter;
L = tubing length;
ρ = density of the fluid;
V_d = transducer fluid volume displacement; and
n = viscosity of the fluid

Arterial Cannulation Sites

Factors that influence the site of arterial cannulation include the location of surgery, the possible compromise of arterial flow attributable to patient positioning or surgical manipulations, CPB cannulation and perfusion techniques, and any history of ischemia or prior surgery on the limb to be cannulated. Surgeons may use the axillary artery as the site of cannulation for CPB in patients who require anterograde selective cerebral perfusion or with a severely diseased ascending aorta.[24–26] Depending upon the surgical technique, possible complications associated with axillary artery cannulation include distal limb ischemia (direct axillary artery cannulation with the CPB arterial cannula), or limb overcirculation with systemic hypoperfusion (as may occur with axillary side graft anastomosis with graft perfusion).[27] Most clinicians monitor the arterial pressure in the contralateral upper extremity, but some have also advocated additional monitoring of the radial artery on the ipsilateral side to detect overcirculation or hypoperfusion of the arm and to intervene accordingly. Monitoring arterial BP at two or more sites may be warranted in complex cases with complex perfusion techniques and/or long CPB times. For example, a radial arterial pressure may be supplemented by more central aortic pressures obtained from the femoral or axillary arteries or the aorta itself in the surgical field. The advantage of a central arterial tracing is the increased accuracy compared with radial arterial pressure in patients after separation from CPB.[28,29] Although reasons for the difference between central and peripheral measurements of BP after separation from CPB are not entirely clear, they were transiently present in 17% to 40% of patients in several studies.[28,30,31] Kanazawa and associates[32] suggested that a decrease in the arterial elasticity is responsible for instances in which lower radial artery pressures (compared with aortic pressures) are observed after CPB. Temporary central aortic pressure monitoring can be achieved by using a needle (attached to pressure tubing) that is placed in the aorta or by pressure tubing connected to the aortic CPB cannula or the anterograde cardioplegia cannula. Central aortic monitoring is usually only necessary for several minutes until the problem resolves; in rare cases, a femoral arterial cannula is placed from the surgical field. Sites generally chosen for arterial cannulation are discussed in the following paragraphs.

Radial and Ulnar Arteries

The radial artery is the most commonly used artery for continuous BP monitoring because it is easy to cannulate, readily accessible during surgery, and the collateral circulation is usually adequate and easy to check. The ulnar artery provides most of the blood flow to the hand in approximately 90% of patients.[33] The radial and ulnar arteries are connected by a palmar arch, which provides collateral flow to the hand in the event of radial artery occlusion. The palm showed that if ulnar collateral flow is adequate, then circulatory perfusion pressure to the fingers is adequate after radial arterial catheterization.[34] Some clinicians perform the Allen test before radial artery cannulation to assess the adequacy of collateral circulation to the hand; however, the predictive value of the Allen test has been challenged. Barbeau and colleagues[35] compared the modified Allen test with pulse oximetry and plethysmography in 1010 consecutive patients undergoing percutaneous radial artery cannulation for cardiac catheterization. Pulse oximetry and plethysmography were more sensitive than the Allen test for detecting inadequate collateral blood supply, and only 1.5% of patients were not suitable for radial artery cannulation.

The Allen test is performed by compressing the radial and ulnar arteries and by exercising the hand until it is pale. The ulnar artery is then released (with the hand open loosely), and the time until the hand regains its normal color is noted.[36] With a normal collateral circulation, the color returns to the hand in approximately 5 seconds. If, however, the hand takes longer than 15 seconds to return to its normal color, then cannulation of the radial artery on that side is controversial. The hand may remain pale if the fingers are hyperextended or widely spread apart, even in the presence of a normal collateral circulation.[37] Variations on the Allen test include using a Doppler probe or pulse oximeter to document collateral flow.[38–40] If the Allen test demonstrates that the hand depends on the radial artery for adequate filling, then another cannulation site should be chosen. Rarely, if other cannulation sites are not available, then the ulnar artery may be selected.[41]

Brachial and Axillary Arteries

The brachial artery lies medial to the bicipital tendon in the antecubital fossa in close proximity to the median nerve. Brachial artery pressure tracings resemble those in the femoral artery with less systolic augmentation than radial artery tracings.[42] Brachial arterial pressures were found to reflect central aortic pressures more accurately than radial arterial pressures before and after CPB.[43] A few series of patients with perioperative brachial arterial monitoring have documented the relative safety of this technique.[28,44] Armstrong and associates[45] published data on 1326 patients with peripheral vascular disease undergoing angiography with percutaneous brachial artery access and found an overall complication rate of 1.28% with a higher risk of thrombosis in female patients. Since there is little or no collateral flow to the hand if brachial artery occlusion occurs, then most clinicians choose other sites, if possible.

The axillary artery is normally cannulated by the Seldinger technique near the junction of the deltoid and pectoral muscles. Because the tip of the 15- to 20-cm catheter may lie within the aortic arch, the use of the left axillary artery is recommended to minimize the risk of cerebral embolization during flushing. Lateral decubitus positioning or adduction of the arm occasionally results in kinking of axillary catheters with damping of the pressure waveform.

Femoral Artery

The femoral artery may be cannulated for monitoring purposes and typically provides a more reliable central arterial pressure after discontinuation of CPB. Scheer and colleagues[46] have reviewed the literature on peripheral artery cannulation for hemodynamic monitoring, including 3899 femoral artery cannulations. Temporary occlusion was found in 10 patients (1.45%), whereas serious ischemic complications requiring extremity amputation were reported in 3 patients (0.18%).

Other complications that were summarized from the published data were pseudoaneurysm formation (0.3%), sepsis (0.44%), local infection (0.78%), bleeding (1.58%), and hematoma (6.1%). Older literature stated that the femoral area was intrinsically dirty and that catheter sepsis and mortality were significantly increased, compared with other monitoring sites. This assertion could not be confirmed in the more recent literature; however, recent infection prevention guidelines discourage femoral cannulation.[47,48]

In patients undergoing thoracic aortic surgery, distal aortic perfusion (using partial CPB, left-sided heart bypass, or a heparinized shunt) may be performed during aortic cross-clamping to preserve spinal cord and visceral organ blood flow. In these situations, measuring the distal aortic pressure at the femoral artery or a branch vessel is useful (ie, dorsalis pedis or posterior tibial artery) to optimize the distal perfusion pressure. In repairs of aortic coarctation, simultaneous femoral and radial arterial monitoring may help determine the adequacy of the surgical repair by documenting the pressure gradient after the repair. Consulting the surgeon before cannulating the femoral vessels is necessary, because these vessels may be used for extracorporeal perfusion or placement of an intraaortic balloon pump during the surgical procedure.

Dorsalis Pedis and Posterior Tibial Arteries

The two primary arteries to the foot are the dorsalis pedis artery and the posterior tibial artery, which form an arterial arch on the foot that is similar to the one formed by the radial and ulnar arteries in the hand. The dorsalis pedis artery or the posterior tibial artery is a reasonable alternative to radial arterial catheterization.[49] The SBP is usually 10 to 20 mm Hg higher in the dorsalis pedis artery than in the radial or brachial arteries, whereas the DBP is 15 to 20 mm Hg lower (see Fig. 13.1).[50] These vessels should not be used in patients with severe peripheral vascular disease from diabetes mellitus or other causes.

Indications

The indications for invasive arterial monitoring are provided in Box 13.3.

BOX 13.3 INDICATIONS FOR INTRAARTERIAL MONITORING

- Major surgical procedures involving large fluid shifts or blood loss
- Surgery requiring cardiopulmonary bypass
- Surgery of the aorta
- Patients with pulmonary disease requiring frequent arterial blood gases
- Patients with recent myocardial infarctions, unstable angina, or severe coronary artery disease
- Patients with decreased left ventricular function (congestive heart failure) or significant valvular heart disease
- Patients in hypovolemic, cardiogenic, or septic shock, or with multiple organ failure
- Procedures involving the use of prolonged deliberate hypotension or deliberate hypothermia
- Massive trauma cases
- Patients with right-sided heart failure, chronic obstructive pulmonary disease, pulmonary hypertension, or pulmonary embolism
- Patients requiring inotropes or intraaortic balloon counterpulsation
- Patients with electrolyte or metabolic disturbances requiring frequent blood samples
- Inability to measure arterial pressure noninvasively (eg, extreme morbid obesity)

Contraindications

The contraindications to arterial cannulation include local infection, coagulopathy, vaso-occlusive disorders, and surgical considerations. Coagulopathy is a relative contraindication because it may result in hematoma formation during arterial cannulation. Applying direct arterial pressure with failed attempts or when the catheter is removed when using more central cannulation sites is more difficult. Therefore in anticoagulated patients, it is recommended that more peripheral arterial cannulation sites be considered when this form of monitoring is required. Radial and brachial arterial cannulations are contraindicated in patients with a history of Raynaud syndrome or Buerger disease (thromboangiitis obliterans). This consideration is especially important in the perioperative setting with Raynaud syndrome, because hypothermia of the hand is the primary trigger for vasospastic attacks.[51] It is recommended that large arteries, such as the femoral or axillary, be used for intraarterial monitoring if indicated in patients with either of these diseases.

Insertion Techniques

Direct Cannulation

Proper technique is helpful in obtaining a high degree of success in arterial catheterization. The wrist is often placed in a dorsiflex position on an armboard over a pack of gauze and immobilized in a supinated position. Overextension of the wrist should be avoided, since this flattens and decreases the cross-sectional area of the radial artery[52] and may cause median nerve damage by stretching the nerve over the wrist. When the artery is entered, the angle between the needle and skin is reduced to 10 degrees, the needle is advanced another 1 to 2 mm to ensure that the tip of the catheter also lies within the lumen of the vessel, and the outer catheter is then threaded off the needle. If blood ceases flowing while the needle is being advanced, then the needle has penetrated the back wall of the vessel.

Alternatively, the artery can be transfixed by the passage of the catheter-over-needle assembly "through-and-through" the artery. The needle is then completely withdrawn. As the catheter is slowly withdrawn, pulsatile blood flow emerges from the catheter when its tip is within the lumen of the artery. At this point the catheter can either be advanced in the lumen of the artery or a guide wire advanced into the lumen first, followed by advancing the catheter over the wire (modified Seldinger technique). Compared with a direct cannulation method, using the Seldinger technique increases the success rate of arterial catheter placement.[53] Rarely, a surgical cutdown may be required. An incision is made in the skin overlying the artery, and the surrounding tissues are dissected away from the arterial wall. Proximal and distal ligatures are passed around the artery to control blood loss but are not tied down. Under direct vision, the artery is cannulated with a catheter-over-needle assembly.

Ultrasound and Doppler-Assisted Techniques

Before the more widespread availability of high-resolution two-dimensional (2D) ultrasound devices, the acoustic signal of Doppler flow probes was frequently used to localize arterial vessels for cannulation.[54,55] In today's practice, Doppler-assisted techniques have been supplanted by 2D ultrasonic methods.[56] Most studies comparing a 2D ultrasound-guided (UG) technique to the traditional method of palpating the artery have shown a higher success rate at first attempt with UG techniques and fewer attempts overall. An UG technique is probably most useful in patients with severe peripheral vasculopathy, as well as in infants and small children. Levin and associates[57] randomized patients in a prospective study to UG radial artery cannulation versus the classic palpation technique. The use of ultrasound resulted in a higher success rate on the first attempt, and fewer subsequent attempts were required to place the arterial catheter. The overall time for catheter placement was not significantly different between the two groups (trend for shorter overall time in UG group). In a similar study, Shiver and colleagues[58] randomized patients in the emergency department to

UG versus the traditional palpation technique of placing the arterial catheter. Patients in the UG group required a significantly shorter time (107 vs 314 seconds; $P = .0004$), fewer placement attempts (1.2 vs 2.2; $P = .001$), and fewer sites required for successful arterial catheter placement.

The use of ultrasound in guiding arterial catheter placement is easy to learn when proper training in this technique is provided. There is, however, a significant learning curve, and studies reporting on the success rate of UG arterial cannulation compared with a traditional palpation technique have to be interpreted accordingly. Ganesh and associates,[59] for example, did not find a significant difference in the time and number of attempts required in a pediatric patient population randomized to palpation versus UG radial artery catheter placement. None of the designated operators, however, had significant experience with this technique, with 19 out of 20 pediatric subspecialty trainees and/or fully trained consultant anesthesiologists reporting experience with fewer than five cases. Fig. 13.3 shows a proper full-sterile set up for UG arterial cannulation. Fig. 13.4 demonstrates the "triangulation" technique typically applied with UG venous and/or arterial cannulation. The ultrasound imaging plane and the needle plane can be viewed as the two sides of a triangle that should meet and intersect at the depth of the structure (eg, radial artery) for which cannulation is attempted. The experienced operator will choose the distance (needle insertion site vs imaging plane) and insertion angle, depending on the depth of the target vessel. After perforating the skin, the ultrasound plane and the needle insertion angle both have to be adjusted further to follow the needle tip when viewed in the transverse (short-axis) approach. Failure to align the ultrasound plane accurately with the needle tip results in viewing the needle shaft instead. Figs. 13.5 and 13.6 show typical ultrasound images obtained during short-axis (transverse) cannulation. Note the anatomic variation with a larger radial artery (*A1*) next to the smaller artery (*A2*) positioned laterally. After puncturing the vessel, the catheter can be advanced into the lumen. A significantly higher success rate can usually be achieved using the through-and-through and modified Seldinger techniques.

If a longitudinal ("in-plane") approach is chosen (ie, the vessel is viewed in its long axis), the needle tip can be followed more easily as it is advanced; however, structures adjacent to the ultrasound plane (lateral to the vessel) cannot be viewed simultaneously. Exactly aligning the needle and vessel axis together in a 2D echo plane, particularly with a tortuous atherosclerotic artery, is technically more difficult. Although many practitioners prefer the transverse out-of-plane approach, studies comparing the two techniques show inconsistent findings.[60,61] Fig. 13.7 shows the arterial catheter entering the radial artery using the longitudinal (in-plane) approach. Aseptic technique, including sterile sheaths, should always be followed when using the UG technique of intraarterial catheter placement to prevent catheter-related

Fig. 13.3 Demonstration of aseptic technique for ultrasonic guidance of radial artery cannulation.

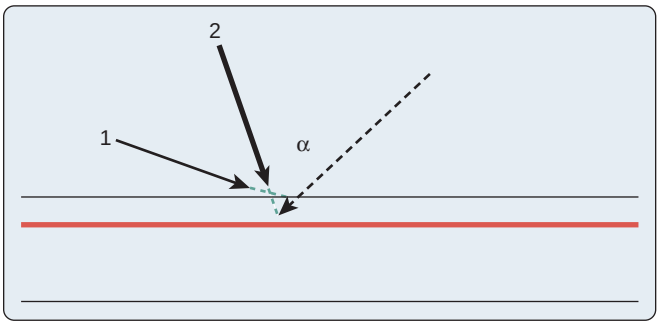

Fig. 13.4 Demonstration of the "triangulation" technique typically applied with ultrasound-guided (UG) venous and/or arterial cannulation in the transverse imaging approach. The echo imaging plane and the needle plane can be viewed as the two sides of a triangle that should meet and intersect at the depth of the structure (eg, radial artery *[red line]*) for which cannulation is attempted. The experienced operator will change the angle *(α)* between the two planes (ultrasound and needle) and the distance (needle insertion site vs imaging plane), depending on the depth of the structure. To follow the needle tip in the transverse approach (vessel viewed in short axis), the echo plane or needle insertion angle has to be further adjusted from needle entry through the skin to the perforation of the vessel. A greater angle is used (echo plane angled toward the skin *[1]*) to visualize the needle tip after it penetrates the skin, and then a more perpendicular angle relative to the skin is applied to see the needle tip entering the vessel lumen *(2)*.

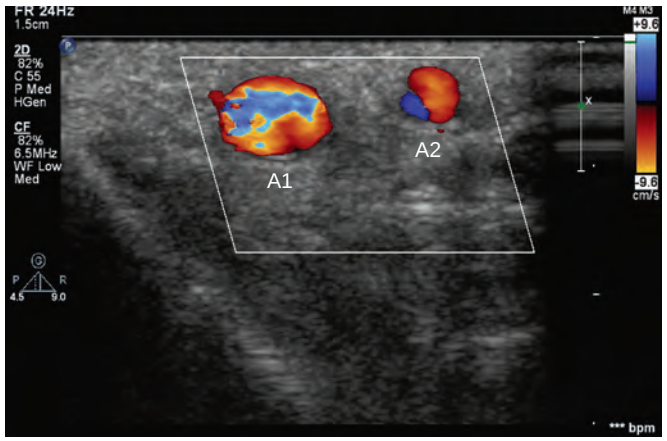

Fig. 13.5 A typical ultrasound image with color Doppler during short-axis (transverse) cannulation. Note the anatomic variation with a larger radial artery (*A1*) next to a smaller artery (*A2*) positioned laterally.

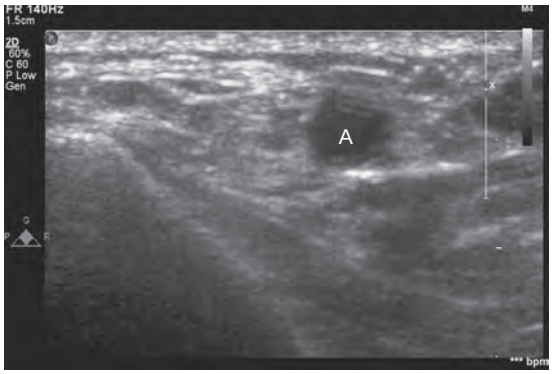

Fig. 13.6 Typical ultrasound image during short-axis (transverse) cannulation.

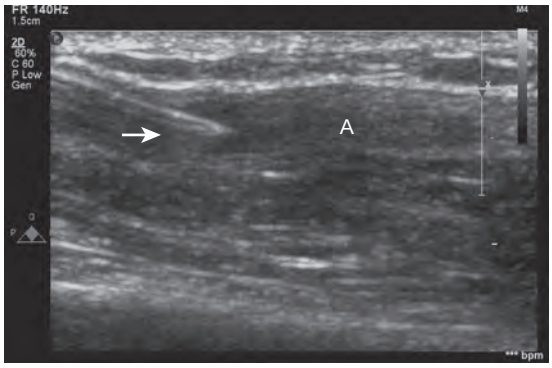

Fig. 13.7 Catheter entering the radial artery using the longitudinal (in-plane) approach.

BOX 13.4 ULTRASOUND-GUIDED ARTERIAL CANNULATION

Benefits

- Higher success rate on first attempt
- Fewer overall attempts
- Increased patient comfort (fewer attempts)
- Fewer complications (eg, anticoagulated patients)
- Demonstration of vessel patency, anatomic variants
- Low pulsatile or nonpulsatile flow (eg, nonpulsatile assist devices, extracorporeal membrane oxygenation, shock)
- Nonpalpable or weakly palpable pulses (eg, peripheral edema, hematoma)
- Emergency access (eg, catheter placement during resuscitation)

Concerns

- Risk of catheter-related infections if poor aseptic technique is applied
- Additional training required
- Costs involved with equipment required

infections. A high-frequency linear array ultrasonic transducer (8 to 12 MHz) is optimal for UG arterial catheter placement, since higher frequencies are needed for high-resolution imaging of the near field. Box 13.4 summarizes the potential benefits and concerns related to UG arterial catheter placement.

Complications

Infection from indwelling catheters is a common complication to all forms of invasive monitoring. In a recent prospective study evaluating 834 arterial catheters with a total of 3273 catheter days in a critical care unit setting, 13% were found to be colonized. Bacteremia was confirmed in 11 cases, resulting in a bloodstream infection rate of 1.3%, or 3.4 per 1000 catheter days.[62] Similarly, a metaanalysis showed an incidence of arterial catheter–related bloodstream infections of 2.9 per 1000 catheter days.[63] Another recent large metaanalysis included 49 studies with a total of 30,841 arterial catheters. Arterial catheter–related bloodstream infections were found in 222 cases, with a calculated incidence of catheter-related infections of 3.4 in 1000 catheters or 0.96 per 1000 catheter days. The prevalence was higher in studies that cultured all catheters, compared with those studies that cultured only when the arterial catheter was thought to be the source of infection. The risk of infection was also higher for the femoral site of insertion, compared with radial artery access.[64] Other studies have found similar infection rates, confirming that colonization and catheter-related bloodstream infection rates are comparable with central venous catheters.[65,66] These findings clearly stress the importance of using strict aseptic technique when inserting peripheral arterial catheters. In contrast to central venous catheterization, however, some of the published data on vascular catheter infections did not find that full sterile barriers during arterial catheter placement reduced the risk of infection.[67,68]

Guidelines for the prevention of intravascular catheter-related infections have been published by the Healthcare Infection Control Practices Advisory Committee (HICPAC) and the Centers for Disease Control and Prevention (CDC).[69] To summarize these guidelines, there is a category IA level of evidence for maintaining sterility for all components of the pressure monitoring system, using an antiseptic wipe before drawing blood from an arterial catheter other than a stopcock and avoiding the use of dextrose-containing flush solutions. Category IB level of evidence was found for avoiding the femoral and axillary insertion sites. The advisory committee recommends a minimum of a cap, mask, sterile gloves, and a small sterile fenestrated drape to be used during peripheral arterial catheter insertion (Category IB), whereas during axillary or femoral artery catheter insertion, maximal sterile barriers precautions should be used (Category II).

Hemorrhage from disconnecting the catheter-tubing assembly carries the potential risk of major blood loss or exsanguination. Temporary *arterial spasm* can be observed after radial artery cannulation and typically resolves without intervention. Arterial *thrombosis* is more frequently observed with prolonged duration of cannulation,[70] large catheters,[71] and a small radial artery size (ie, a greater proportion of the artery is occupied by the catheter).[72] However, despite the widespread use of radial artery cannulation, hand complications are rarely reported.[73–75] Because thrombosis may appear several days after the catheter has been removed, examinations should be continued through the postoperative period. Any evidence of hand ischemia should be investigated and treated promptly to prevent morbidity.[76] Traditional treatment for arterial occlusion or thrombosis with adequate collateral flow has been conservative. However, fibrinolytic agents (eg, streptokinase), stellate ganglion blockade, and surgical intervention are modalities that should be considered.[77]

Embolization of air or particulate matter that is flushed forcefully into an arterial catheter can move proximally and distally within the artery. Cerebral embolization is most likely from axillary cannulation sites but is also possible with brachial and radial artery catheters.[78,79] Emboli from the right arm are more likely to reach the cerebral circulation than those from the left arm because of the usual anatomy and direction of blood flow in the aortic arch. Other factors that influence the likelihood of cerebral embolization include the volume of flush solution, the rapidity of the injection, and the proximity of the intraluminal end of the catheter to the central circulation.[80,81]

Hematoma formation is common especially in patients who are anticoagulated and is usually well controlled with direct pressure application. *Nerve damage* is possible if the nerve and artery lie in a fibrous sheath (eg, the brachial plexus) or in a limited tissue compartment (eg, the forearm).[82] Direct nerve injuries may also occur from needle trauma during attempts at arterial cannulation. The median nerve is in close proximity to the brachial artery, and the axillary artery lies within the brachial plexus sheath. Pseudoaneurysm formation is a late vascular complication[83] and rarely progresses into an arteriovenous fistula.[84,85]

Despite the great advantages of intraarterial monitoring, limitations of invasive BP monitoring must be recognized. The monitoring system may be incorrectly zeroed, baseline drifting may occur, or the transducers may not be appropriately leveled with the heart as the reference point. Dampening of the pressure waveform is observed with kinking or partially thrombosed catheters. In vasoconstricted patients, those in hypovolemic shock, and during the post-CPB period, the brachial and radial artery pressures may be significantly lower than the true central aortic pressure. Another possible cause of inaccurate measurements is unsuspected arterial stenosis proximal to the monitored artery, as occurs with thoracic outlet syndrome and subclavian stenosis. Unsuspected Raynaud syndrome also can yield unreliable BP readings from peripheral arteries.

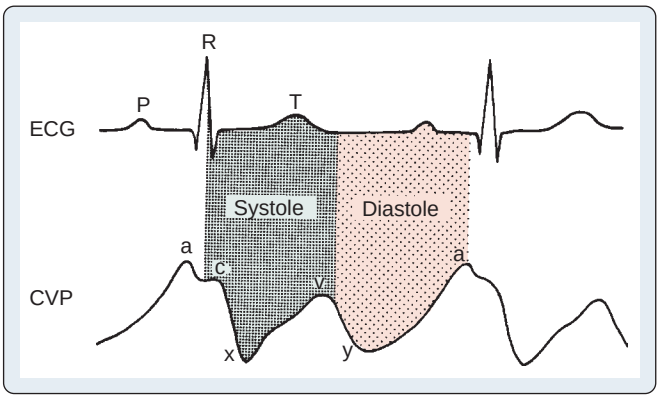

Fig. 13.8 Relationship of the central venous pressure (*CVP*) tracing to the electrocardiogram (*ECG*) in normal sinus rhythm. The normal CVP waveform consists of three upward deflections (*a*, *c*, and *v* waves) and two downward deflections (*x* and *y* descents). The *a* wave is produced by right atrial contraction and occurs just after the *P* wave on the ECG. The *c* wave occurs because of the isovolumic ventricular contraction forcing the tricuspid valve to bulge upward into the right atrium (RA). The pressure within the RA then decreases as the tricuspid valve is pulled away from the atrium during right ventricular ejection, forming the *x* descent. The RA continues to fill during late ventricular systole, forming the *v* wave. The *y* descent occurs when the tricuspid valve opens and blood from the RA empties rapidly into the right ventricle during early diastole. *(Adapted from Mark JB. Central venous pressure monitoring: clinical insights beyond the numbers.* J Cardiothorac Vasc Anesth. *1991;5:163–173.)*

Fig. 13.9 Relationship of the central venous pressure tracing to the electrocardiogram during junctional (atrioventricular nodal) rhythm. The contraction of the atrium against the closed tricuspid valve results in the cannon *A* waves. Note that the P wave is hidden within the QRS complex of the electrocardiogram.

Central Venous Pressure Monitoring

Central venous pressure (CVP) catheters are used to measure the filling pressure of the RV, give an estimate of the intravascular volume status, and assess right ventricular function. For accurate pressure measurement, the distal end of the catheter must lie within one of the large intrathoracic veins or the right atrium (RA). As in any pressure monitoring system, having a reproducible landmark, such as the midaxillary line with a closed chest or the left atrium (LA) during surgery, as a zero reference is necessary. Frequent changes in patient positioning without proper leveling of the transducers relative to the heart produce proportionately larger errors compared with arterial pressure monitoring.

The normal CVP waveform consists of three upward deflections (A, C, and V waves) and two downward deflections (X and Y descents) (Fig. 13.8). The A wave is produced by right atrial contraction and occurs just after the P wave on the electrocardiogram (ECG). The C wave occurs because of the isovolumic ventricular contraction, forcing the tricuspid valve (TV) to bulge upward into the RA. The pressure within the RA then decreases as the TV is pulled away from the atrium during right ventricular ejection, forming the X descent. Right atrial filling continues during late ventricular systole, forming the V wave. The Y descent occurs when the TV opens and blood from the RA empties rapidly into the RV during early diastole.[86]

The CVP waveform may be useful in the diagnosis of pathologic cardiac conditions. For example, the onset of an irregular rhythm and loss of the A wave suggest atrial flutter or fibrillation. Cannon A waves occur as the RA contracts against a closed TV, as occurs in junctional (atrioventricular [AV] nodal) rhythm, complete heart block, and ventricular arrhythmias (Fig. 13.9). This occurrence is clinically relevant because nodal rhythms are frequently seen during anesthesia and may produce hypotension attributable to a decrease in SV. Cannon A waves may also be present when resistance to RA emptying is increased, as in tricuspid stenosis, right ventricular hypertrophy, pulmonary stenosis, or pulmonary hypertension. Early systolic or holosystolic "cannon V waves" (or C-V waves) occur if the degree of tricuspid regurgitation is significant. Large V waves may also appear later in systole if the ventricle becomes noncompliant as a result of ischemia or right ventricular failure. Tachycardia produces a blending of the waveforms, especially the A and C waves. It must be recognized, though, that many peaks and troughs in the CVP waveform are artifactually created from the transducer-tubing monitoring system. A comprehensive review of CVP waveform analysis in various pathophysiologic states has been published.[87]

Pericardial constriction produces characteristic waveforms in the CVP tracing (Fig. 13.10). The venous return is decreased because of the inability of the heart chambers to dilate as a result of the constriction. This causes prominent A and V waves and steep X and Y descents (creating an M configuration) resembling that observed with diseases that cause decreased right ventricular compliance. Egress of blood from the RA to the RV is initially rapid during early diastolic filling of the RV (creating a steep Y descent) but is short-lived and abruptly halted by the restrictive, noncompliant RV. The right atrial pressure then increases rapidly and reaches a plateau until the end of the A wave, at the end of diastole. This portion of the waveform is analogous to the ventricular diastolic dip-and-plateau sign.[87] With pericardial tamponade, the X descent is steep but the Y descent is not present, because early diastolic run-off is impaired by the pericardial fluid collection.

The CVP is a useful monitor if the factors affecting it are recognized and its limitations are understood. Thromboses of the vena cavae and alterations of intrathoracic pressure, such as those induced by positive end-expiratory pressure (PEEP), also affect measurement of the CVP.[88] The correlation with left-sided heart filling pressures and assessment of left ventricular preload is poor.[89–92] Clinically, following serial measurements (trends) rather than individual numbers is often more relevant. The response of the CVP to a volume infusion, however, is a useful test.

Techniques and Insertion Sites

Percutaneous central venous cannulation may be accomplished by catheter-through-needle, catheter-over-needle, or catheter-over-wire (Seldinger) techniques. The considerations for selecting the site of cannulation include the experience of the operator, ease of access, anatomic anomalies, and the ability of the patient to tolerate the position required for catheter insertion.

Internal Jugular Vein

Cannulation of the internal jugular vein (IJV) was first described by English and colleagues[93] in 1969. Advantages of this technique include the high success rate as a result of the relatively predictable relationship of the anatomic structures; a short, straight course to the RA that

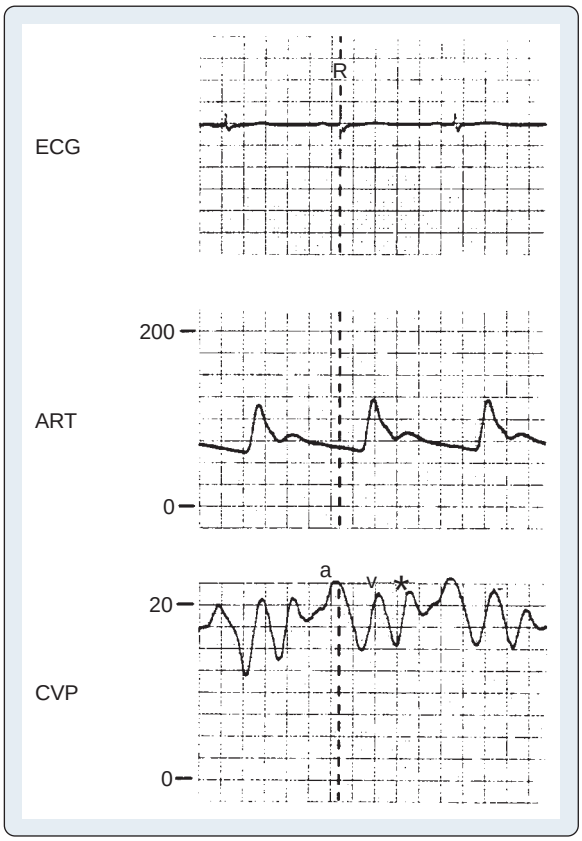

Fig. 13.10 Central venous pressure (*CVP*) waveform during pericardial constriction. The characteristic M configuration with prominent *a* and *v* waves, accompanied by steep x and y descents, is evident. An additional wave *(asterisk)* is present because of an impairment of ventricular filling by the rigid pericardial shell. *ART,* Arterial pressure; *ECG,* electrocardiogram. *(Adapted from Mark JB. Central venous pressure monitoring: clinical insights beyond the numbers.* J Cardiothorac Vasc Anesth. *1991;5:163–173.)*

almost always ensures RA or superior vena cava (SVC) localization of the catheter tip; and easy access from the head of the surgical table. The IJV is located under the medial border of the lateral head of the sternocleidomastoid (SCM) muscle (Fig. 13.11). The carotid artery is usually deep and medial to the IJV; however, this spatial relationship can vary and puncture of the carotid artery is best avoided by using an UG technique. The right IJV is preferred, because this vein takes the straightest course into the SVC, the right cupola of the lung may be lower than the left, and the thoracic duct is on the left side.[94] Unless a persistent left SVC is present, the right IJV has a larger diameter, compared with the left IJV.

The *middle approach* to the right IJV is shown in Fig. 13.12. The Trendelenburg position is chosen to distend the IJV. The head is then turned toward the contralateral side, and the fingers of the left hand are used to palpate the two heads of the SCM muscle and the carotid pulse. The needle is inserted slightly lateral to the carotid pulse at a 45-degree angle to the skin and directed toward the ipsilateral nipple until venous blood return is obtained. Alternatively, the use of a small-gauge *finder* needle can be used to avoid carotid puncture with a large-bore needle. When venous return is present, the whole assembly is lowered to prevent the needle from going through the posterior wall of the central vein and advanced an additional 1 to 2 mm until the tip of the catheter is within the lumen of the vein. Aspiration of blood must be confirmed before the catheter is then threaded into the vein. It is recommended by the ASA practice guidelines,[95] and often mandated by institutional protocols, that the correct intravenous catheter position be confirmed before placing a large-bore introducer sheath. Various techniques have been suggested. The small-bore catheter can be attached to a transducer by sterile tubing to observe the pressure waveform.[96–98] Another option is to attach the cannula to sterile tubing and allow blood to flow retrograde into the tubing.[99] The tubing is then held upright as a venous manometer, and the height of the blood column is observed. If the catheter is in a vein, then it will stop rising at a level consistent with the CVP and demonstrate respiratory variation. Despite its reported use in the past, color comparison and observation of nonpulsatile flow are notoriously inaccurate methods of determining that the catheter is not in the carotid artery. A guidewire is then passed through the 18-gauge catheter, and the catheter is exchanged for the wire. With the more widespread use of echocardiography, the

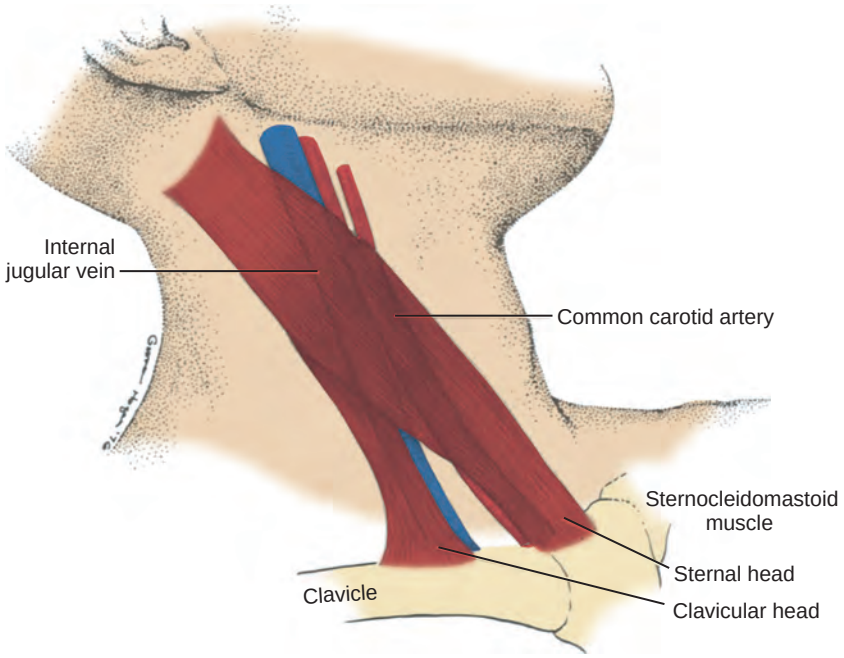

Fig. 13.11 The internal jugular vein is usually located deep to the medial border of the lateral head of the sternocleidomastoid muscle, just lateral to the carotid pulse. *a,* Artery; *v,* vein.

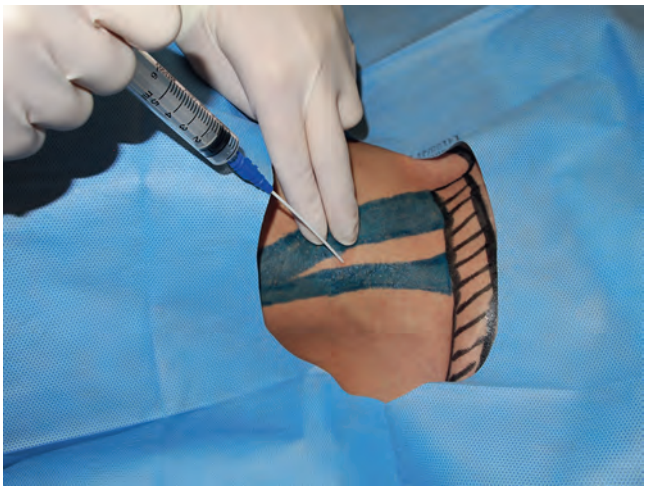

Fig. 13.12 Preferred middle approach to the right internal jugular vein. The needle enters the skin at the apex of the triangle formed by the sternal and clavicular heads of the sternocleidomastoid muscle. The needle is held at a 30- to 45-degree angle to the skin and directed toward the ipsilateral nipple.

correct intravenous position can also be confirmed by following the Seldinger wire along its course in the IJV more distally by handheld transcutaneous probes or demonstrated within the RA if the TEE probe was inserted before IJV cannulation. The use of more than one technique to confirm the venous location of the guidewire may provide additional reassurance of correct placement before cannulation of the vein with a larger catheter or introducer. Once it is certain that the guidewire is in the venous circulation, the CVP catheter is passed over it and the wire is removed. Although the described technique is most commonly performed for IJV cannulation, many other approaches to the right IJV have been described.[100–102] Additionally, with ultrasound guidance, strict adherence to external landmarks has become less important.

Ultrasound-Guided Internal Jugular Vein Cannulation

Clinical Evidence for Ultrasound-Guided Internal Jugular Vein Cannulation

Ultrasound has been increasingly used for central venous access, in particular to guide IJV cannulation and to define the anatomic variations of the IJV.[103] Using ultrasound to guide central venous cannulation increases the success rate and helps prevent complications and thus may ultimately help improve patient outcomes. Troianos and associates[104] compared UG IJV cannulation to a traditional landmark technique. Fewer attempts to successful cannulation were required, and the rate of complications such as carotid artery puncture was decreased in the UG group. More recent prospective studies confirmed these findings. In a prospective observational study, Serafimidis and colleagues[105] compared UG IJV cannulation to a landmark technique (347 patients vs 204 patients, respectively). UG cannulation had a higher success rate, required fewer attempts, took less time, and had fewer complications. Further evidence comes from several published metaanalyses comparing the UG versus traditional IJV landmark techniques.[106,107] Overall, most studies have demonstrated that 2D UG IJV cannulation has a higher success rate on the first attempt and fewer complications.[108–112] Those findings also were confirmed in pediatric patients.[113–118] Only one study reported that UG IJV cannulation in children was less successful, had a higher incidence of arterial puncture, but had no time difference compared with the landmark method.[119] However, US operators in this study had no experience in UG cannulation, only highlighting that the learning curve associated with this technique is significant.

Box 13.5 lists some of the recognized benefits and concerns of UG central venous cannulation. Circumstances in which ultrasound guidance of IJV cannulation can be particularly advantageous include patients with difficult neck anatomy (eg, short neck, obesity), prior neck surgery, anticoagulated patients, and infants.

BOX 13.5 ULTRASOUND-GUIDED CENTRAL VENOUS CANNULATION

Benefits
- Higher success rate on first attempt
- Fewer overall attempts
- Facilitates access with difficult neck anatomy (obesity, prior surgery)
- Fewer complications (eg, carotid artery puncture, anticoagulated patients)
- Demonstration of vessel patency, anatomic variants
- Relatively inexpensive technology

Concerns
- Training personnel to maintain aseptic technique when using sterile probe sheaths
- Additional training required
- Lack of observation of surface anatomy
- Potential loss of landmark-guided skills when needed for emergency central venous catheterization.

Technical Aspects

Ultrasound provides instantaneous and patient-specific information regarding the structural relationship between the IJV, the carotid artery, and adjacent anatomic structures (see Fig. 13.11). The spatial relationships can vary significantly, and the IJV may be absent or completely or partially overlapping the carotid artery.[120] Troianos and associates[121] found that in 54% of patients, greater than 75% of the IJV overlay the carotid artery. Patients who were older than 60 years were more likely to have this type of anatomy. Fig. 13.13 shows the anatomic relationship between the IJV and the carotid artery in two patients. In pediatric patients, Alderson and colleagues[122] found that the carotid artery coursed directly posterior to the IJV in 10% of patients. Sulek and associates[123] observed that the overlap of the IJV and the carotid artery was greater when the head is rotated 80 degrees, compared with head rotation of only 0 to 40 degrees. The data from 2 and 4 cm above the clavicle did not differ, and the percentage overlap was larger on the left side of the neck, compared with the right. Excessive rotation of the head of the patient toward the contralateral side may distort the normal anatomy in a manner that increases the risk of inadvertent carotid artery puncture. Ultrasound has also been used to demonstrate that the Valsalva maneuver increases IJV cross-sectional area by approximately 25% and that the Trendelenburg position increases it by approximately 37%.[124] Parry[125] showed that maximal right IJV diameter can be achieved by placing the patient in 15 degrees Trendelenburg position, slightly elevating the head with a small pillow, keeping the head close to midline and releasing the pressure administered to palpate the carotid artery before IJV cannulation. Box 13.6 summarizes some of the positional considerations in UG IJV cannulation.

For central venous catheterization, full aseptic technique is mandatory. After patient positioning and sterile preparation of the neck, a full-body sterile drape is applied and the probe is covered in a sterile sheath. Fig. 13.14 demonstrates proper sterile technique and positioning of the ultrasound probe. A triangulation technique as previously described for the radial artery is typically used. Although the long-axis (in-plane) approach allows better visualization of the true needle tip throughout the insertion and vessel penetration, the simultaneous display of the IJV and its relationship to the carotid artery is lost. Additionally, the size of the ultrasound probe in patients with short neck anatomy often does not provide adequate room for an in-plane approach to the IJV. Most practitioners therefore choose the short-axis (out-of-plane) approach to UG IJV cannulation. The most important

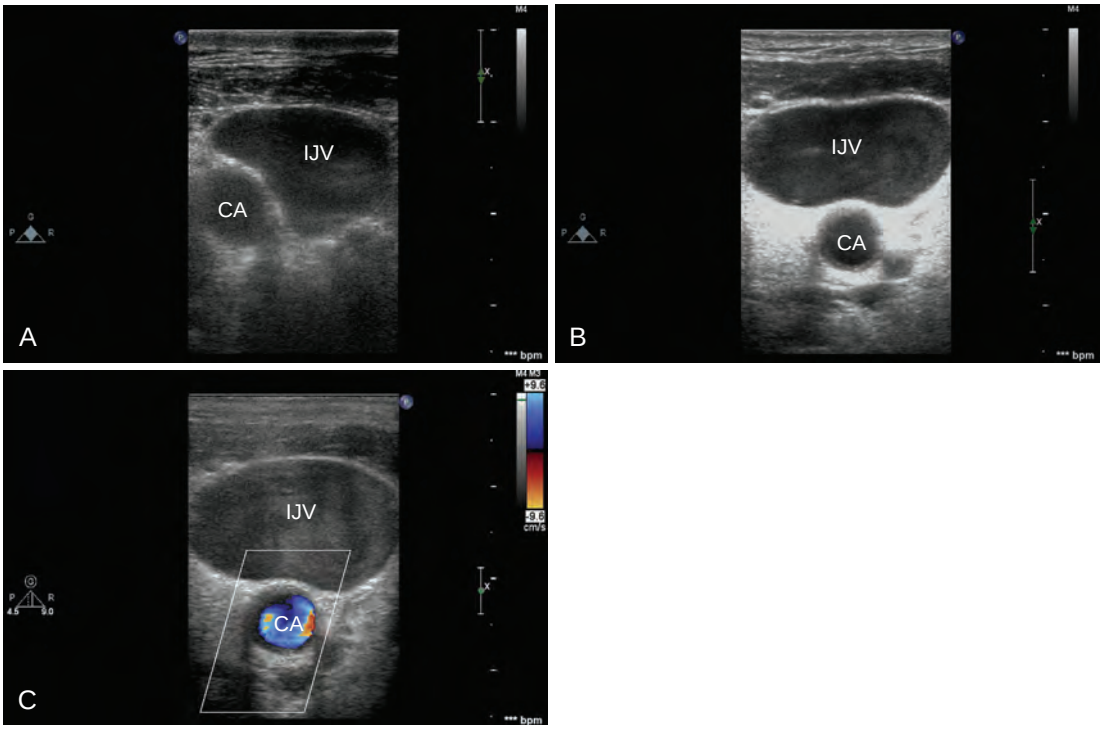

Fig. 13.13 Anatomic relationship between the internal jugular vein (*IJV*) and the carotid artery (*CA*) in two patients. (A) The IJV partially overlies the CA. (B) The CA is situated deep to the IJV. (C) Color Doppler demonstrates the flow in the CA.

BOX 13.6 POSITIONAL CONSIDERATIONS IN ULTRASOUND-GUIDED RIGHT INTERNAL JUGULAR VENOUS CANNULATION

- Slight Trendelenburg position
- Head turned slightly away from the cannulation side (turning too far may flatten the internal jugular venous [IJV] and rotate the IJV above the carotid artery)
- Overextension of the head should be avoided, mild head elevation can be advantageous (overextension flattens IJV)
- Minimal neck pressure by manual palpation and/or ultrasonic probe so as to avoid compression of the IJV
- Ultrasound probe should scan the course of the IJV to find the best cannulation site (largest IJV diameter and least overlap with the carotid artery)

Fig. 13.14 The aseptic technique and positioning of the ultrasound probe for internal jugular vein cannulation is demonstrated.

aspect of imaging a needle out-of-plane is avoiding the mistake of visualizing the needle shaft rather than the needle tip. Otherwise, the needle tip could be in a structure not being imaged, such as the carotid artery or pleura. With training and experience, the practitioner learns to sweep the ultrasonic plane inferiorly along the course of the needle shaft until the needle tip is identified. Adjusting the ultrasonic plane and the angle of the needle insertion enables visualization of the needle tip as it enters the IJV. An extremely favorable sign of needle tip visualization during needle advancement is indentation of the anterior wall of the IJV as the needle tip encounters the vessel wall (Fig. 13.15). An alternative technique combining the advantages of a long- and short-axis approach, visualizing the needle during insertion while maintaining a view of both the carotid artery and the IJV has been described and termed medial oblique approach.[126]

It is important to realize that UG IJV cannulation has reduced, but not eliminated, inadvertent carotid arterial cannulation, and that

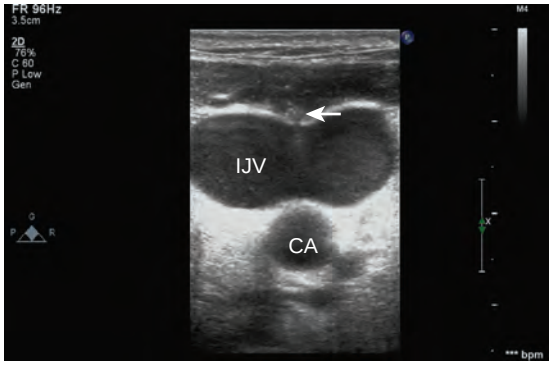

Fig. 13.15 The thin-walled internal jugular vein (*IJV*) is compressed by the advancing needle *(arrow)* during IJV cannulation. *CA,* Carotid artery.

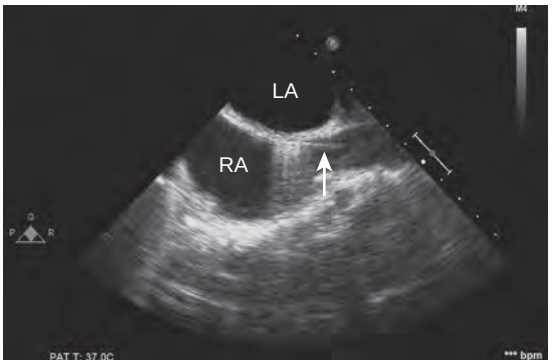

Fig. 13.16 The midesophageal bicaval transesophageal echocardiography view allows confirmation of the guidewire position in the right atrium *(arrow)*. *LA*, Left atrium; *RA*, right atrium.

the insertion of large catheters into the carotid artery with ultrasound guidance has been reported.[127–131] Venous cannulation always should be confirmed before advancing the dilators or inserting the large-bore catheter and introducer sheath. As previously noted, manometry, pressure transduction, blood gas analysis, or guidewire visualization using fluoroscopy or TEE imaging of the guidewire in the SVC or RA (Fig. 13.16) are all reasonable methods of ensuring venous cannulation before inserting a large-bore sheath.

Current Recommendations

Several specialty societies and national medical agencies have released guidelines and recommendations that strongly support the use of UG IJV cannulation. The Agency for Healthcare Research and Quality (AHRQ) in the United States lists UG central catheter placement as 1 of 11 patient safety practices with the greatest strength of evidence supporting its use to improve patient outcomes.[129] The National Institute of Clinical Excellence in the United Kingdom[130] also recommends UG IJV cannulation for children and adults. More recently, the American Society of Echocardiography and the Society of Cardiovascular Anesthesiologists have released a guideline document outlining the technique and the existing level of evidence that supports the use of an UG approach.[131] The taskforce recommended the use of UG IJV cannulation to improve success rate and reduce the incidence of complications in adult and pediatric patients. Although the writing committee did not recommend the routine use of UG for alternative central venous access (ie, subclavian and femoral vein) and arterial access, the committee did so merely based on the existing level of evidence from the published literature, not on the technical feasibility, safety concerns, or efficacy of using an UG technique. Additionally, the ASA has published practice guidelines for central venous cannulation.[95] The use of UG is recommended for vessel localization and needle guidance and can be used to verify correct intravascular position before the insertion of a large-bore catheter. Lastly, the HICPAC/CDC infection guidelines list a Category 1B level of evidence (strongly recommended) for using UG to place central venous catheters (if this technology is available) to reduce the number of cannulation attempts and mechanical complications. These guidelines further state that UG should only be used by those who are fully trained in this technique.[69] Based on the overwhelming evidence demonstrating efficacy and safety benefits, UG central venous access has become a standard at many institutions. Despite its increasingly widespread use, there is ongoing controversy whether UG for central venous cannulation has become a standard of care, which is a legal and not a medical determination.[132,133] The equipment needs[134] and the associated capital and training costs have been raised as reasons for the lack of universal adoption of this technique, despite the fact that UG central catheter can be cost-effective even when initial hardware purchase and training are taken into consideration.[135]

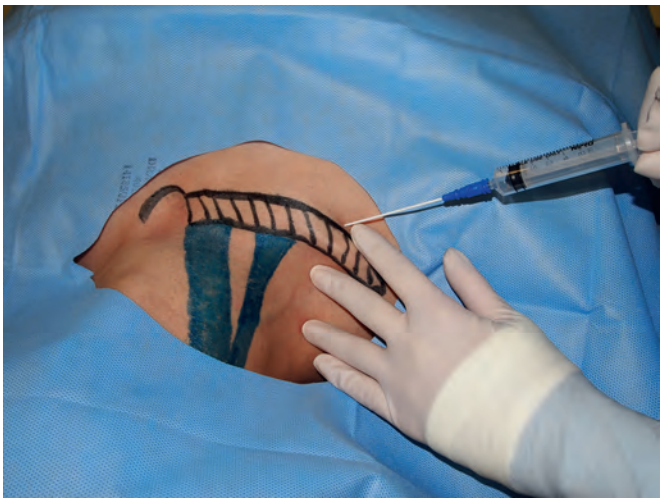

Fig. 13.17 The infraclavicular approach to the right subclavian vein. The patient is positioned with a rolled towel between the scapulae to increase the distance between the clavicle and the first rib. The needle enters the skin 1 cm inferior to the midpoint of the clavicle and is directed underneath the clavicle toward the sternal notch. If the needle is directed too far posteriorly, then the pleura may be punctured, resulting in a pneumothorax.

External Jugular Vein

Although the external jugular vein (EJV) is another means of reaching the central circulation, the success rate with this approach is lower because of the tortuous path followed by the vein. A valve is usually present at the point where the EJV perforates the fascia to join with the subclavian vein. Placing the patient in the Trendelenburg position and using a guidewire with the curved tip (ie, J-wire) can help increase the cannulation success rate.[136] The curved tip is necessary to negotiate the tortuous course between the EJV and the SVC. Manipulation of the shoulder and rotation of the guidewire between the operator's fingers may be useful maneuvers when difficulty is encountered in passing the wire into the SVC. The primary advantage of this technique is that advancing a needle into the deeper structures of the neck is not needed.

Subclavian Vein

The subclavian vein is readily accessible from supraclavicular or infraclavicular approaches and has long been used for central venous access.[137] The risk of causing a pneumothorax is higher compared with an IJV or EJV approach. Other complications associated with subclavian vein cannulation are subclavian arterial puncture, misplacement of the catheter tip, aortic injury, cardiac tamponade, mediastinal hematoma, and hemothorax.[138,139] The subclavian vein may be the cannulation site of choice, however, when CVP monitoring is indicated in patients undergoing carotid artery surgery. It is also useful for parenteral nutrition or for prolonged CVP access because the site is easier to maintain and well tolerated by patients.

The *infraclavicular approach* is performed with the patient supine or in the Trendelenburg position; additional maneuvers may include placing a folded sheet between the scapulae and pulling the shoulder inferiorly[140] (Fig. 13.17). The head is turned to the contralateral side. A thin-walled needle or intravenous catheter is inserted approximately 1 cm below the midpoint of the clavicle and advanced toward the suprasternal notch under the posterior surface of the clavicle. When a free flow of venous blood is obtained, the guidewire is passed into the subclavian vessel and is exchanged for a CVP catheter.

The *supraclavicular approach* is performed with the patient in the Trendelenburg position with the head turned away from the side of the insertion. This approach is usually not performed on the left side because of the risk of injuring the thoracic duct. The needle is inserted

at the lateral border of the SCM at the point of insertion into the clavicle, and directed to bisect the angle between the SCM and the clavicle and approximately 15 to 20 degrees posteriorly.

For both infraclavicular and supraclavicular subclavian vein access, the use of UG can greatly improve the identification of the vein, as well as help avoid arterial and pleural puncture.[141–143] However, these routes require more experience and training compared with UG IJV cannulation.

Antecubital Veins

Another route for CVP monitoring is through the basilic or cephalic veins. The advantages of this approach are the low likelihood of complications and the ease of access intraoperatively if the arm is exposed. The major disadvantage is that placement of the catheter in a central vein is often difficult to ensure. Chest radiographs are usually necessary to confirm that the tip of the catheter has been appropriately placed. Exact positioning of the catheter tip is crucial because movement of the arm will result in significant catheter migration and could cause cardiac perforation and tamponade.[144–146] Unsuccessful attempts result most frequently from the failure to pass the catheter past the shoulder or cannulation of the ipsilateral IJV. Turning the head to the ipsilateral side may help prevent IJV placement of the catheter.[147] Correct positioning is also required when used for the aspiration of air emboli in neurosurgical patients. Transducing the pressure waveform,[148] electrocardiography,[149] and the use of echocardiography[150] all have been described for correct positioning at the SVC-RA junction. Although peripherally placed central venous catheters avoid the placement of needles into deep venous structures, significant risks are still associated with their use.[151–154] Peripherally inserted central catheters are rarely used for monitoring purposes.

Femoral Vein

Cannulation of the femoral vein is technically simple, and the success rate is high. Cannulation of the vessel should be performed approximately 1 to 2 cm below the inguinal ligament. The vein typically lies medial to the artery. The older literature reported a high rate of catheter sepsis and thrombophlebitis with this approach. More recently published studies comparing the femoral access to the IJV and subclavian vein access were included in a large metaanalysis. No significant difference in the rate of catheter-related bloodstream infections was observed among the three sites.[155] This is probably due to using a stricter aseptic technique, disposable catheter kits, improved catheter technology, and the use of chlorhexidine in more recent trials instead of iodine-based antiseptic skin preparation in older studies. Despite these recent findings, the HICPAC/CDC infection guidelines list a Category 1A level of evidence (strongly recommended) to avoid using the femoral vein for central venous access in adult patients.[69] In patients with SVC obstruction, the femoral vein is necessary for intravenous access and to obtain a true CVP measurement. It is prudent for practitioners to document reasons supporting the use of the femoral site for monitoring purposes because of these guidelines.

Indications

In addition to hemodynamic monitoring, central venous access is typically warranted to establish a secure venous access route for the administration of vasoactive or irritating drugs, the rapid infusion of intravenous fluids, and total parenteral nutrition. Perioperative indications for the insertion of a central venous catheter are listed in Box 13.7. The limitations of CVP monitoring for assessing intravascular volume status are significant. The accuracy and reliability of CVP monitoring depend on many factors including the functional status of the right and left ventricles, the presence of pulmonary disease, and ventilatory factors, such as PEEP. The CVP may reflect left-sided heart-filling pressures but only in patients with good left ventricular function.

Despite obvious limitations, the CVP should be monitored continually in all patients during CPB. Although the catheter tip is ideally located at the SVC-RA junction, transducing the pressure from the most proximal catheter port or the introducer side-port is warranted during CPB (especially with bicaval cannulation). The venous pressure should be measured cephalad to the SVC CPB cannula, reflecting intracranial venous pressure. Insufficient drainage of the SVC attributable to cannula malposition, kinking, and surgical manipulation is detected by a significant increase in CVP and must be corrected promptly to restore optimal cerebral perfusion pressure (CPP = MAP − ICP or CVP) and to avoid cerebral edema. Problems with SVC drainage may be falsely inferred because of artifactually elevated CVP readings from inaccurate leveling of transducer height, compression of the catheter lumen from cannulation or surgical manipulation, and rapid fluid administration close to the transduced catheter port.

BOX 13.7 INDICATIONS FOR CENTRAL VENOUS CATHETER PLACEMENT

- Major operative procedures involving large fluid shifts or blood loss in patients with good heart function
- Intravascular volume assessment when urine output is not reliable or unavailable (eg, renal failure)
- Major trauma
- Surgical procedures with a high risk of air embolism, such as sitting-position craniotomies during which the central venous pressure catheter may be used to aspirate intracardiac air
- Frequent venous blood sampling
- Venous access for vasoactive or irritating drugs
- Chronic drug administration
- Inadequate peripheral intravenous access
- Rapid infusion of intravenous fluids (only when using large-bore cannulae)
- Total parenteral nutrition

Contraindications

The SVC syndrome is a contraindication to placing a CVP catheter in the jugular veins, subclavian veins, or upper extremities. Venous pressures in the head and upper extremities are elevated by the SVC obstruction and do not reflect right atrial pressure. Medications that are administered into the obstructed venous circulation reach the central circulation by collateral vessels in a delayed fashion. Rapid fluid administration into the obstructed venous circulation may exacerbate the elevated venous pressures and cause more pronounced edema. The mild SVC syndrome seen with some ascending aortic aneurysms, however, does not represent a contraindication to central venous cannulation of the upper body. Patients with certain types of congenital heart disease, such as single ventricle after Fontan palliation, now often survive into adulthood and may undergo cardiac surgery. Although not an absolute contraindication, many practitioners avoid placing large-bore catheters into the IJV to avoid the risk of thrombosis. Coagulopathies increase the risk for hemorrhagic complications of CVP placement, and needles should be inserted where pressure can easily be applied in case of a hematoma. Newly inserted pacemaker and/or automatic implantable cardioverter defibrillator (AICD) wires may be dislodged during the insertion of central venous catheters. If the patient is pacemaker dependent, then severe arrhythmias could result.

Complications

The complications of central venous cannulation can be divided into three categories: vascular access, catheter insertion, and catheter presence. These complications are summarized in Box 13.8, and specific information regarding several of the complications is detailed in this section.

BOX 13.8 COMPLICATIONS OF CENTRAL VENOUS CATHETERIZATION

Complications of Central Venous Access and Cannulation

- Arterial puncture with hematoma
- Arteriovenous fistula
- Hemothorax
- Chylothorax
- Pneumothorax
- Nerve injury
- Brachial plexus injury
- Stellate ganglion injury (Horner syndrome)
- Air embolus
- Catheter or wire shearing
- Guide wire loss and embolization
- Right atrial or right ventricular perforation

Complications of Catheter Presence

- Thrombosis, thromboembolism
- Infection, sepsis, endocarditis
- Arrhythmias
- Hydrothorax

Inadvertent arterial puncture during central venous cannulation is not uncommon.[156,157] The primary reasons this phenomenon occurs are that all veins commonly used for cannulation lie in close proximity to arteries (except the EJV and cephalic) and that the venous anatomy is quite variable. Localized hematoma formation is the usual consequence, which may be minimized if a small-gauge needle is initially used to localize the vein or UG is employed. If the arterial puncture is large or if the patient has a coagulopathy, then a massive hematoma may form. In the neck, this may lead to airway obstruction requiring urgent tracheal intubation. If the artery is cannulated with a large-bore catheter, then leaving the catheter or introducer sheath in place and requesting surgical consultation for further management are recommended.[95,158] Reports about successful percutaneous repair of inadvertent arterial injuries after central venous cannulation have been published.[159,160]

Arteriovenous fistula formation from the carotid artery to the IJV also has been reported after central venous cannulation.[161,162] Hemothorax may occur if the subclavian artery is lacerated during cannulation attempts. Symptoms of hypovolemia may predominate because of the large capacity of the pleural cavity.[163] Especially in smaller patients, the long and relatively stiff dilator of large introducer sheaths could possibly perforate at the SVC-innominate junction or the RA and cause massive hematoma, hemothorax, or pericardial tamponade.

Injury to the thoracic duct resulting in chylothorax has been reported after left IJV and left subclavian vein cannulation,[164–166] and is one the reasons for selecting right-sided IJV and subclavian approaches for central venous cannulation.

If the pleural cavity is entered and lung tissue is punctured during a cannulation attempt, then a pneumothorax may result. Tension pneumothorax is possible if air continues to accumulate as a result of a "ball-valve" effect. Pneumothorax is most common with subclavian punctures.

The brachial plexus, stellate ganglion, and phrenic nerve all lie in close proximity to the IJV and subclavian vein. These structures may be injured during cannulation attempts.[167,168] Transient deficits may result from the deposition of local anesthetic in the brachial plexus, stellate ganglion, or cervical plexus. Pseudoaneurysm has been reported after central venous cannulation.[169] Hematoma and true aneurysm formation resulted in vagal nerve palsy after inadvertent arterial puncture.[170]

Venous air embolism is a potentially fatal complication that can occur when there is negative pressure in the venous system. Paradoxical embolization is a risk if there is a patent foramen ovale or another intracardiac defect, such as an atrial or ventricular septal defect. During central venous cannulation, air embolism usually can be prevented with positional maneuvers, such as the Trendelenburg position, which increase the venous pressure in the vessel. Once the CVP catheter has been placed, it is important to ensure that the catheter is firmly attached to its connecting tubing. Air embolism may even occur after the catheter has been removed, if the subcutaneous tract persists.[171] The risk of air embolization is higher in spontaneously breathing patients.

The diagnosis of venous air embolism is likely when there is a sudden onset of tachycardia associated with pulmonary hypertension and systemic hypotension. A new murmur may be heard as a result of turbulent flow in the right ventricular outflow tract. Echocardiography (transesophageal or transthoracic) and precordial Doppler probe monitoring are highly sensitive methods of detecting air embolism. Venous air embolism may be effectively treated by aspirating the air by a catheter positioned at the SVC-RA junction. In the acute situation, and particularly if cardiovascular collapse occurs, the patient should be placed in a left lateral head down position to move the air embolus out of the right ventricular outflow tract. This maneuver may temporarily maintain left ventricular filling, CO, and systemic BP.

Catheter or guidewire fragments may be sheared off by the inserting needle and embolize to the right heart and pulmonary circulation when catheter-through-needle or Seldinger-type cannulation kits are used. Losing a guidewire within the patient is also possible by not withdrawing a sufficient length of the wire before inserting the catheter.[172] The catheter fragment or wire position within the circulation will determine whether surgery or percutaneous transvenous techniques are necessary for removal. To avoid catheter fragment embolization, the catheter must never be withdrawn through the inserting needle. Reinsertion of needles into standard (catheter-over-needle) intravenous cannulae cannot be recommended, particularly if the cannula is kinked. Additionally, guidewires should not be withdrawn through inserting needles when resistance is encountered. The needle and catheter or needle and guidewire should then be withdrawn simultaneously.

If right atrial or right ventricular perforation occurs during central venous cannulation, then pericardial effusion or tamponade may result. The likelihood of this complication is increased when inflexible guidewires, long dilators, or catheters are used. If pericardial tamponade is imminent, then immediate pericardiocentesis is indicated. If the catheter tip is placed extravascularly in the pleural cavity or erodes into this position, then the fluid that is infused into the catheter will accumulate in the pleural cavity (hydrothorax). A pleurocentesis or thoracostomy (chest) tube may be necessary, and surgical consultation may be required.

Transient atrial and ventricular arrhythmias commonly occur as the guidewire is passed into the RA or RV during central venous cannulation using the Seldinger technique. These arrhythmias most likely result from the relatively inflexible guidewire, causing extrasystoles as it contacts the endocardium. Ventricular fibrillation during guidewire insertion has been reported.[173] There are also reports of complete heart block from impingement of the wire in the region of the right bundle branch during insertion.[174] These cases can be managed successfully by quickly withdrawing the wire and, if persistent, by using a temporary transvenous or external pacemaker.

Strict aseptic technique and maximal sterile barrier precautions are required to minimize central line–associated bloodstream infections (CLABSIs), which are monitored as a quality indicator.[175] Subcutaneous tunneling of central venous catheters inserted into the internal jugular and femoral veins,[176,177] antiseptic barrier-protected hubs for central venous catheters,[178] and antiseptic/antibiotic-impregnated short-term central venous catheters[179,180] have been shown to reduce catheter-related infections.[181] Chlorhexidine-based skin preparations are now recommended for skin antisepsis,[69,95] and are associated with a reduced risk of CLABSI, despite studies suggesting that povidone-iodine solution was equally effective.[182–185] The routine replacement of central venous catheters to prevent catheter-related infections is not recommended.[69,186,187] When strict adherence to an aseptic technique during insertion cannot be guaranteed (ie, catheters inserted during an emergency), the catheter should be replaced as soon as possible.[69]

Pulmonary Arterial Pressure Monitoring

Clinical Efficacy and Related Trends in Pulmonary Artery Catheter Usage

At the time of the introduction of the flow-directed PAC in 1970,[188] the amount of diagnostic information that could be obtained at the bedside dramatically increased. Some of the earlier studies showed that clinicians were often unaware of hemodynamic problems or incorrectly predicted preload and CO without PAC monitoring.[189,190] Although PAC-derived data can help in the differential diagnosis of hemodynamic instability and guide treatment,[191] the clinical significance has been questioned. In 1996, Connors and colleagues[192] published the results of a large prospective cohort study with data collected from five U.S. teaching hospitals between 1989 and 1994. They enrolled 5735 critically ill adult patients in intensive care unit (ICU) settings and found that PAC monitoring was associated with increased mortality in this patient population. Further prospective randomized studies either confirmed these findings or showed no benefit associated with PAC monitoring. The results from this study were surprising to most clinicians and heavily debated. However, the level of evidence steadily increased, and eventually the PAC use started to decline significantly.

Between 1993 and 2004, PAC use in the United States alone decreased by 65% for all medical admissions.[193] The most significant decrease in PAC use was documented in patients with acute myocardial infarction, whereas those patients diagnosed with septicemia showed the least decline in use. These findings were almost identical to the surgical patient population, in which PAC use decreased by 63% in the same observed period. In another retrospective analysis, PAC use in patients hospitalized with acute coronary syndromes decreased from 5.4% in 2000 to 3.0% in 2007.[194] Similarly, a large multicenter longitudinal study at academic hospitals in Canada found that PAC use decreased by 50% between 2002 and 2006.[195] Leibowitz and Oropello[196] published data on PAC use in patients admitted to a surgical ICU (approximately 600 perioperative patients admitted per year) over an 8-year period. The number of PACs inserted decreased significantly from 23% of all admissions having a PAC inserted in 2000 to less than 2% in 2006. The patient risk profile (Acute Physiologic Assessment and Chronic Health Evaluation II [APACHE II] score) did not change, although hospital and ICU mortality in that patient population was slightly reduced in the observed period (Fig. 13.18). Similar findings were reported from other ICU settings.[197]

Concurrent with the decline of PAC use, echocardiography and less invasive CO monitors became increasingly available, often replacing the PAC as effective and less invasive or noninvasive bedside diagnostic tools. Currently, the incidence of right heart (PAC) catheterization is highly variable among hospitals and within hospitals according to service. A recent survey among the members of the Society of Cardiovascular Anesthesiologists found that a majority of practitioners (68.2%) still frequently (>75%) use a PAC for cases with CPB.[198] However, the use of a PAC differed significantly between private (79.2%), academic (64.5%), and governmental (34%) practice settings. With decreasing exposure to PACs, clinicians may become less likely to make the best use of PAC-derived hemodynamic data.[199]

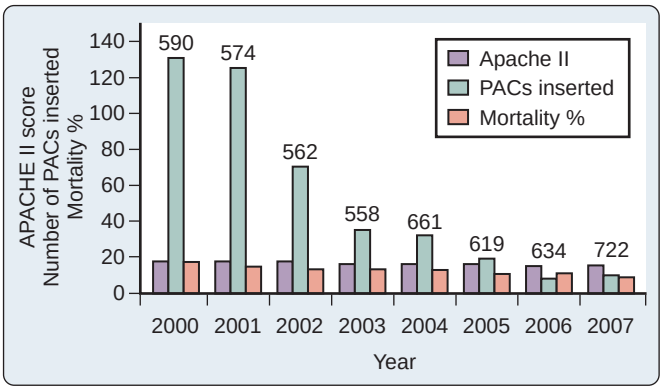

Fig. 13.18 Annual decrease in pulmonary artery catheter (*PAC*) use with stable risk scoring and mildly decreased mortality in one intensive care unit over an 8-year period. *APACHE II,* Acute Physiologic Assessment and Chronic Health Evaluation II. *(From Afessa B, Spencer S, Khan W, et al. Association of pulmonary artery catheter use with in-hospital mortality.* Crit Care Med. *2001;29:1145–1148. Used with permission.)*

Several large studies have addressed the controversies regarding the indications, risks, and benefits associated with PAC monitoring in various clinical settings after the publication of Connor's findings that PAC use may be harmful. However, as more studies have been published, evidence that PACs have little or no positive impact on patient outcomes is increasing.[200–204]

Noncardiac Surgery Setting

In 2001, Polanczyk and associates[205] published the results of an observational study on 4059 patients undergoing major elective noncardiac surgical procedures, examining the relationship between PACs and postoperative cardiac complications. Right-sided heart catheterization was associated with an increased incidence of major postoperative cardiac events. Similarly, a prospective randomized study by Rhodes and colleagues[206] found no significant difference in mortality in critically ill patients treated with or without the use of a PAC. Adjusting for the severity of illness, Murdoch and associates[207] found that the use of the PAC in ICU patients was safe, but no beneficial effect was demonstrated. Sandham and colleagues[208] reported a prospective, randomized, controlled outcome study of 1994 high-risk patients (ASA III or IV) scheduled for major noncardiac surgery, followed by ICU stay, that were managed with or without the use of a PAC. No benefit to therapy directed by PAC compared with standard care (without the use of PAC) was found, with a higher risk of adverse events in the PAC group. Yu and associates[209] performed a prospective cohort study of the relationship between PAC use and outcome in 1010 patients with severe sepsis. PAC monitoring did not improve outcomes in this patient population. Outcomes of patients with shock and acute respiratory distress syndrome (ARDS) also were not affected by PAC placement in a multicenter, randomized, controlled trial.[210] Sakr and colleagues[211] looked at outcomes related to PAC use in 3147 adult patients admitted to an ICU; this was a subanalysis of a large multicenter prospective observational study designed to evaluate the epidemiologic factors of sepsis in European countries. After propensity-score matching, no significant difference in outcome with or without PAC placement was found. Interestingly, significant differences in PAC use were reported between the various participating countries. The PAC-Man study was a randomized, controlled trial that enrolled 1041 patients from 65 ICUs throughout the United Kingdom.[212] Patients were randomly assigned to management with or without PAC placement. Treatment in both arms of the study was at the discretion of the treating clinician. Neither benefit nor harm related to PAC use was found. Two randomized, controlled studies did not show improved patient outcomes with PAC use in patients with ARDS.[210,213] Randomized trials including patients with acute myocardial infarction seemed to also confirm these data.[214,215] Cohen and associates[216] retrospectively studied 26,437 patients with acute coronary syndromes. A PAC was inserted in 2.8% of patients. In the United States, patients were 3.8 times more likely to have a PAC placed than non-US patients. After adjustment for confounding factors, PAC use was associated with a 2.6-fold increase in hospital mortality. The subset of patients who developed cardiogenic shock had similar outcomes both with and without PAC use.

The ESCAPE trial (Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness)[217] included patients with symptoms of severe heart failure (HF). This multicenter, randomized, controlled trial enrolled 433 patients at 26 sites but had no specific treatment algorithm. However, the use of inotropes was discouraged and investigators were asked to follow national guidelines for the treatment of HF, which promote the use of diuretics and

vasodilators. The target in both groups was improvement of clinical symptoms of HF. In the PAC group, there was an additional target of a pulmonary capillary wedge pressure (PCWP) of 15 mm Hg and a CVP of 8 mm Hg. Overall, mortality did not differ between groups; however, more adverse events were recorded in the PAC group. Exercise and quality-of-life measures improved in both groups, and the investigators reported a statistically insignificant trend toward greater improvement with PAC use.

In a more recent prospective, observational multicenter HF trial in Japan (Acute Decompensated Heart Failure Syndromes [ATTEND] Registry), retrospective analysis with propensity-score matching showed decreased in-hospital mortality with PAC use in patients with low SBP or inotropic therapy.[218]

A metaanalysis by Barone and associates[219] asserted that only four prospective studies were adequately randomized and that the use of the PAC did not improve outcome in vascular surgery patients. In 2006, the Centers for Medicare and Medicaid Services and the AHRQ requested that the Tufts Medical Center Evidence-based Practice Center conduct a technology assessment report on PAC use in critical care settings. The primary goal of the review was to assess the utility of PAC monitoring regarding its relative effect and safety and how it affects outcomes in the Medicare population (ie, people at least 65 years old) hospitalized in critical care settings.[220] An elaborate and extensive (1966 to 2006) literature review and metaanalysis of various outcomes was performed, and the results published in 2008. Only prospective randomized trials meeting established quality criteria were included in the analyses. Outcomes assessed were mortality, length of ICU and hospital stays, and the incidence of medical morbidities (eg, time on mechanical ventilation, renal failure), as well as a summary of reports on complications associated with PAC use. Overall, the authors did not find evidence supporting the routine PAC use in the ICU setting. The report acknowledges, though, that the PAC provides an unparalleled way to assess hemodynamic data in critically ill patients and suggests its judicious use on an individual basis.

Cardiac Surgery Setting

Schwann and colleagues[221] assessed the outcome of 2685 patients undergoing coronary artery bypass grafting (CABG) in whom the decision to place a PAC was based on patient characteristics and risk factors. Using a highly selective strategy, no PAC was used in the majority of cases (91%), and the outcomes were comparable. In another retrospective trial, Ramsey and associates[222] found that PACs in elective CABG surgery were associated with increased in-hospital mortality, longer lengths of stay, and higher total costs. This effect was more pronounced in those hospital settings with low overall PAC use. Schwann and associates[223] retrospectively analysed patients who were enrolled in the Epidemiology II Multicenter Study of Perioperative Ischemia (McSPI) multicenter study (5065 patients, 70 centers). Using propensity-score matching, patients with and without PAC use were compared. All-cause mortality and a higher risk of severe end-organ complications were noted in patients with PAC use.

Resano and colleagues[224] looked at PAC use compared with CVP monitoring in patients undergoing off-pump coronary artery bypass (OPCAB) surgery and found no difference in outcome. In a prospective observational study, Djaiani and associates[225] looked at 200 consecutive patients undergoing CABG surgery during which PACs were placed, but the surgeon and anesthesiologist were blinded to numerical data other than CVP. Patients were managed as per routine, and data could be unblinded if required clinically. Twenty-three percent of patients required unblinding of data; within this subgroup, preliminary diagnosis was confirmed in 14%, and treatment was modified in 9%. The patients in the unblinded group went on to experience further morbidity. The investigators concluded that placement of a PAC can be safely delayed until the clinical need arises either intraoperatively or in the ICU. Overall, studies looking specifically at patients undergoing myocardial revascularization do not find clear evidence that the routine use of PACs is associated with improved outcomes.

The studies previously cited assessed clinical outcomes associated with PAC use in various clinical settings. Several investigators have attempted to address the hypothesis that patients in the ICU have diseases too far advanced to make invasive hemodynamic monitoring useful and that early goal-directed therapy (GDT) in the surgical unit may prevent major end-organ damage by means of earlier intervention.[226] Older studies that had reported improved outcome used invasive hemodynamic monitoring to optimize oxygen delivery in the perioperative period.[227–230] In their metaanalysis, Heyland and colleagues[231] similarly argued that "maximizing oxygen delivery" in the perioperative setting (ie, before the onset of irreversible organ damage) is more effective, in comparison with the chronic ICU setting. Based on the intention-to-treat analysis of patients with preoperative PAC placement, they reported improved survival. Chittock and associates[232] demonstrated that severity of illness may play an important role in defining subgroups of patients who may benefit from PAC monitoring. Of 7310 critically ill adult patients admitted to the ICU, those with APACHE II scores greater than 31 showed decreased mortality with PAC monitoring, whereas patients with lower APACHE II scores had increased mortality. Another metaanalysis by Ivanov and colleagues[233] showed a significant reduction in morbidity when PAC-guided strategies were applied. In a prospective randomized trial, Pölönen and associates[234] applied goal-directed PAC-guided therapy aimed at maintaining a mixed venous saturation >70% and blood lactate <2 mmol/L in patients after cardiac surgery. Using this strategy, they found that increasing oxygen delivery in the immediate postoperative period shortened hospital stay and decreased morbidity. In a retrospective database analysis of trauma patients admitted to an ICU (National Trauma Data Bank, 53.312 patients enrolled), severely injured and older patients had decreased mortality associated with PAC use.[235]

There may be various explanations as to why the great majority of findings do not favor PAC use. Placing a PAC is a highly invasive procedure. Vascular structures are accessed with large-bore introducer sheaths with all the possible complications listed. Most importantly, even in the best of all circumstances with uncomplicated PAC placement and correct data collection and interpretation, it has to be recognized that a PAC is only a monitoring tool. As such, a change in patient outcome cannot be expected unless the treatment that is initiated based on the PAC measurements is effective for improving patient outcome. In some of the most critically ill patients, such as those with sepsis, ARDS, or massive trauma, mortality remains high despite efforts to find new treatment strategies. Furthermore, diagnoses often can be made on clinical grounds only, and treatment strategies once thought to improve patient outcome actually may be harmful.

Despite the large number of outcome studies regarding PACs, flaws in study design and insufficient statistical power are still an issue. The most common design flaws are a lack of therapeutic protocols or treatment algorithms and inadequate randomization, which introduce observer bias.[236] Physician knowledge is another confounding variable, as demonstrated in a multicenter study that indicated competency in interpreting PAC-derived data was lacking in many individuals and depended on such factors as the level of training and the frequency of use.[237] In one study, 47% of physicians could not correctly determine the PCWP to within 5 mm Hg.[238]

In summary, there are no convincing data showing improved outcomes in patients undergoing cardiac surgery with PAC placement compared with CVP monitoring alone.[239] The perioperative literature on the subject suggests that PAC use in patients undergoing low-risk cardiac surgery may be harmful.[240] Clinical evidence gained from the majority of well-designed prospective studies indicates that patients undergoing low-risk cardiac surgery can be managed safely without PAC placement. Many clinicians, however, still consider high-risk cardiac surgery and, in particular, patients with right-sided HF or pulmonary hypertension to be indications for PAC placement (see Chapter 26). An understanding of the potential benefits and pitfalls of pulmonary artery (PA) catheterization will therefore remain essential for cardiac anesthesiologists for the foreseeable future.

Technical Aspects of Pulmonary Artery Catheter Use

Considerations for the insertion site of a PAC are the same as for CVP catheters. The HICPAC/CDC infection guidelines list specific recommendations regarding PAC use, strongly recommending use of a sterile sleeve to protect the PAC during insertion (Category IB).[69] Because of technical reasons related to the specifics of cardiac surgery, the right IJV approach remains the preferred access route for many practitioners. This is because of the direct path between this vessel and the RA during IJV approach and the frequent kinking of the introducers during sternal retraction when subclavian access is chosen.[241] However, with modern retractors and smaller incisions, catheter kinking occurs much less frequently, even with the introducer in the subclavian position. For infection prevention purposes, the HICPAC/CDC advisory actually recommends the subclavian route for PAC insertion.

Passage of the PAC from the vessel introducer to the PA can be accomplished by monitoring the pressure waveform from the distal port of the catheter or under fluoroscopic or echocardiographic (TEE) guidance. Waveform monitoring is the most common technique for perioperative right-sided heart catheterization in the surgical unit. First, the catheter must be advanced through the vessel introducer (15 to 20 cm) before inflating the balloon. The inflation of the balloon facilitates further advancement of the catheter through the RA and RV into the PA. Normal intracardiac pressures are shown in Table 13.1. The pressure waveforms seen during advancement of the PAC are illustrated in Fig. 13.19. In patients with prior TV ring annuloplasty, significant TR, and tricuspid stenosis, advancing the catheter past the TV may be cumbersome or even impossible. Catheter manipulation and positional changes may be useful. Trendelenburg positioning places the RV more superior to the RA and thus may aid in advancing the PAC past the TV. TEE guidance can prove invaluable in these cases. The experienced echocardiographer can assist in guiding the catheter tip toward the TV orifice by directing catheter and positional manipulations. The right atrial waveform is seen until the catheter tip crosses the TV and enters the RV. In the RV, there is a sudden increase in SBP but little change in DBP, compared with the right atrial tracing. Arrhythmias, particularly premature ventricular complexes, usually occur at this point, but they almost always resolve without treatment once the catheter tip has crossed the pulmonary valve. The catheter is advanced through the RV toward the PA. The reverse Trendelenburg and right lateral tilt minimize arrhythmias and facilitate catheter passage through the right ventricular outflow tract and pulmonary valve into the PA.[242] As the catheter crosses the pulmonary valve, a dicrotic notch appears in the pressure waveform, and the diastolic pressure suddenly increases. The PCWP (also termed *pulmonary capillary occlusion pressure*) tracing is obtained by advancing the catheter approximately 3 to 5 cm farther until a change in the waveform associated with a drop in the measured mean pressure occurs. Deflation of the balloon results in the reappearance of the PA waveform and an increase in the mean pressure value. Using the right IJV approach, the RA is entered at 25 to 35 cm, the RV at 35 to 45 cm, the PA at 45 to 55 cm, and the PCWP at 50 to 60 cm in most patients.

If the catheter does not enter the PA by 60 cm (from the right IJV approach), the balloon should be deflated and the catheter should be withdrawn into the RA or the inflow portion of the RV. Further attempts can then be made to advance the catheter into proper position using the techniques previously described. Excessive coiling of the catheter in the RA or RV should be avoided to prevent catheter knotting. The balloon should be inflated only for short periods to measure the PCWP. The PA waveform should be monitored continually to be certain that the catheter does not advance into a constant wedge position, which may lead to PA rupture or pulmonary infarction. Not infrequently, the PAC must be withdrawn a short distance because the catheter softens and advanced more peripherally into the PA over time, or on CPB attributable to the decreased size of the heart.

The PCWP waveform is analogous to the CVP waveform described previously. The A, C, and V waves seen when the PAC balloon is inflated (pulmonary capillary wedge position) are similarly timed in the cardiac cycle. Large V waves can be seen on the PCWP waveform during mitral regurgitation, left ventricular diastolic noncompliance, and episodes of myocardial ischemia.[243] They also are seen on the PA waveform (PAC not wedged) as large ("giant") V waves that occur slightly later than the typical upstroke on the PA tracing.[244] The V waves cause the PA waveform to become wider and to lose the dicrotic notch (Fig. 13.20). The cause of large V waves during myocardial ischemia is probably a decrease in diastolic ventricular compliance, or mitral regurgitation induced by ischemic papillary muscle dysfunction and annular dilatation from ventricular distension. In this instance, the V waves may occur earlier during the onset of the C wave (as seen with the onset of ventricular contraction) and are termed *C-V waves*.

Specific information that can be gathered with the PAC and the quantitative measurements of cardiovascular and pulmonary function that can be derived from this information are listed in Tables 13.2 and 13.3. One of the primary reasons that clinicians measure PCWP and PA diastolic (PAD) pressure is that these parameters are estimates of LAP, which can serve as an estimate of left ventricular preload.[245] The relationship between left ventricular end-diastolic pressure (LVEDP) and left ventricular end-diastolic volume (LVEDV) is described by the left ventricular compliance curve. This nonlinear curve is affected by many factors, such as ventricular hypertrophy and myocardial ischemia.[246–248] The relationship of these parameters is diagrammed in Fig. 13.21. In the echo era, left ventricular preload in the surgical unit is better evaluated using TEE measures, such as end-diastolic area or volume. However, elevation of either PCWP or LAP is still a useful criterion in estimating acute exacerbation of HF.

The PCWP and PAD pressure will not accurately reflect LVEDP in the presence of incorrect position of the PAC catheter tip, pulmonary vascular disease, high levels of PEEP, or mitral valvular disease. The patency of vascular channels between the distal port of the PAC and the LA is necessary to ensure a close relationship between the PCWP and

TABLE 13.1 Normal Intracardiac Pressures

Location	*Mean (mm Hg)*	*Range (mm Hg)*
Right atrium	5	1–10
Right ventricle	25/5	15–30/0–8
Pulmonary arterial systolic and diastolic pressures	23/9	15–30/5–15
Mean pulmonary arterial	15	10–20
Pulmonary capillary wedge pressure	10	5–15
Left atrial pressure	8	4–12
Left ventricular end-diastolic pressure	8	4–12
Left ventricular systolic pressure	130	90–140

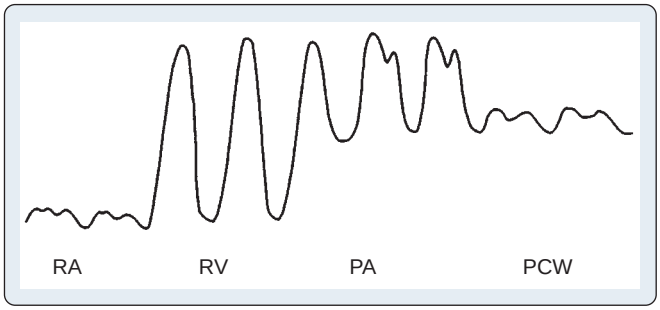

Fig. 13.19 The waveforms encountered during the flotation of a pulmonary artery catheter from the venous circulation to the pulmonary capillary wedge *(PCW)* position. Notice the sudden increase in systolic pressure as the catheter enters the right ventricle *(RV)*, the sudden increase in diastolic pressure as the catheter enters the pulmonary artery *(PA)*, and the decrease in mean pressure as the catheter reaches the PCW position. *RA*, Right atrium.

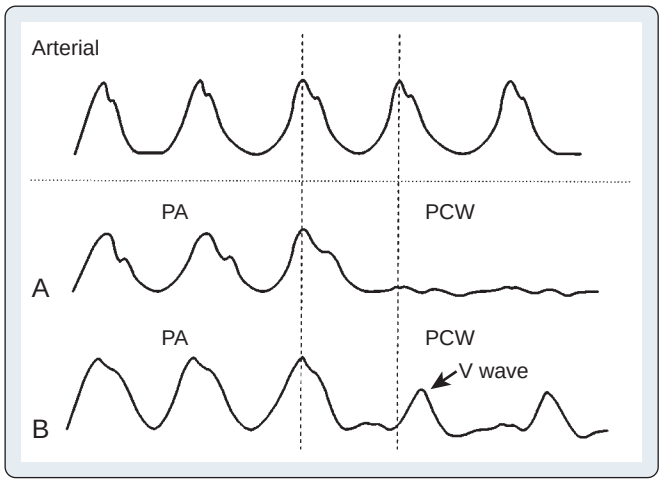

Fig. 13.20 The relationship of the systemic arterial waveform, the pulmonary arterial (*PA*) waveform, and the pulmonary capillary wedge (*PCW*) waveform in the normal situation (A) and in the presence of V waves (B). Note the widening of the PA waveform and the loss of the dicrotic notch in the presence of V waves. The peak of the *V wave (arrow)* occurs after the peak of the systemic arterial waveform.

TABLE 13.2 Derived Hemodynamic Parameters

Formula	*Normal Values*
Cardiac index (CI) CI = CO/BSA	2.6–4.2 L/min/m^2
Stroke volume (SV) SV = CO*1000/HR	50–110 mL (per beat)
Stroke index (SI) SI = SV/BSA	30–65 mL/beat/m^2
Left ventricular stroke work index (LVSWI) LVSWI = 1.36* (MAP–PCWP)* SI/100	45–60 gram-meters/m^2
Right ventricular stroke work index (RVSWI) RVSWI = 1.36* (MPAP–CVP)* SI/100	5–10 gram-meters/m^2
Systemic vascular resistance (SVR) SVR = (MAP–CVP)* 80/CO	900–1400 dynes·sec·cm^{-5}
Systemic vascular resistance index (SVRI) SVRI = (MAP–CVP)* 80/CI	1500–2400 dynes·sec·cm^{-5}/m^2
Pulmonary vascular resistance (PVR) PVR = (MPAP–PCWP)* 80/CO	150–250 dynes·sec·cm^{-5}
Pulmonary vascular resistance index (PVRI) PVRI = (MPAP–PCWP)* 80/CI	250–400 dynes·sec·cm^{-5}/m^2

BSA, Body surface area; *CO*, cardiac output; *CVP*, central venous pressure; *HR*, heart rate; *MAP*, mean arterial pressure; *PAP*, pulmonary arterial pressure; *PCWP*, pulmonary capillary wedge pressure.

LAP. This condition is met only in the dependent portions of the lung (West zone III), in which the pulmonary venous pressure exceeds the alveolar pressure.[249] Otherwise, the PCWP will reflect alveolar pressure and not LAP. High levels of PEEP decrease the size of West zone III, and adversely affect the correlation between the PCWP and LAP, especially in the hypovolemic patient.[250–252] In patients on high levels of PEEP it is not clear what percentage of the increased intrathoracic pressure is actually transmitted to the catheter tip, and how much this affects the estimation of left ventricular preload. However, temporary removal of high levels of PEEP (eg, >10 mm Hg) is discouraged, because rapid reduction in the functional residual capacity and associated lung atelectasis might have acute adverse respiratory consequences. Conversely, low levels of PEEP applied to prevent atelectasis may actually maintain vascular patency and the correlation with left-sided filling pressures since hypoxia is associated with pulmonary vasoconstriction. In patients with ARDS the relationship between the PCWP and LAP

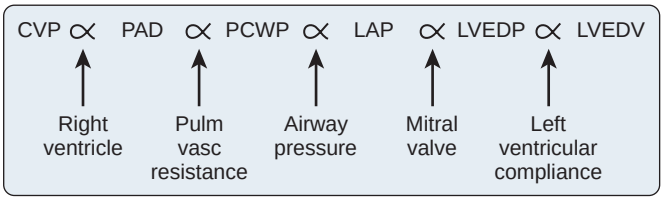

Fig. 13.21 The left ventricular end-diastolic volume (*LVEDV*) is related to left ventricular end-diastolic pressure (*LVEDP*) by the left ventricular compliance. The LVEDP is related to the left atrial pressure (*LAP*) by the diastolic pressure gradient across the mitral valve. The pulmonary capillary wedge pressure (*PCWP*) is related to the LAP by the pulmonary capillary resistance. The pulmonary artery diastolic (*PAD*) pressure is an estimate of the PCWP. The central venous pressure (*CVP*) will reflect the PAD pressure if right ventricular function is normal.

TABLE 13.3 Oxygen Delivery Parameters

Formula	*Normal Values*
Arterial oxygen content (CaO_2) $CaO_2 = (1.39^* Hb^* SaO_2) + (0.0031^* PaO_2)$	18–20 mL/dL
Mixed venous oxygen content (CvO_2) $CvO_2 = 1.39^* Hb^* SvO_2 + 0.0031^* PvO_2$	13–16 mL/dL
Arteriovenous oxygen content difference ($avDO_2$) $avDO_2 = CaO_2 - CvO_2$	4–5.5 mL/dL
Pulmonary capillary oxygen content (CcO_2) $CcO_2 = 1.39^* Hb^* ScO_2 + 0.0031^* PcO_2$	19–21 mL/dL
Pulmonary shunt fraction (Qs/Qt) $Qs/Qt = 100^* (CcO_2 - CaO_2)/(CcO_2 - CvO_2)$	2–8 %
Oxygen delivery (DO_2) $DO_2 = 10^* CO^* CaO_2$	800–1100 mL/min
Oxygen consumption (VO_2) $VO_2 = 10 * CO * (CaO_2 - CvO_2)$	150-300 mL/min

CcO_2, Capillary oxygen content; *Hb*, hemoglobin; *PaO_2*, arterial partial pressure of oxygen; *PcO_2*, pulmonary capillary oxygen tension; *PvO_2*, venous oxygen tension; *SaO_2*, arterial oxygen saturation; *ScO_2*, pulmonary capillary oxygen saturation; *SvO_2*, venous oxygen saturation.

From McGrath RB. Invasive bedside hemodynamic monitoring. *Prog Cardiovasc Dis.* 1986; 29:129–144.

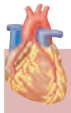
was preserved even when high levels of PEEP up to 20 cm water were applied.[253]

In general, the PCWP should be determined at end-expiration in both spontaneously breathing patients and those on mechanical ventilation. Significant valvular disease greatly increases the difficulty in correctly interpreting the PCWP. The presence of large V waves in the PCWP tracing of patients with mitral regurgitation leads to an overestimation of the LVEDP.[254] In patients with mitral stenosis, PCWP will be elevated despite decreased left ventricular preload (LVEDV). Significant aortic regurgitation will lead to premature mitral valve closure; as a result, LVEDV will be underestimated. Additionally, immediately after CPB, the PCWP may be inaccurate in assessing LAP and LVEDP.[255] Box 13.9 provides a summary of conditions that may alter the relationship between the PCWP and the LVEDP.

Special purpose PACs for continuous CO, continuous mixed venous oxygen saturation (SvO_2), pacing, and thermodilution right ventricular ejection fraction (RVEF) have been investigated clinically and are described later in this chapter; however, commercial availability is becoming more limited.

Indications

In a global sense, the indications for using a PAC are assessing hemodynamic parameters such as loading conditions of the heart (preload, afterload), CO, and indices useful in assessing oxygen delivery and demand (ie, SvO_2). In 2003, the American Society of Anesthesiologists Task Force on Pulmonary Artery Catheterization published updated practice guidelines for PA catheterization.[256] These guidelines



BOX 13.9 CONDITIONS RESULTING IN DISCREPANCIES BETWEEN PULMONARY CAPILLARY WEDGE PRESSURE AND LEFT VENTRICULAR END DIASTOLIC PRESSURE

PCWP > LVEDP
- Positive pressure ventilation
- High levels PEEP
- Increased intrathoracic pressure
- Non–West lung zone III PAC placement
- Chronic obstructive pulmonary disease
- Increased pulmonary vascular resistance
- Left atrial myxoma
- Mitral valve disease (eg, stenosis, regurgitation)

PCWP < LVEDP
- Noncompliant left ventricle (eg, ischemia, hypertrophy)
- Aortic regurgitation (premature closure of the mitral valve)

LVEDP, Left ventricular end diastolic pressure; *PAC*, pulmonary artery catheter; *PCWP*, pulmonary capillary wedge pressure; *PEEP*, positive end-expiratory pressure.
Adapted from Tuman KJ, Carroll GC, Ivankovich AD. Pitfalls in interpretation of pulmonary artery catheter data. *J Cardiothorac Vasc Anesth*. Update. 1991;2:1–24.

emphasized that the patient, surgery, and practice setting had to be considered when deciding on the use of a PAC. Generally, the routine use of PACs is indicated in high-risk patients (eg, ASA IV or V) and high-risk procedures, during which large fluid changes or hemodynamic disturbances are expected. The practice setting is important, because evidence suggests that inadequate training or experience may increase the risk for perioperative complications associated with the use of a PAC. The recommendation is that the routine use of a PAC should be confined to centers with adequate training and experience in the perioperative management of patients with PACs (Box 13.10). The authors of this chapter have composed a list of possible procedural indications (Box 13.11).

Historically, the use of the PAC contributed to the understanding and care of patients with cardiac disease. The risks associated with perioperative PAC monitoring, however, seem to outweigh the benefits in low-to-moderate risk patients, whereas some high-risk patients undergoing major surgery may benefit from right-sided heart catheterization.

Contraindications

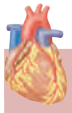
Contraindications to PA catheterization are summarized in Box 13.12.

Absolute Contraindications

Contraindications to the use of a PAC include severe tricuspid or pulmonic valvular stenosis. It is unlikely that a PAC would be able to cross the stenotic valve, and it might worsen the obstruction to flow if it did. Friable right atrial or right ventricular masses (ie, tumor, thrombus) are also absolute contraindications. The catheter may dislodge a portion of the mass, causing pulmonary or paradoxical embolization.

Relative Contraindications

The use of a PAC may be contraindicated in patients with severe arrhythmias. Transient atrial and ventricular arrhythmias are common during PAC placement. The risk of inducing an arrhythmia in a patient prone to malignant arrhythmias must be weighed against the potential benefits of the information gained from PAC monitoring. Appropriate preparations must be undertaken for the administration of antiarrhythmic drugs and cardiopulmonary resuscitation, as well as electrical cardioversion, defibrillation, or pacing, if required. In patients with preexisting left bundle branch block (LBBB), a complete heart block



BOX 13.10 AMERICAN SOCIETY OF ANESTHESIOLOGISTS' PRACTICE GUIDELINES FOR PULMONARY ARTERY CATHETER USE

Opinions
- PA catheterization provides new information that may change therapy, with poor clinical evidence of its effect on clinical outcome or mortality.
- There is no evidence from large, controlled studies that preoperative PA catheterization improves outcome regarding hemodynamic optimization.
- Perioperative PAC monitoring of hemodynamic parameters leading to goal-directed therapy has produced inconsistent data in multiple studies and clinical scenarios.
- Having immediate access to PAC data allows important preemptive measures for selected subgroups of patients who encounter hemodynamic disturbances that require immediate and precise decisions about fluid management and drug treatment.
- Experience and understanding are the major determinants of PAC effectiveness.
- PA catheterization is inappropriate as routine practice in surgical patients and should be limited to cases in which the anticipated benefits of catheterization outweigh the potential risks.
- PA catheterization can be harmful.

Recommendations
- The appropriateness of PA catheterization depends on a combination of patient-, surgery-, and practice setting–related factors.
- Perioperative PA catheterization should be considered in patients with significant organ dysfunction or major comorbidity that pose an increased risk for hemodynamic disturbances or instability (eg, ASA IV or V patients).
- Perioperative PA catheterization in surgical settings should be considered based on the hemodynamic risk of the individual case rather than generalized surgical setting–related recommendations. High-risk surgical procedures are those during which large fluid changes or hemodynamic disturbances can be anticipated and procedures that are associated with a high risk of morbidity and mortality.
- Because of the risk of complications from PA catheterization, the procedure should not be performed by clinicians or nursing staff or in practice settings in which competency in safe insertion, accurate interpretation of results, and appropriate catheter maintenance cannot be guaranteed.
- Routine PA catheterization is not recommended when the patient, procedure, or practice setting poses a low or moderate risk for hemodynamic changes.

ASA, American Society of Anesthesiologists; *PA*, pulmonary artery; *PAC*, pulmonary artery catheter.

BOX 13.11 POSSIBLE CLINICAL INDICATIONS FOR PULMONARY ARTERY CATHETER MONITORING

Major procedures involving large fluid shifts or blood loss in patients with:
- Right-sided heart failure, pulmonary hypertension
- Severe left-sided heart failure not responsive to therapy
- Cardiogenic or septic shock or with multiple-organ failure
- Orthotopic heart transplantation
- Left ventricular–assist device implantation

BOX 13.12 CONTRAINDICATIONS FOR PULMONARY ARTERY CATHETERIZATION

Absolute Contraindications
- Severe tricuspid or pulmonary stenosis
- Right atrial or right ventricular mass
- Tetralogy of Fallot

Relative Contraindications
- Severe arrhythmias
- Left bundle branch block (consider pacing PAC)
- Newly inserted pacemaker wires, AICD, or CRT
- Severe coagulopathy

AICD, Automatic implantable cardioverter defibrillator; *CRT*, cardiac resynchronization therapy; *PAC*, pulmonary artery catheter.

may result and cause significant hemodynamic instability. The benefits of placing a PAC in these patients should clearly outweigh the risks, and using a pacing or paceport PAC should be considered, allowing for immediate pacing should a complete heart block occur. Alternatively, external pacing leads should be placed before the procedure.

Coagulopathy may be a relative contraindication to the use of a PAC and may be related to the potential complications of obtaining central venous access in the patient with a coagulopathy. The risk of inducing endobronchial hemorrhage with inadvertent migration of the PAC or prolonged balloon inflation may be increased.

Newly inserted pacemaker wires may be a contraindication, because of the risk of displacing them during PAC insertion or withdrawal. In approximately 4 to 6 weeks, the pacemaker wires become firmly embedded in the endocardium, and wire displacement becomes less likely. The risk is even higher with multiple electrodes in place such as with an AICD or for cardiac resynchronization therapy.

Complications

The complications associated with PAC placement include almost all of those detailed in the section on CVP placement. Additional complications that are unique to the PAC are detailed in the following paragraphs. The American Society of Anesthesiologists Task Force on Pulmonary Artery Catheterization concluded that serious complications attributable to PAC catheterization occur in 0.1% to 0.5% of patients monitored with a PAC.[256] Higher estimates are found in the literature and probably represent different patient populations, hospital settings, level of experience with PAC management, and other factors.[257]

Arrhythmias

The most common complications associated with PAC insertion are transient arrhythmias, especially premature ventricular contractions.[258] However, fatal arrhythmias have rarely been reported.[259,260] A positional maneuver entailing 5-degree head-up and right lateral tilt was associated with a statistically significant decrease in malignant arrhythmias (compared with the Trendelenburg position) during PAC insertion.[242]

Complete Heart Block

Complete heart block may develop during PA catheterization in patients with preexisting LBBB.[261–264] This potentially fatal complication is most likely due to electrical irritability from the PAC tip causing transient right bundle branch block (RBBB) as it passes through the right ventricular outflow tract. The incidence of developing RBBB was 3% in a prospective series of patients undergoing PA catheterization.[265] However, none of the patients with preexisting LBBB developed complete heart block in that series. In another study of 47 patients with LBBB, complete heart block occurred in 2 patients with recent-onset LBBB.[266] Having an external pacemaker immediately available or using a pacing PAC when placing a PAC in patients with LBBB is imperative.

Endobronchial Hemorrhage

Numerous cases of iatrogenic rupture of the PA have been recorded.[267–269] The incidence of PAC-induced endobronchial hemorrhage in one large series was 0.064% to 0.20%.[258] The ASA PAC guidelines report an incidence of 0.03% to 1.5% from the reviewed literature.[256] Regardless of the exact incidence, this rare complication is associated with a high mortality rate. Hannan and colleagues[270] reported a 46% mortality rate in a review of 28 cases of PAC-induced endobronchial hemorrhage, but the mortality rate was 75% in anticoagulated patients. From these reports, several risk factors have emerged: advanced age, female sex, pulmonary hypertension, mitral stenosis, coagulopathy, distal placement of the catheter, and balloon hyperinflation. Balloon inflation in distal PAs is probably accountable for most episodes of PA rupture because of the high pressures generated by the balloon.[271] Hypothermic CPB also may increase risk attributable to distal migration of the catheter tip with movement of the heart and hardening of the PAC.[272,273] Pulling back the PAC approximately 3 to 5 cm when CPB is instituted is common practice.

Consideration of the cause of the hemorrhage when forming a therapeutic plan is important. If the hemorrhage is minimal and a coagulopathy coexists, then correction of the coagulopathy may be the only necessary therapy. Protection of the uninvolved lung is of prime importance. Tilting the patient toward the affected side and placing a double-lumen endotracheal tube, as well as other lung-separation maneuvers, should protect the contralateral lung.[274] Strategies proposed to stop the hemorrhage include the application of PEEP, the placement of bronchial blockers, and pulmonary resection.[275] The clinician is obviously at a disadvantage unless the site of hemorrhage is known. A chest radiograph will usually indicate the general location of the lesion. Although the cause of endobronchial hemorrhage may be unclear, the bleeding site must be unequivocally located before surgical treatment is attempted. A small amount of radiographic contrast dye may help pinpoint the lesion if active hemorrhage is present. In severe hemorrhage and with recurrent bleeding, transcatheter coil embolization has been used and may emerge as the preferred treatment method.[276,277]

Pulmonary Infarction

Pulmonary infarction is a rare complication of PAC monitoring. An early study suggested that a 7.2% incidence of pulmonary infarction was reported with PAC use.[278] However, continuously monitoring the PA waveform and keeping the balloon deflated when not determining the PCWP (to prevent inadvertent wedging of the catheter) were not standard practice at that time. Distal migration of PACs may also occur intraoperatively as a result of the action of the RV, uncoiling of the catheter, and softening of the catheter over time. Inadvertent catheter wedging occurs during CPB because of the diminished right ventricular chamber size and retraction of the heart to perform the operation. Embolization of thrombus formed on a PAC also could result in pulmonary infarction.

Catheter Knotting and Entrapment

Knotting of a PAC usually occurs as a result of coiling of the catheter within the RV. Insertion of an appropriately sized guidewire under fluoroscopic guidance may aid in unknotting the catheter.[279] Alternatively, the knot may be tightened and withdrawn percutaneously along with the introducer if no intracardiac structures are entangled.[280] If cardiac structures, such as the papillary muscles, are entangled in the knotted catheter, then surgical intervention may be required.[281,282] Sutures placed in the heart may inadvertently entrap the PAC. Reports of such cases and the details of the percutaneous removal have been described.[283]

Valvular Damage

Withdrawal of the catheter with the balloon inflated may result in injury to the tricuspid[284] or pulmonary valves.[285] Placement of the PAC

with the balloon deflated may increase the risk of passing the catheter between the chordae tendineae.[286] Septic endocarditis has also resulted from an indwelling PAC.[287,288]

Thrombocytopenia

Mild thrombocytopenia has been reported historically with PAC use.[289] Although heparin-coated PACs may reduce this risk, these catheters can trigger heparin-induced thrombocytopenia.[290]

Thrombus Formation

The PAC is a foreign body that may serve as a nidus for thrombus formation,[291] but this is rarely seen with modern heparin-bonded PACs[292] and short-term use. Antifibrinolytic therapy may increase the risk of thrombus formation.[293,294]

Incorrect Placement

Aside from monitoring the pressure waveform from the distal lumen, TEE can be used to direct the PAC through the TV and into the correct position in the proximal PA. Without TEE guidance, incorrect placement of the PAC is not uncommon. Most frequently, the PAC is advanced too far and may result in spontaneous wedging of the catheter during CPB. Placement of the PAC in the liver has been described; the wedged hepatic venous pressures may mimic the PA pressure waveform.[295] Cannulation of the left IJV in patients with an unknown persistent left SVC would result in advancing the PAC through the CS.[296] In patients with a persistent foramen ovale or atrial or ventricular septal defect, the catheter may pass into the left side of the heart. In a case report of a patient with an ascending aortic aneurysm, compression of the SVC by the aneurysm led to traumatic placement of the PAC directly into the pulmonary vein.[297] Venous cannula obstruction has occurred in patients during CPB.[298–300] The temporal association with the abrupt loss of venous return and the negative pressure recorded on the distal lumen tracing are important indicators that this may be occurring. This stresses the importance of monitoring the pressure waveforms during CPB. TEE has proved invaluable for confirming the proper placement of PACs.

Balloon Rupture

Balloon rupture is not uncommon when the PAC has been left in place for several days or when the balloon is inflated with more than 1.5 mL of air. Small volumes of air injected into the PA are of little consequence, and balloon rupture is apparent if the injected air cannot be withdrawn from the balloon and blood is aspirated instead.

Ventricular Perforation

Right ventricular perforation is a rare complication with a balloon-tipped catheter, but it has been reported in the literature.[301]

Artifacts and Erroneous Measurements

Measuring the PCWP to determine the volume status of patients is particularly prone to errors, which can lead to spurious numbers and incorrect treatment of the patient. Incorrect leveling of the transducer height with the LA and interference from mechanical ventilation (Fig. 13.22) are both very common sources of erroneous measurements. "Catheter whip" is an artifact that is associated with long catheters and thus can be observed with PACs. Because the catheter tip moves within the bloodstream of great vessels, the fluid contained within the catheter is accelerated, resulting in superimposed pressure waves of 10 mm Hg in either direction. With echocardiography being almost uniformly available in cardiac surgical units, multiple monitoring tools and parameters are available to the practitioner confirming individual pressure readings.

Special Purpose Pulmonary Artery Catheters

With decreasing use of PACs, the availability of special purpose catheters is also decreasing.

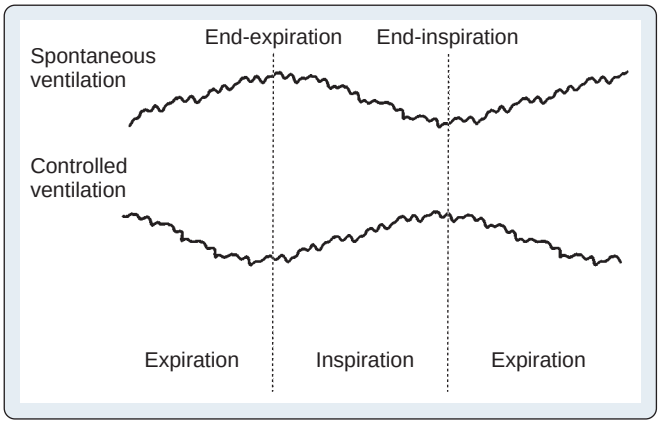

Fig. 13.22 Respiratory variation of the pulmonary capillary wedge pressure waveform during spontaneous and mechanical ventilation. Inspiration is marked by negative mediastinal pressure in the spontaneously breathing patient and by positive mediastinal pressure in the mechanically ventilated patient.

BOX 13.13 INDICATIONS FOR PERIOPERATIVE PLACEMENT OF PACING PULMONARY ARTERY CATHETERS

- Sinus node dysfunction or symptomatic bradycardia
- Hemodynamically relevant second-degree (Mobitz II) atrioventricular block
- Complete (third-degree) atrioventricular block
- Need for atrioventricular sequential pacing
- Left bundle branch block

Pacing Pulmonary Artery Catheters

Electrode-coated PACs and pacing wire catheters are available commercially. The possible indications for placement of a pacing PAC are shown in Box 13.13.

Electrode Catheters

This multipurpose PAC (Edwards Lifesciences Corp., Irvine, CA) contains three atrial and two ventricular electrodes for atrial, ventricular, or AV sequential pacing. The intraoperative success rates for atrial, ventricular, and AV sequential capture have been reported as 80%, 93%, and 73%, respectively.[302]

Pacing Wire Catheters

The Paceport and A-V Paceport PA catheters (Edwards Lifesciences Corp., Irvine, CA) have lumens for the introduction of a ventricular wire or both atrial and ventricular wires for temporary transvenous pacing. The success rate for ventricular and AV capture with Paceport PACs is higher, compared with electrode pacing PACs.[303,304] The use and indications for the placement of pacing PAC in a series of cardiac surgery patients has been published.[305–307]

Mixed Venous Oxygen Saturation Catheters

Monitoring the SvO_2 is a means of providing a global estimation of the adequacy of oxygen delivery relative to the needs of the various tissues (oxygen supply-demand ratio). The formula for SvO_2 calculation can be derived by modifying the Fick formula and assuming that the effect of dissolved oxygen in the blood is negligible:

$$SvO_2 = SaO_2 - \frac{\dot{V}O_2}{CO \cdot 1.34 \cdot Hb}$$

A decrease in the SvO_2 can indicate one of the following situations: decreased CO, increased oxygen consumption, decreased arterial oxygen saturation, or decreased hemoglobin (Hb) concentration. To measure SvO_2 in the laboratory, blood is aspirated from the distal port of the PAC slowly, so as not to contaminate the sample with oxygenated alveolar blood.

The addition of fiberoptic bundles to PACs has enabled the continuous monitoring of SvO_2 using reflectance spectrophotometry. The catheter is connected to a device that includes a light-emitting diode and a sensor to detect the light returning from the PA. SvO_2 is calculated from the differential absorption of various wavelengths of light by the saturated and desaturated Hb.[308] The values obtained with various fiberoptic catheter systems showed good agreement with in vitro (co-oximetry) SvO_2 measurements.[309–312]

The usefulness of the catheter may primarily be its ability to continuously monitor the balance between oxygen delivery and consumption.[313–316] However, severe deterioration in the condition of critically ill patients is often not predicted by changes in SvO_2.[317–319] London and colleagues[320] published a prospective, multicenter, observational study in which continuous monitoring of SvO_2 was compared with standard PAC monitoring in 3265 cardiac surgical patients. They failed to show any improved outcome associated with the use of continuous SvO_2 catheters and only a small reduction in resource use. Several recent studies found an association not only between low but also between supranormal central venous oxygen saturations and poor outcome measures, including in patients undergoing cardiac surgery.[321–324]

Cardiac Output Monitoring

The CO is the amount of blood delivered to the tissues by the heart each minute. This measurement reflects the status of the entire circulatory system, not just the heart, because it is governed by autoregulation from the tissues. The CO is equal to the product of the SV and the HR. Preload, afterload, HR, and contractility are the major determinants of the CO. This section describes the methods of CO monitoring including thermodilution CO derived from the PAC. Interestingly, a metaanalysis performed as part of the OPTIMISE trial published in 2014,[325] found that CO-guided hemodynamic therapy in noncardiac surgery was associated with fewer complications than control treatment.

Fick Method

The Fick formula is derived from the concept that oxygen consumed by the tissues per unit time is equal to the amount of oxygen extracted per unit time from the circulation. The oxygen extracted from the circulation is the product of the arteriovenous oxygen content difference and the CO:

$$VO_2 = (CaO_2 - CvO_2) \times CO$$

Rearranging the equation, CO is calculated using the following formula:

$$CO = \frac{VO_2}{(CaO_2 - CvO_2)}$$

in which CO is the cardiac output, VO_2 is the oxygen consumption, CaO_2 is the arterial oxygen content, and CvO_2 is the mixed venous oxygen content.

In the direct Fick method, oxygen consumption is measured by indirect calorimetry using algorithms based on inspired and expired oxygen concentrations and volumes. Oxygen consumption can be calculated when the rate of fresh gas flow, respiratory rate, and change of oxygen concentration are known. Arterial oxygen content is measured from an arterial blood sample, and mixed venous oxygen content can be obtained from the PAC. Because of technical difficulties, oxygen consumption in pediatric patients is commonly estimated using the formulas of LaFarge and Miettinen[326] with the use of gender, HR, and age as variables. Oxygen consumption and arteriovenous oxygen content differences must be measured at steady state because the Fick principle is valid only when tissue oxygen uptake equals lung oxygen uptake.

The accuracy and reproducibility of the direct Fick CO technique have been determined in a variety of animal and human experiments. Both measures usually have been found to be high.[327] The major limitations of the direct Fick technique are related to errors in sampling and analysis, difficulty in obtaining oxygen uptake continuously in the surgical unit, the presence of bulky equipment surrounding the endotracheal tube, or the inability to maintain steady-state hemodynamic and respiratory conditions.[328,329]

Some of these problems have been overcome with the introduction of metabolic modules for the measurement of oxygen consumption that are incorporated into the patient monitoring system and that do not depend on collecting gases in bulky sample chambers.[330] No flow or volume transducers are incorporated into these systems. Rather, continuous measurement of expiratory carbon dioxide (CO_2) concentrations in a constant flow allows for the calculation of the amount of CO_2 eliminated by the patient. This method is referred to as the "modified carbon dioxide Fick method." Inspiratory and expiratory oxygen and CO_2 concentrations are measured to obtain the respiratory quotient, which is then used to derive oxygen consumption.

In the indirect Fick method of calculating CO, expired gases such as CO_2 (intermittent partial rebreathing of CO_2) or acetylene replace oxygen consumption in the Fick equation.[331] Substituting CO_2 production for oxygen consumption, capnographic measurement of CO_2 concentrations may be used to provide a noninvasive Fick estimate of CO. The rebreathing technique is used to estimate mixed venous partial pressure of CO_2. In the clinical setting, patients are sedated and mechanically ventilated, and capnometry equipment is attached to a processor that calculates CO.[332] Studies comparing the CO_2 rebreathing method with standard measures of CO have yielded conflicting results.[333–337] Binder and Parkin[338] studied postoperative cardiac surgical patients. They compared the CO_2 method with the thermodilution method and showed a good correlation. In contrast, van Heerden and colleagues,[339] using a different device, found that CO measurements in cardiac surgery patients were overestimated using the CO_2 rebreathing technique.

Indicator Dilution

The indicator dilution method is based on the observation that, for a known amount of indicator introduced at one point in the circulation, the same amount of indicator should be detectable at a downstream point. The amount of indicator detected at the downstream point is equal to the product of CO and the change in indicator concentration over time. CO is calculated using the Stewart-Hamilton equation:

$$CO = I \times 60 \div \int C\,dt$$

in which CO is cardiac output, I is amount of indicator injected, and $\int C\,dt$ is the integral of indicator concentration over time (60 converts seconds to minutes).

Cold saline (ie, thermodilution) or lithium ions are used as indicators, whereas dye (eg, indocyanine green [ICG]) or radioisotopes are rarely used in current practice.[340] Blood flow is directly proportional to the amount of the indicator delivered and inversely proportional to the amount of indicator that is present at a sampling site distal to the injection site.

Thermodilution

Intermittent Thermodilution Cardiac Output

The thermodilution method, using the PAC, is the most commonly used method at present for invasively measuring CO in the clinical setting. With this technique, multiple CO measurements can be obtained at frequent intervals using an inert indicator and without blood withdrawal. A bolus of cold fluid is injected into the RA, and the resulting temperature change is detected by the thermistor in the PA.[341]

When a thermal indicator is used, the modified Stewart-Hamilton equation is used to calculate CO:

$$CO = \frac{V(T_B - T_I) \times K_1 \times K_2}{\int_0^\infty \Delta T_B(t)dt}$$

in which CO is the cardiac output (L/min), V is the volume of injectate (mL), T_B is the initial blood temperature (degrees Celsius), T_I is the initial injectate temperature (degrees Celsius), K_1 is the density factor, K_2 is the computation constant, and $\int_0^\infty \Delta T_B(t)dt$ is the integral of blood temperature change over time.

A computer that integrates the area under the temperature versus time curve is used to perform the calculation. CO is inversely proportional to the area under the curve.

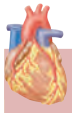
Accuracy

Accuracy describes the ability of a monitoring device to produce results close to the actual true value. With thermodilution CO, several factors may affect the accuracy of the system, including the temperature of the injectate, the speed and amount of injected volume, and technical errors such as fluid administration during CO measurement.

Most of the validation studies on thermodilution CO date back to when the PAC was introduced. Bilfinger and associates,[342] for example, found that the average difference between the thermodilution measurements and the reference values was 7% to 8% with room-temperature injectate and 11% to 13% with ice-cold saline injectate. Under strictly controlled in vitro conditions, the accuracy of the thermodilution CO technique varied from +/−7% to +/−13%. In early studies comparing thermodilution measurements with the direct Fick method, correlation coefficients of 0.96 were obtained.[343,344] Pelletier[345] compared total electromagnetic flow, including coronary blood flow, with thermodilution CO in dogs. He observed that, on average, thermodilution overestimated total aortic flow by +/−3%, compared with electromagnetic flow, whether iced or room-temperature injectate was used. When CO measurements were compared using the thermodilution and ICG methods, the results varied among various studies, with some investigators finding excellent correlations over a wide range of outputs, whereas others observed that thermodilution systematically overestimated dye dilution CO.[346–348]

The temperature-versus-time curve is the crux of this technique, and any circumstances that affect it have consequences for the accuracy of the CO measurement. Specifically, anything that results in less "cold" reaching the thermistor, more "cold" reaching the thermistor, or an unstable temperature baseline will adversely affect the accuracy of the technique. Less "cold" reaching the thermistor would result in overestimation of the CO, which could be caused by a smaller amount of indicator, an indicator that is too warm, a thrombus on the thermistor, or partial wedging of the catheter. Conversely, underestimation of the CO will occur if excessive volume of injectate or injectate that is too cold is used to perform the measurement. In patients with large intracardiac shunts, PAC-derived thermodilution CO is not recommended for accurate CO measurement. Box 13.14 lists common errors in PAC thermodilution CO measurements.

Wetzel and Latson[349] observed variations of up to 80% in measured CO when the rate of administration of intravenous crystalloid infusions caused fluctuations in baseline blood temperature. The rapid temperature decrease seen after weaning from hypothermic CPB has been shown to result in the underestimation of CO by 0.6 to 2.0 L/min.[350] In that study, the temperature decrease after CPB was 0.14 degrees C/min. Latson and colleagues[351] also found that the normal changes in the PA that occur with each respiratory cycle appear to be exaggerated in the early phase after hypothermic CPB. This may cause peak-to-peak errors in estimation of intermittent CO of up to 50% if initiated at different times during the ventilatory cycle. This effect was significantly decreased with thermal equilibration, approximately 30 minutes after CPB. Currently, this problem is less prevalent, because hypothermic CPB is used less.



BOX 13.14 COMMON ERRORS IN PULMONARY ARTERY CATHETER THERMODILUTION CARDIAC OUTPUT MEASUREMENTS

Underestimation of True Cardiac Output
- Injectate volume greater than programmed volume (typically 10 mL)
- Large amounts of fluid administered simultaneous to cardiac output measurement (Rapid infusions should be stopped.)
- Injectate colder than measured temperature injectate (Injectate temperature probe next to heat-emitting hardware instead of injectate fluid.)

Overestimation of True Cardiac Output
- Injectate volume less than programmed volume
- Injectate warmer than measured temperature injectate

Other Considerations
- Surgical manipulation of the heart
- Fluid administration from aortic CPB cannula
- Arrhythmias

CPB, Cardiopulmonary bypass.

TR generally has been considered as a source of error in thermodilution CO determinations. The scientific data, however, are contradictory. Some experimental reports indicate that TR does not impair the accuracy of thermodilution CO when compared with the Fick method[352] and electromagnetic flow probes.[353,354] In contrast, Heerdt and associates[355] reported that thermodilution CO had wide variability in the direction and magnitude of error compared with Doppler and electromagnetic CO in a single patient with acute TR. The severity of TR also seems to be important in determining its effect on CO measurements by thermodilution, with underestimation of CO occurring in the presence of more severe TR.[356]

Slowing of the HR has been described as a side effect of rapid injection of cold injectate into the heart.[357] In a prospective study, Harris and colleagues[358] observed that with the use of iced injectate, a decrease in HR of more than 10% occurred in 22% of the determinations. Nishikawa and Dohi[359] reported that a slowing HR was more likely in patients with a low cardiac index (CI), low mean PA pressure, and high SVR.

Precision

Precision describes the ability of a monitoring system to produce the same results with repeated measurements when all other variables remain unchanged. In vivo precision can be assessed by obtaining a large number of thermodilution CO measurements and calculating their average (mean) and standard deviation. Hoel[360] postulated that a true CO could be measured by calculating the average of an infinite number of thermal injections. Using probability calculus, he found that with two injections there was only a 50% probability of being within 5% of the true CO. With three injections, there was an 89% probability of being within 10% of the true CO. In an attempt to better delineate the reproducibility of the technique, Stetz and associates[361] reviewed 14 publications on the use of thermodilution in clinical practice. They concluded that with the use of commercial thermodilution devices, a minimal difference of 12% to 15% (average, 13%) between determinations was required for statistical significance, provided that each determination was obtained by averaging three measurements.

A few studies also have evaluated the effects of the timing of the injection in the respiratory cycle on the reproducibility of thermodilution CO. In mechanically ventilated dogs, Snyder and Powner[362] observed that CO variations were present in each respiratory cycle and were usually greater than 10%. Stevens and colleagues[363] studied the

effects of the respiratory cycle on thermodilution CO in critically ill patients. They confirmed that injections at specific times in the respiratory cycle resulted in less variability, but possibly decreased accuracy. Nevertheless, they concluded that in clinical practice, the improvement in reproducibility was more important than the decrease in accuracy.

The effects of injectate volume and temperature on the variability of thermodilution CO have also been studied in critically ill patients.[364] Six combinations of injectate volume (3, 5, and 10 mL) and temperature (iced and room temperature) were studied in 18 adult, intubated patients. The best reproducibility was obtained with 10-mL injections at 0°C or room temperature.

In summary, the precision of the thermodilution CO technique is not very good but can be improved by ensuring that, for each determination, the rate and duration of the injection are kept as constant as possible.[365] Whenever possible, 10-mL volumes of injectate should be used, and the timing of the injection in the respiratory cycle should be the same. However, if injection is always at the same point in the respiratory cycle, some loss in accuracy is to be expected.

Continuous Thermodilution Cardiac Output

Pulmonary arterial catheters with the ability to measure CO continuously were introduced into clinical practice in the 1990s. The method that has gained the most clinical use functions by mildly heating the blood—originally using a "pseudorandom stochastic" fashion. In vitro as well as in vivo studies have shown that good correlations exist between this method and other measures of CO.[366–371] Unfortunately, the correlation with CO measurements using the intermittent thermodilution method is inconsistent,[372,373] particularly with rapidly changing hemodynamics, for example, in the initial phase after separating from CPB.[374] In contrast, an excellent correlation exists between intermittent and continuous CO measurements obtained in more physiologically stable periods. Perhaps the reason for this observation lies in the unstable thermal baseline after hypothermic CPB that was described in the previous section. Based on the existing literature failing to show improved outcomes, the routine use of continuous CO PACs in cardiac surgery cannot be supported.

Dye Dilution

Before the introduction of the thermodilution method, the indicator dilution method using ICG dye had been the most popular technique of CO measurement. The dye was injected into a central vein and continuously sampled from arterial blood and passed through a densitometer to measure the change in indicator concentration over time. A computer calculated the area under the dye concentration curve by the integration of the dye concentrations over time and computed CO. After determining the CO, the sampled blood was returned to the patient. Recirculation of the indicator distorted the primary time-concentration curve, and the buildup of indicator in the blood resulted in high background concentrations, which limited the total number of measurements that could be obtained.

The introduction of lithium chloride as the indicator has led to a renaissance of the indicator dilution technique for the measurement of CO.[375–378] A lithium chloride solution is injected through a central venous catheter, and a lithium-selective electrode (that is connected to a standard intraarterial cannula) measures plasma lithium concentrations. Only intraarterial and central venous catheters are required. The Lithium Dilution CO system (LiDCO, Lake Villa, IL), only requires a peripheral venous catheter for injection of small doses of lithium and an arterial catheter equipped with a blood withdrawal system and lithium sensor. Agreement with PAC thermodilution is acceptable in most clinical settings.[379] This system also includes a continuous CO calculation capability based on the arterial pulse wave that must be calibrated to the lithium dilution value (see the following text).

Alternative Techniques for Assessing Cardiac Output

The development of less invasive technologies that allow measuring CO and assessing volume status independently from PA catheterization is flourishing. Numerous technologies based on methods such as transpulmonary thermodilution, indicator dilution (lithium), ultrasound, calibrated and uncalibrated arterial waveform analysis (invasive and noninvasive), and electrical bioimpedance and bioreactance are commercially available. These devices also provide hemodynamic parameters previously not easily accessible; for example, providing the practitioner with information regarding fluid responsiveness.

BOX 13.15 PARAMETERS DERIVED FROM TRANSPULMONARY THERMODILUTION

Discontinuous Parameters

- Thermodilution cardiac index (CI) and stroke volume (SV) index
- Global end-diastolic volume index (GEDVI)
- Cardiac function index (CFI)
- Global ejection fraction (GEF)
- Extravascular lung water index (EVLWI),
- Pulmonary vascular permeability index (PVPI)
- Oxygen delivery index (DO_2I)

Continuous Parameters

- Pulse contour CI and SV index
- Stroke volume variation (SVV)
- Pulse pressure variation (PPV)
- Cardiac power index (CPI)
- Left ventricular contractility (dPmax)

Transpulmonary Thermodilution

Transpulmonary thermodilution allows estimating CO, intrathoracic and global end-diastolic blood volume, extravascular lung water (EVLW), as well as additional parameters describing myocardial performance and pulmonary vascular permeability (Box 13.15). The underlying principle is used in commercially available bedside monitoring devices such as the PiCCO2 (PULSION Medical Systems SE, Munich, Germany) and the EV1000 and VolumeView (Edwards Lifesciences, Corp., Irvine, CA). The placement of a central venous catheter and a modified arterial catheter equipped with both temperature and pressure sensors are required. The tip of the arterial catheter is positioned in a central artery through access from the femoral (PiCCO2, VolumeView), brachial, axillary, or radial arteries (only PiCCO2). Hemodynamic parameters are measured and derived that may be useful in the differential diagnosis and decision making of critically ill patients. SV, CO and CI, static volume assessment, such as global end-diastolic volume index (GEDVI) and EVLW index, as well as dynamic indices, such as stroke volume variation (SVV) and pulse pressure variation (PPV) are displayed as absolute values and trends, facilitating GDT. Transpulmonary thermodilution–derived CO correlates well with PAC measurements.[380–382] For continuous CO measurements, an in vivo calibration has to be performed. Calibration is achieved by injecting a defined volume of a cold solution (VolumeView, PiCCO2) or room temperature solution (PiCCO2) into the central venous catheter. Earlier methods also incorporated calibration techniques, not simply based on temperature changes, such as cold ICG, but also referred to as double-indicator dilution technique. After transpulmonary passage, temperature (or dye concentration) changes are detected via the thermistor sensor, which is incorporated at the tip of the arterial catheter. The recorded thermodilution curve is used to compute CO based on the Stewart-Hamilton equation equivalent to PAC-derived CO measurements. Since transpulmonary fluid passage and peripheral arterial detection computes CO over a longer period, compared with PAC-derived CO, these methods are less susceptible to respiratory variations. With the COLD system (PULSION Medical Systems SE, Munich, Germany), the double-indicator dilution technique was used. As the cold fluid equilibrated rapidly with the extravascular space, intrathoracic thermal volume (ITTV) volumes in the RA, RV, pulmonary blood volume (PBV), EVLW, LA, and LV could be

derived from the product of CO and the mean transit time (MTT) of the cold indicator:

$$ITTV = CO * MTT_{(cold)}$$

The volumetric parameter intrathoracic blood volume (ITBV) (volumes in the RA, RV, PBV, LA, and LV) is calculated as the product of CO and the MTT of the dye indicator, which rapidly bonds to proteins and remains in the vascular system:

$$ITBV = CO * MTT_{(dye)}$$

The EVLW is calculated as the difference between ITTV and ITBV:

$$EVLW = ITTV - ITBV$$

For clinical purposes, the former cumbersome method of transpulmonary double-indicator (cold fluid and dye) dilution technique has been replaced by a single-indicator thermodilution (cold fluid only) method.[383] The largest mixing chamber (pulmonary thermal volume [PTV]) predominantly determines the slope of the downstream indicator dilution curve and can be measured as the product of the downslope time (DST) of the thermodilution curve and CO. PTV is then calculated as:

$$PTV = CO \times DST_{(cold)}$$

By using this equation, global end-diastolic volume can be calculated:

$$GEDV = ITTV - PTV$$

Since ITBV can be calculated from GEDV (ITBV = 1.25 × GEDV), calculating EVLW is possible using the single indicator technique[384] by using the following equation:

$$EVLW = ITTV - ITBV = ITTV - (1{,}25 \times GEDV)$$

The EV1000/VolumeView uses the same general assumptions; however, this device implements a slightly different algorithm, which also allows for adjustments in patients with lung resections.[385]

The clinical relevance and utility of incorporating some of these parameters into treatment algorithms and the potential impact on patient outcomes has been investigated. Several studies found that volumetric parameters, such as GEDVI and ITBVI, offer advantages in estimating cardiac preload compared with pressure-based measures.[386–389] In patients undergoing CABG surgery, prediction of the hemodynamic response to volume administration was improved, compared with pressure-based parameters, such as CVP and PCWP.[390] However, a recent metaanalysis also suggested that SV response can even be better predicted with dynamic parameters such as SVV and PPV.[391] Many clinicians find the information gained from measuring EVLW with transpulmonary thermodilution to be useful in managing critically ill patients. EVLW correlates with pulmonary edema and has been shown to have good prognostic value. In a retrospective analysis of 373 critically ill patients, the mortality rate was 65% in patients with an EVLW >15 mL/kg and only 33% in patients with an EVLW <10 mL/kg.[392]

Cardiac Output Measurements Using Ultrasound Technology

Measurements of SV and CO can be accomplished using various echocardiographic techniques. Adequate image quality is important in all echocardiographic estimates of CO, regardless of whether 2D, three-dimensional (3D), or Doppler-based techniques are used. (For a comprehensive review of echocardiography including echo-derived hemodynamic parameters see Chapters 14 through 16).

Two- and Three-Dimensional Echocardiography

Two-dimensional echocardiography allows for the calculation of CO using the following formula:

$$CO = (EDV - ESV) \times HR$$

in which CO is cardiac output, EDV is the end-diastolic volume, ESV is the end-systolic volume, and HR is the heart rate. Two-dimensional echo-derived left ventricular volume and CO determinations are based on geometric assumptions of chamber size and shape (ie, modified Simpson rule). Reliable estimation of CO depends on adequate imaging that allows for exact tracing of the endocardial border.[393–395] Single-beat 3D volume assessment is available and advances in processor speed and echocardiographic technology have already helped overcome some of the earlier problems of this technology. Good correlation and accuracy was demonstrated when 3D echocardiographic estimates of volumetric measures were compared with established methods.[396–398] In their recent update, the European Society of Cardiology recommended 3D estimation of ventricular volumes whenever feasible.[399]

Recently, a miniaturized monoplane TEE probe has become available. The probe can remain in place for up to 72 hours for continuous hemodynamic TEE monitoring. The views that are obtained are limited; however, the benefit of this technology is the continuous availability of cardiac imaging in high-risk patients. There are limited reports of the use of continuous TEE in patients who have undergone complicated cardiac surgery for algorithm-guided extracorporeal membranous oxygenation (ECMO) weaning,[400] and managing patients with ventricular-assist devices postoperatively.[401] Future studies will be required to demonstrate outcome benefits compared with conventional intermittent TEE or TTE imaging in the ICU.[402]

Doppler Ultrasound

Ultrasound can be used for the measurement of CO based on the Doppler principle. Information on blood flow is obtained by applying Doppler frequency shift analysis to echoes reflected by the moving red blood cells. Blood flow velocity, direction, and acceleration can be instantaneously determined. From this information, SV and CO are calculated using the following formula:

$$SV = VTI \times CSA$$

in which SV is stroke volume, VTI is the Doppler velocity-time integral (ie, area under the pulsed-wave Doppler spectral display curve), and CSA is the cross-sectional area at the site of flow measurement. The SV is then multiplied by HR to calculate the CO. Theoretically, CO may be measured at all anatomic sites in which a CSA is determined and a Doppler beam positioned. Technical limitations include the accuracy of the valve or outflow tract area calculations, and the degree of alignment between the ultrasound beam and the direction of blood flow.

Doppler-derived technology has also been incorporated into esophageal probes (CardioQ-System, Deltex Medical, Chichester, West Sussex, UK) allowing for beat-to-beat SV and CO measurements. The descending aortic blood flow velocities are interrogated, and SV and CO determination is based on the Doppler equation and nomograms incorporating the patient's age, weight, and height. Limitations are the use of nomogram estimates and Doppler alignment, as well as restricting measurements to blood flow in the descending aorta. Validation studies have shown good correlation with PAC-derived CO as long as technical errors can be avoided.[403] In addition to SV, this technology also determines systolic flow time, which is corrected for HR (flow time corrected [FTc]). As an indicator of cardiac afterload, FTc is inversely associated with SVR; however, the clinical value of FTc to optimize volume status is limited. The peak systolic velocity of the Doppler-derived blood flow is related to myocardial contractility and has been used to assess left ventricular performance and response to inotropic therapy. Most studies incorporating this technology into GDT have been performed in the noncardiac surgical setting.[404–406]

In cardiac surgery, esophageal Doppler-guided hemodynamic management was associated with reduced ICU and hospital lengths of stay[407] and reduced the incidence of gut mucosal hypoperfusion.[408]

Cardiac Output Derived From Arterial Pulse Wave Analysis

Waveform analysis is another method currently being used in several CO devices. The arterial pulse wave is obtained either invasively from transducing an indwelling arterial catheter or noninvasively using the volume-clamp method. It has long been known that pulsatility in the arterial tree is proportional to SV: the greater the SV, the greater the amplitude of the resulting pressure wave. This proportionality allows computing CO if a calibration constant, based on various factors including the resistance and compliance of the vessels, is known.[409] Variations of this originally described model are still the basis of modern pulse contour analysis devises.

$$PC-SV = cal \times \int_{systole} \left(\frac{P(t)}{SVR} + C(p) \times \frac{dP}{dt} \right) dt$$

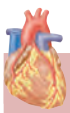
In this equation, PC – SV is pulse contour stroke volume, cal is the calibration factor, P(t) is the arterial BP, C(p) is the arterial compliance, and dp/dt is the shape of the arterial pressure curve. Pulsatility is easily assessed using parameters, such as the area under the pressure wave, area under the systolic portion of the wave, or standard deviation of the wave.

Calibrated Pulse Contour Cardiac Output

Deriving the calibration factor is more complex. A common approach has been to first measure the SV by another method (eg, lithium dilution, transpulmonary thermodilution), measure the pulsatility, and then determine the individual calibration factor. This calibration factor can subsequently be used to calculate SV continuously from the pulsatility of the wave. Several commercially available devices including the EV1000 and PiCCO2, as well as the LiDCOplus are using this approach.[410] The LiDCOplus System uses lithium chloride as an indicator for initial calibration and the calculation of the calibration factor. The dose of lithium needed for calibration is minimal and has no known therapeutic side effects.[411] In a modified version, the LiDCOplus System, the indicator can be injected into a peripheral vein and no central venous access is required. After the initial calibration, an autocalibration algorithm (PulseCO algorithm) is used for continuous assessment of beat-to-beat SV, CO, and variables such as SVV are displayed (Box 13.16).[412] The PiCCO2 system and the EV1000 Clinical Platform use transpulmonary thermodilution CO measurements to calibrate the continuous pulse contour CO algorithm. Recalibration of the device is required at least every 4 to 8 hours.[413]

Studies comparing lithium or thermodilution calibrated pulse wave analysis-derived CO to PAC-derived CO show acceptable correlations in many clinical settings,[379,410,414] including in patients following cardiac surgery.[415,416] However, other studies found significant limitations of this technology in cardiac surgery patients. For example, the accuracy of the PulseCO algorithm may be compromised in patients with aortic valve regurgitation, after aortic reconstruction, and in patients with an intraaortic balloon pump. A dampened arterial pulse signal or pronounced peripheral arterial vasoconstriction may result in inaccurate CO readings.[417] If the system is not recalibrated frequently when significant changes in vascular tone occur (eg, during weaning from CPB), then SV calculation may also yield inaccurate results.[418,419] In OPCAB surgery, agreement between the PiCCO2 pulse-contour analysis and PAC was acceptable; however, recalibration of the pulse-contour analysis improved the agreement further.[420]

In summary, calibrated pulse contour CO monitoring devices are a less invasive alternative to measuring CO. In case of rapid hemodynamic changes and alterations in vascular tone (eg, weaning from CPB or OPCAB surgery), these devices should be recalibrated frequently.



BOX 13.16 PARAMETERS DERIVED FROM PULSE CONTOUR ANALYSIS

Continuous Parameters (Not for All Monitoring Devices)

- Pulse contour/Pulse wave cardiac index and stroke volume index
- Stroke volume variation (SVV)
- Pulse pressure variation (PPV)
- Systemic vascular resistance (SVR)
- Cardiac power index (CPI)
- Left ventricular contractility (dPmax)

Uncalibrated and Autocalibrated Pulse Contour and Pulse Wave Technology

A trend to less invasive monitoring technologies can also be seen in the development of continuous CO devices that do not require invasive (ie, transpulmonary thermodilution) calibration. Two of these devices, the ProAQT (PULSION Medical Systems SE, Munich, Germany) and the LiDCOrapid System (LiDCO Ltd, Lake Villa, IL) estimate CO and dynamic parameters such as SVV and PPV from arterial pulse contour and pulse wave analysis without external calibration, using patient demographics such as age, height, weight, and gender. The ProAQT System uses a dedicated pressure transducer that is connected to any standard arterial catheter. In a third system, the FloTrac sensor is connected to a proprietary monitor (eg, EV1000 or Vigileo) that uses arterial pulse pressure instead of MAP to determine SV to minimize the absolute influence of vascular resistance on measurements.

Arterial pressure–based CO (APCO) can be described as shown:

$$APCO = HR \times \sigma_{AP} \times \chi$$

in which HR represents the heart rate; the product of σ_{AP}; and χ represents the SV. The arterial waveform is characterized using σ_{AP} (standard deviation of arterial pressure) and a calibration factor Chi (χ), which is estimated from patient demographics. The applied algorithm uses advanced statistical models to account for changes in vascular tone and its effect on the patient's pulse pressure.[421] The mathematical model adjusts the calculation of χ, using factors such as the mean, variance, skewness, and kurtosis of sampled arterial pressure data.

Clinical trials comparing uncalibrated and autocalibrated pulse contour and pulse wave technology to established calibrated systems including PAC thermodilution and transpulmonary thermodilution technology show inconsistent results. In a recent study in patients after liver surgery, the LiDCOrapid CO device failed to achieve criteria for accurate CO measurement, using transpulmonary thermodilution as a reference.[422] In patients undergoing CABG surgery, CO measured with the LiDCOrapid device before and after CPB resulted in unreliable CO readings (poor precision), compared with PAC-derived CO; only after external calibration did the percentage error decrease to 28%.[423] These findings were confirmed in other studies in patients undergoing cardiac surgery; primarily showing that uncalibrated CO methods such as the FloTrac suffer from a large bias and wide limits of agreement compared with thermodilution CO.[415,424–426]

However, these technologies are advancing rapidly, and recent software upgrades improved the accuracy and precision compared with thermodilution CO.[427–429] In a metaanalysis including 65 studies, the authors came to the conclusion that the accuracy and precision of the latest software version of the FloTrac-Vigileo system can be regarded as sufficient (percentage error <30%) for routine clinical use in "hypodynamic or normodynamic conditions" in the absence of large changes in vascular tone.

In conclusion, the results from these different validation studies indicate that this is a technology in evolution. At present, the application of uncalibrated arterial waveform analysis–based CO systems—especially for cardiac surgery patients—will remain controversial.

Cardiac Output Derived From Noninvasive Devices

Completely noninvasive devices for continuous BP monitoring and SV estimation have been developed. Although technologically interesting,

their use in cardiac surgery is limited since invasive arterial access is typically required for reasons other than BP and CO measurement.

Cardiac Output Derived From Volume-Clamp Monitoring Devices

In the early 1980s, Truijen and associates[430] developed a method for continuous noninvasive BP monitoring using the *volume-clamp* technology. The principle of this technology is based on the idea that blood volume in the arterial vascular bed varies during the cardiac cycle. The blood volume in the respective finger can be held constant using a rapid response finger pressure cuff (*volume clamping*). The cuff pressure and volume required correlates with BP and SV changes and allows reconstructing a continuous beat-to-beat BP curve and CO measurement.[431] The first generation devices such as the Finometer PRO (Finapres Medical Systems, Amsterdam, Netherlands) showed the actual BP of the finger artery. More recent devices show a reconstructed brachial artery BP (ClearSight system, Edwards Lifesciences, Irvin, CA; BMEYE Nexfin monitor, St. Louis, MO). Validation studies comparing volume clamp–based devices to invasive BP monitoring have yielded some promising results,[432] including cardiac surgery patients.[433–435] However, compared with invasive BP monitoring and thermodilution CO, the volume clamp–based devices still lack the accuracy for clinical use in patients with rapid hemodynamic changes and vasoactive drug administration.[436,437]

Cardiac Output Derived From Bioimpedance and Bioreactance Technology

Bioimpedance CO is based on the principle that cyclical increases in blood volume in the great vessels in the chest, as well as the alignment of red blood cells in the thoracic aorta resulting from increased velocity during the ejection phase, cause concomitant changes in electrical impedance. To measure thoracic electrical bioimpedance, an alternating current of low amplitude is introduced and simultaneously sensed by electrodes placed around the neck and laterally on the thorax or abdomen. Changes in thoracic bioimpedance are induced by ventilation and pulsatile blood flow, and processing of the measured signal results in a characteristic impedance (Z) waveform. Only the cardiac-induced pulsatile component of the total change in electrical impedance is analyzed time-dependent impedance change (dZ/dt) and the respiratory component is filtered out.

Volumetric and static variables including SV, CO, SVR, and thoracic fluid content can be determined with this technique. The limitations to this technology are still significant,[438] particularly in patients undergoing cardiac surgery.

Bioreactance is a further development of the bioimpedance principle estimating CO from the frequency of relative phase shifts of the electrical currents traversing the chest. Higher cardiac SV is associated with larger phase shifts. The benefits over the bioimpedance technique is that bioreactance CO is less affected by the precision of electrode placement, body movement, or respiratory excursions. Several validation studies comparing bioreactance CO with established methods have yielded conflicting results.[439–441] At this point, the data for a final evaluation of this technology are insufficient in cardiac surgery patients.

A summary of alternative methods of CO measurement is presented in Table 13.4

Right Ventricular Ejection Fraction and End-Diastolic Volume

Using rapid-response thermistors that are incorporated into PACs, determining the RVEF from the exponential decay of the thermodilution curve is possible. End-diastolic temperature points in the thermodilution curve are identified using the R-wave signal from an ECG input.[442,443] From these data, SV, right ventricular end-diastolic volume, and right ventricular end-systolic volume may be calculated. Assumptions that are essential to the accuracy of the technique include a regular RR interval, "instantaneous" mixing of the injectate or thermal heat signal with the right ventricular blood, and the absence of TR. The use of this type of monitoring could be justified in patients with severe right ventricular dysfunction attributable to myocardial infarction, right-sided coronary artery disease (CAD), pulmonary hypertension, right-sided HF, or intrinsic pulmonary disease. The accuracy of this technique has been questioned, however,[444,445] and RVEF catheters are rarely used, especially with TEE becoming more prevalent in the surgical unit setting.

Left Atrial Pressure Monitoring

In this invasive technique, a catheter is placed by the surgeon into the right superior pulmonary vein and advanced into the LA. A Teflon-pledgetted purse-string suture is placed around the catheter to provide a surface for clotting upon removal of the catheter. The catheter is brought out through the skin in the subxiphoid region and is sutured in place. Maintaining positive airway pressure or distending the LA in some other way during insertion of the catheter is important to prevent air entry into the pulmonary vein and the left side of the heart. An alternative method of placing an LAP via IJV access and advancement in the surgical field across the atrial septum has been described.[446]

Although important information can be gained from LAP monitoring, significant risks are associated with this monitoring technique. The possibility of air embolism to the coronary or cerebral circulations is always present. This problem exists on insertion and during its continued use postoperatively in the ICU. There is also the risk of clot formation on the catheter and subsequent embolization when the catheter is flushed or removed; therefore a continuous flushing system is necessary to avoid thrombus formation on the catheter tip in the postoperative period. Postoperatively, bleeding is also a risk when the LAP catheter is removed. It therefore should be removed while the chest tubes are still in place to diagnose and treat this problem. Other reported complications include catheter retention and prosthetic valve entrapment.[447] In the echo era, LAP monitoring is rarely performed.

Coronary Sinus Catheterization

In some centers, an endovascular CS catheter is placed to enable the administration of retrograde cardioplegia during minimally invasive cardiac surgical procedures. It is usually the responsibility of the cardiac anesthesiologist to place the CS catheter via the right IJV while being guided by TEE and fluoroscopy. The CS pressure and waveform can be measured during insertion and cardioplegia infusion. This procedure raises a number of issues including how deep to place the catheter and what pressures and flows to use with the administration of the cardioplegia. Retrograde cardioplegia flow rate is usually set at 150 to 200 mL/min with CS pressure over 30 mm Hg.

The insertion of the CS catheter (Fig. 13.23) can be difficult even with TEE and fluoroscopic monitoring. A modified bicaval view at approximately 110 degrees allows visualization of the catheter from the SVC to the CS (Fig. 13.24). After the catheter enters the CS, its final position is usually guided by fluoroscopy. The balloon is then inflated while looking for a change in the pressure tracing from a typical venous pressure tracing to a pulsatile tracing attributable to the transmission of the pressure back from the left ventricle (ventricularizaton) (Fig. 13.25). The ultimate sign of proper positioning is the establishment of asystole upon cardioplegia infusion. Further details of the insertion procedure can be found in articles by Lebon and colleagues[448] and Clements and associates.[449] Lebon and colleagues were able to position 95 of 96 CS catheters with a mean time of 6.3 minutes. Fluoroscopic confirmation took another 9.1 minutes for a total time of approximately 16 minutes. Ventricularization was observed in 86% of cases, and the CS pressure was greater than 30 mm Hg in 87.5% of patients.

Safety is another major concern with this technique. CS rupture and dissections have been reported by a number of authors.[450] If this catheter is used as part of port-access CPB, then it is one of only a few catheters that have to be monitored for malpositioning and possible complications (see Chapters 31 and 32).

TABLE 13.4 Summary of Alternative Means of Determining Cardiac Output

Technology	*Examples of Devices Available*	*Accuracy vs PAC*	*Potential Sources of Inaccuracy*	*Potential for Cardiac Surgery, Advantages*
TEE Doppler	Standard TEE	++++	Doppler beam misalignment Inaccurate 2D cross-sectional area measurement	+++ Minimally invasive Potentially very accurate Access to right and left side for shunt determination
Transesophageal Doppler	CardioQ-ODM (Deltex Medical) TECO (Medicina)	++	Distribution of blood flow, lower vs upper body Readjustment necessary before making decisions based on the Doppler values Possible small deviations of the absolute value of the parameters in individual cases Electric cauterization interferes with signal quality Not feasible in anatomical variations (ie, congenital anomalies)	++ Minimally invasive May be used postoperatively GDT algorithms available Outcome studies available in cardiac surgery
TEE 2D	Standard TEE	+++	Exceptions to Simpson's rule (ventricular aneurysm) Measurement of LV area	++ Minimally invasive
hTEE		+++	Technical limitations: Bad acoustic window Inability to evaluate all three demanded cross-sectional views Owing to the monoplane probe, not possible to interrogate all valves, only semiquantitative evaluation	+++ Minimally invasive Smaller probe, compared with standard TEE Direct visualization of RV, preload, RV, and LV function and effusion, continuous, can guide hemodynamic optimization by visualization
Indicator Dilution (Lithium)	LiDCO (LiDCO Group)	++++	Technical error, muscle relaxants, ingestion of lithium medication	++ Minimally invasive
Transpulmonary Thermodilution	PiCCO (PULSION Medical Systems) VolumeView (Edwards Lifesciences)	++++	Technical errors, thermal changes in chest, arrhythmia	+++ Less invasive, goal-directed algorithm available Outcome study in cardiac surgery showed benefit Beat-to-beat SV, SVV, and PPV Global end-diastolic volume Extravascular lung water
Arterial Pulse Wave	LiDCOrapid (LiDCO Group) ProACT (PULSION Medical Systems) FloTrac (Edwards Lifesciences)	++ ++	Arterial wave artifact Intraaortic balloon Aortic regurgitation Rapid changes in vascular tone	++ Minimally invasive Continuous Dynamic parameters provided No requirement for external calibration
Volume-clamp Method	Nexfin (BMEYE) ClearSight (Edwards Lifesciences) CNAP (CNSystems Medizintechnik) Finometer (FMS)	++	Imprecise in unstable hemodynamic conditions	+ Noninvasive Continuous Dynamic parameters provided
Bioimpedance Velocimetry	BioZ (Sonosite) LIFEGARD ICG (CAS Medical Systems) HIC-4000 (Microtronics Corporation; Bio-Impedance Technology) ICON (Osypka Medical, Cardiotronic) PhysioFlow (Manatec Biomedical) ECOM (ConMed Corporation) AESCULON (Osypka Medical GmbH)	++	Positioning of sensors may be problematic during cardiac surgery Ventilation pattern Lung water Opening and closing of chest	+ Noninvasive Continuous Technology improving
Bioreactrance	NICOM (Cheetah Medical)	+++	Inaccuracy attributable to variations in the thoracic blood volume as a result of respiration or arrhythmias	++ Noninvasive Continuous
Rebreathing Fick	NICO (Philips Respironics) Innocor (Innovision A/S)	+	Need for intubation and mechanical ventilation with fixed ventilator settings and minimal gas exchange abnormalities Increased pulmonary shunt fraction and hemodynamic instability	+ Noninvasive Semicontinuous or intermittent

Assessments at the time of writing are based on the available literature and experience.

Analysis and Interpretation of Hemodynamic Data

The information provided by hemodynamic monitoring permits the calculation of various derived parameters that assist in evaluating patients clinically. The formulas, normal values, and units for the calculation of various hemodynamic parameters are presented in Tables 13.2 and 13.3. These parameters include the SVR, pulmonary vascular resistance (PVR), SV, left ventricular stroke work, and right ventricular stroke work. As an example of information that may be obtained, graphs of PCWP versus SV can be constructed for individual patients; these Starling curves provide insight into the contractile state of the heart. Although these parameters are easily derived using the standard formulas, many modern monitors perform these calculations. To compare data among patients of different body weights and types, the various hemodynamic parameters may be normalized by indexing them to body surface area.

Systemic and Pulmonary Vascular Resistances

Systemic vascular resistance represents an estimation of the afterload of the left ventricle. Afterload is roughly defined as the force that impedes or opposes ventricular contraction. Higher SVR results in increased left ventricular systolic wall stress. This has clinical significance because left ventricular wall stress is one of the major determinants of myocardial oxygen consumption (see Chapters 6 and 7). Clinically, calculations of SVR are used to assess the response to inotropic, vasodilator, and vasoconstrictive agents. The SVR is calculated, and then therapy is instituted accordingly. A repeat calculation of the SVR enables the clinician to titrate the therapy to the appropriate end point. Despite this common use in the surgical unit and ICU settings, good evidence suggests that SVR is not an accurate indicator of true afterload.[451] Nevertheless, SVR remains the most useful clinical technique for measuring afterload at the present time.

PVR remains the traditional measure of afterload of the RV. This is also a flawed assumption because the recruitable nature of the pulmonary vasculature violates the assumptions of the PVR formula in patients without significant pulmonary arterial hypertension.[452] As the PA pressure (PAP) increases, the healthy pulmonary vasculature bed distends (increasing the size of West zone III of the lung).[453] The net gain in the cross-sectional area of the pulmonary vasculature results in a decrease in the measured PVR. However, in patients with a chronically increased PAP, the pulmonary vasculature bed undergoes structural changes, stiffens, and may not be able to accommodate an increase in CO without a significant increase in right ventricular pressure and wall stress. Both PVR and PAP provide clinically useful information regarding the pulmonary vasculature, particularly when managing patients with pulmonary arterial hypertension and right ventricular failure, and both are readily available in patients with PACs.

Frank-Starling Relationships

Myocardial function depends on the contractile state and the preload of the ventricle (sarcomere length at end-diastole). The relationship between the ventricular preload and myocardial work (ventricular stroke work) is the Frank-Starling relationship. The slope of the curve indicates the contractile state of the myocardium (Fig. 13.26). Pressure measurements (ie, PCWP, LAP, LVEDP) are poor estimates of true ventricular preload. The relationship between end-diastolic pressure and volume is usually nonlinear (as described by the diastolic ventricular compliance curve) and is dynamic. The Frank-Starling relationship is extremely sensitive to changes in afterload. Patients with left or

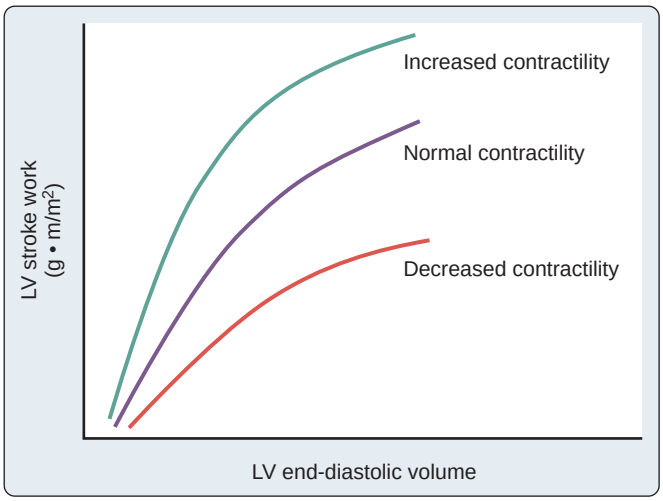

Fig. 13.26 The graph of left ventricular (*LV*) stroke work, stroke volume, or cardiac output, versus LV preload (ie, end-diastolic volume) is known as the Frank-Starling relationship. Shifting of the curve upward and to the left represents increased contractility. Shifting of the curve downward and to the right represents decreased contractility. Alterations in afterload significantly affect the curve.

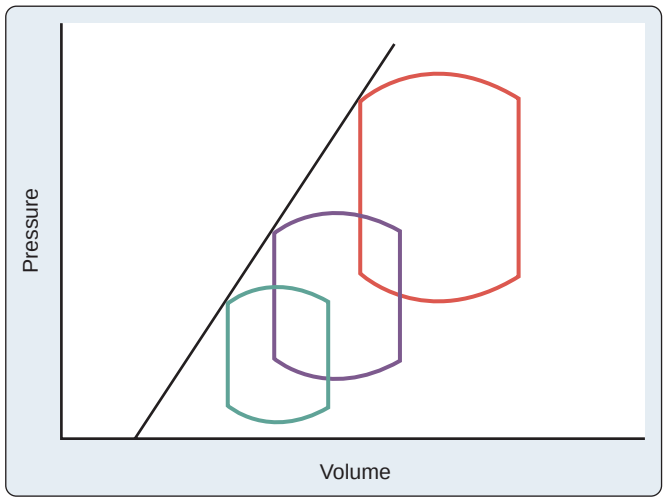

Fig. 13.27 The end-systolic pressure-volume relationship, also known as end-systolic elastance, is the line connecting the end-systolic points of multiple pressure-volume loops that are obtained at various preloads. An increased slope (ie, steeper line) represents increased contractility, and a decreased slope represents decreased contractility. This measurement is relatively insensitive to variations in afterload.

right ventricular dysfunction may have severe decrements in SV with increased SVR or PVR, respectively.

End-Systolic Elastance and Pressure-Volume Loops

An important limitation of isovolumic and ejection phase indices of contractility (eg, the Frank-Starling relationship) is their significant sensitivity to ventricular loading conditions. To overcome this shortcoming, the use of load-independent indices has been explored. One such index is the left ventricular end-systolic pressure-volume relationship (ESPVR), also known as *end-systolic elastance*.[454] To measure this, multiple end-systolic pressures and volumes need to be measured during rapid and, preferably, pronounced alterations in left ventricular preload (eg, inferior vena cava occlusion). On a pressure-volume diagram, points defined by the end-systolic pressures and volumes of the several contractions will be positioned on a single line. The slope of this line is relatively independent of loading conditions and proportional to contractility; the steeper the slope, the greater the contractility (Fig. 13.27) (see Chapter 6).

The intraoperative determination of contractility by this technique has been hampered by difficulties in obtaining accurate ventricular volumes and pressures. Continuous left ventricular pressure-volume loops may be displayed during cardiac surgery using left ventricular conductance and micromanometry catheters that are introduced through the pulmonary veins.[455] ESPVR is not a practical or routine means of assessing left ventricular contractility in the clinical setting.

Pulse Oximetry

Pulse oximetry is one of the most important anesthesia monitoring technologies and has been accepted as a worldwide intraoperative monitoring standard. This is reflected in current practice parameters and recommendations for perioperative anesthetic monitoring published by the ASA.[1] However, the results of outcome studies of pulse oximetry have been inconsistent, and the numbers of patients who would have to be studied in prospective well-controlled trials to show a change in outcome are prohibitively large.[456–458] In a metaanalysis of controlled trials (Cochrane Central Register of Controlled Trials, searched time period 1956 to 2009) with a total of 22,992 patients included in the analysis, using pulse oximetry in the perioperative setting reduced the incidence of hypoxemia in the surgical unit and in the recovery room.[459] Postoperative cognitive function, however, was not influenced by pulse oximetry monitoring. Postoperative complications (eg, cardiovascular, respiratory, neurologic, infectious) did not differ between patients monitored with or without pulse oximetry.

The advantages and limitations of the technique merit discussion to prevent misinterpretation of the data provided by pulse oximetry devices. The absorbance spectra of oxyhemoglobin and reduced Hb differ significantly. Oxyhemoglobin absorbs mostly infrared light (850 nm to 1000 nm) and transmits mostly red light (600 nm to 750nm), whereas deoxygenated Hb absorbs more red light and infrared light passes through. The pulse oximeter uses this principle to determine the relative concentration of oxyhemoglobin in the blood.

Several things in addition to arterial blood also absorb red and infrared light in the tissues. These include capillary blood, venous blood, melanin in the epidermal skin layer, cytochrome c oxidase within the mitochondrial respiratory chain and, to a lesser extent, in soft tissue, fat, and bone. The pulse oximeter uses this pulsatile component of the light absorbance to calculate the arterial oxygen concentration. Many factors interfere with the accuracy of pulse oximetry. Some of these factors include diminished tissue perfusion (eg, limb ischemia, hypothermia, vasoconstricting drugs), ambient light, intravenous dyes, carboxyhemoglobin, and methemoglobin.[460]

As the signal strength of the pulse decreases in relation to the continuous absorption of the tissues, the ratio of absorbance of red-to-infrared light approaches unity. This would normally correlate with a saturation of 85%. Regarding a poor plethysmography tracing with a saturation of 85% as possibly representing artifact and confirming the result with an independent technique are both important. It must also be recognized that standard blood gas analyzers calculate or derive the arterial saturation based on the measured partial pressure of oxygen (PaO_2) in the blood, which may cause significant errors in accurately determining low blood saturations.[461] Standard pulse oximetry devices are usually not calibrated to very low arterial blood saturation as can be observed with many of the mixing congenital heart lesions.[462–464] The gold standard for accurately determining blood saturations is analysis of an arterial blood sample in a device (co-oximeter) that measures oxyhemoglobin, deoxygenated Hb, methemoglobin, and carboxyhemoglobin using absorption of several light wavelengths.

Another problem in cardiac procedures is that the plethysmography tracing often decreases in amplitude over the course of the procedure until the signal-to-noise ratio is too low for accurate oximetry. This is most likely due to hypothermia of the digits but also may be related to positioning, hypovolemia, high catecholamine levels, and extremes

of age. It has been demonstrated that a digital perfusion pressure of 13 mm Hg and temperature of 24° C are the minimum requirements for accurate pulse oximetry readings before and after CPB.[465]

Reich and associates[466] showed that the incidence of pulse oximetry failure in the cardiac surgery setting is very high. The overall incidence of cases that had at least one continuous gap of 10 minutes or more in pulse oximetry data was 31%. The independent preoperative predictors of pulse oximetry data failure included ASA physical status III, IV, or V, and cardiac surgery. Intraoperative hypothermia, hypotension and hypertension, and duration of procedure also were independent risk factors.

The primary disadvantage of pulse oximetry, however, is that the PaO_2 must fall below 100 mm Hg before the device will begin to detect any change, and below 60 mm Hg before rapid changes will occur. Thus the device is not sensitive to changes in PaO_2 over wide ranges that are of clinical significance.

Oxygen Transport Calculations

The ultimate purpose of circulation is the delivery of oxygen to the tissues. Oxygen is bound to Hb and is also dissolved in the plasma (to a much smaller extent). If the Hb concentration, arterial and mixed venous blood gases, and CO are available, then oxygen transport calculations may be performed. Optimization of these parameters are then allowed to improve delivery and uptake of the proper amount of oxygen to the tissues. These calculations are shown in Table 13.2.

Monitoring Coronary Perfusion

Coronary perfusion pressure (CPP) to the LV primarily occurs during diastole and thus is defined as the diastolic arterial BP (DAP) minus the LVEDP:

$$CPP = DAP - LVEDP$$

Elevation of the LVEDP will decrease the gradient of blood flow to the vulnerable subendocardial tissue during diastole as will a decrease in the DBP.[467] If CAD is present, then significant stenosis will decrease the coronary artery DBP well below the aortic DBP, and elevation of LVEDP can seriously jeopardize the subendocardium.[468] An increase in the LVEDP is detrimental in two ways: decreased coronary blood flow and increased myocardial oxygen demand, which partially explains the ischemia that may be observed with over-distention of the left ventricle. Tachycardia is also detrimental because it decreases coronary filling time and increases oxygen demand. Subendocardial ischemia is commonly produced by a combination of tachycardia and elevated LVEDP (see Chapters 6 and 20).

Cerebral Oximetry

Near-infrared spectroscopy (NIRS) and its clinical application in cerebral oximetry devices are reviewed in greater detail in Chapter 18. Briefly, cerebral tissue saturations reflect a mostly venous-weighted signal that is measured continuously. Thus it correlates strongly with jugular bulb saturation, with higher readings attributable to the 25% to 30% admixture of arterial blood in cerebral tissue.[469] In practical terms, measured values reflect the delicate balance between cerebral oxygen delivery and demand, somewhat analogous to mixed venous oxygen saturation for whole body perfusion. Variables affecting cerebral saturations therefore include CO, (CPP = MAP – ICP or CVP), oxygen-carrying capacity, hypocarbia and hypercarbia, anesthetic depth, cerebral temperature, and technical considerations (eg, SVC cannula malposition).

Its use in cardiac surgery has been steadily increasing, attributable to the noninvasive nature of the technology and the magnitude of clinically relevant data that can be derived. Trend monitoring from a baseline value obtained during hemodynamically stable conditions, as well as absolute lower thresholds, have been recommended in clinical practice for decision making. Although, several studies have shown an association between low cerebral saturations and adverse events, few studies show that interventions based on cerebral oximetry monitoring improve outcome. In one of these studies, Murkin and colleagues[470] monitored NIRS and targeted therapy to optimize cerebral tissue oxygen saturation in patients undergoing CABG. They found that a composite measure of postoperative organ dysfunction was substantially improved in the treatment group when GDT aimed to maintain the cerebral tissue oxygen saturation values within 25% of the preinduction baseline. One of the strengths of cerebral oximetry monitoring is the early detection of catastrophic events, particularly during periods of nonpulsatile flow, such as during CPB or with certain left ventricular–assist devices or ECMO.[471–473]

Summary

The choice of appropriate monitoring is a difficult task. Despite many years of clinical experience, no convincing outcome data demonstrate the superiority of more invasive versus less invasive monitoring techniques. Therefore the clinician must make a rational decision based on the following conditions:

- Patient's underlying medical diseases
- Degree of hemodynamic compromise, myocardial ischemia risk, and fluid shift likely to result from the proposed surgery
- Effects of the anesthetic drugs and techniques on the patient's cardiovascular system
- Skills of the practitioner and his or her understanding of the risks, benefits, and alternatives to the different types of hemodynamic monitoring
- Integration of data from hemodynamic monitoring and TEE in the perioperative period

Basic Intraoperative Transesophageal Echocardiography

RONALD A. KAHN, MD | TIMOTHY MAUS, MD, FASE | IVAN SALGO, MD, MBA | MENACHEM M. WEINER, MD | STANTON K. SHERNAN, MD

KEY POINTS

1. An ultrasound beam is a continuous or intermittent train of sound waves emitted by a transducer or wave generator that is composed of density or pressure. Ultrasound waves are characterized by their wavelength, frequency, and velocity.
2. Doppler frequency shift analysis can be used to obtain blood-flow velocity, direction, and acceleration of red blood cells, in which the magnitude and direction of the frequency shift are related to the velocity and direction of the moving target. These velocity flow measurements may be used to determine gradients and blood-flow volumes.
3. *Axial resolution* is the minimum separation between two interfaces located in a direction parallel to the ultrasound beam, enabling them to be imaged as two different interfaces. *Lateral resolution* is the minimum separation of two interfaces aligned along a direction perpendicular to the beam. *Elevational resolution* refers to the ability to determine differences in the thickness of the imaging plane.
4. Absolute contraindications to transesophageal echocardiography in intubated patients include esophageal stricture, diverticula, tumor, recent suture lines, and known esophageal interruption. Relative contraindications include symptomatic hiatal hernia, esophagitis, coagulopathy, esophageal varices, and unexplained upper gastrointestinal bleeding.
5. Horizontal imaging planes are obtained by moving the transesophageal echocardiography probe up and down (upper esophageal: 20–25 cm; midesophageal: 30–40 cm; transgastric: 40–45 cm; deep transgastric: 45–50 cm). Multiplane probes may further facilitate the interrogation of complex anatomic structures by allowing up to 180 degrees of axial rotation of the imaging plane without manual probe manipulation.
6. Diastolic dysfunction has three primary stages: impaired relaxation, pseudonormalization, and restrictive cardiomyopathy. The evaluation of diastolic function may be performed using Doppler analysis of mitral valve inflow and pulmonary vein flow, color M-mode propagation velocities, and tissue Doppler analysis of the mitral valve annulus.
7. Aortic stenosis may be evaluated by planimetry, transaortic gradients, or the continuity equation. The use of planimetry is usually limited by the presence of aortic valvular calcifications. Peak, as well as mean, gradients may be measured using continuous-wave Doppler over the aortic valve in either the deep transgastric or transgastric long-axis view. The continuity equation uses measurement of flow through the left ventricular outflow tract and the aortic valve to determine aortic valve area.
8. Quantification of aortic regurgitation is usually based on the analysis of color-flow Doppler patterns in the left ventricular outflow tract during diastole. The most reliable measurements are the vena contracta width and the ratio of proximal jet width to the width of the left ventricular outflow tract. Analysis of pressure half-time measurement of aortic regurgitant flows provides additional quantification of severity.
9. Mitral stenosis may be evaluated by planimetry of the valve in the transgastric basal short-axis view. Transmitral Doppler spectral analysis may be used to calculate mean transmitral gradient and mitral valve area using the pressure half-time measurement of the E wave.
10. Mitral regurgitation may be quantified by the analysis of color-flow Doppler spectra in the left atrium during ventricular systole. The severity of regurgitation may be further quantified using an analysis of pulmonary venous blood-flow velocities and measurements of regurgitant orifice areas using proximal isovelocity surface area.

Few areas in cardiac anesthesia have developed as rapidly as the field of intraoperative echocardiography. In the early 1980s, when transesophageal echocardiography (TEE) was first used in the surgical unit, its primary application was the assessment of global and regional left ventricular (LV) function. Since that time, there have been numerous technical advances: biplane and multiplane probes; multifrequency probes; enhanced scanning resolution; color-flow Doppler (CFD), pulsed-wave Doppler (PWD), and continuous-wave Doppler (CWD); automatic edge detection; Doppler tissue imaging (DTI); three-dimensional (3D) reconstruction; and digital image processing. With these advances, the number of clinical applications of TEE has significantly increased. The common applications of TEE include (1) assessment of valvular anatomy and function, (2) evaluation of the thoracic aorta, (3) detection of intracardiac defects, (4) detection of intracardiac masses, (5) evaluation of pericardial effusions, (6) detection of intracardiac air and clots, and (7) assessment of biventricular systolic and diastolic function. In many of these evaluations, TEE is able to provide unique and critical information that was not previously available in the surgical unit (Box 14.1).

Basic Concepts

Properties of Ultrasound

In echocardiography, the heart and great vessels are insonated with ultrasound, which is sound above the human audible range. The

BOX 14.1 COMMON APPLICATIONS OF TRANSESOPHAGEAL ECHOCARDIOGRAPHY

- Assessment of valvular anatomy and function
- Evaluation of the thoracic aorta
- Detection of intracardiac defects
- Evaluation of pericardial effusions
- Detection of intracardiac air, clots, or masses
- Assessment of biventricular systolic and diastolic function
- Evaluation of myocardial ischemia

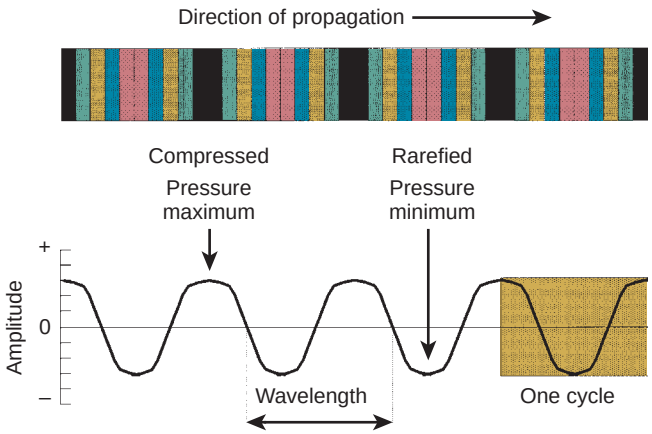

Fig. 14.1 A sound wave is a series of compressions and rarefactions. The combination of one compression and one rarefaction represents one cycle. The distance between the onset (peak compression) of one cycle and the onset of the next is the wavelength. *(From Thys DM, Hillel Z. How it works: basic concepts in echocardiography. In: Bruijn NP, Clements F, eds.* Intraoperative Use of Echocardiography. *Philadelphia: JB Lippincott; 1991:255–318.)*

ultrasound is sent into the thoracic cavity and is partially reflected by the cardiac structures. From these reflections, distance, velocity, and density of objects within the chest are derived.

An ultrasound beam is a continuous or intermittent train of sound waves emitted by a transducer or wave generator. It comprises density or pressure waves and can exist in any medium with the exception of a vacuum (Fig. 14.1). Ultrasound waves are characterized by their wavelength, frequency, and velocity.[1] *Wavelength* is the distance between the two nearest points of equal pressure or density in an ultrasound beam, and *velocity* is the speed at which the waves propagate through a medium. As the waves travel past any fixed point in an ultrasound beam, the pressure cycles regularly and continuously between a high and low value. The number of cycles per second (measured in hertz [Hz]) is called the *frequency* of the wave. Ultrasound is sound with frequencies above 20,000 Hz, which is the upper limit of the human audible range. The relationship among the frequency (f), wavelength (λ), and velocity (v) of a sound wave is defined by the following formula:

$$v = f \times \lambda \qquad \text{[Eq. 14.1]}$$

The velocity of sound varies with the properties of the medium through which it travels. In low-density gases, molecules must traverse long distances before encountering the adjacent molecules; therefore ultrasound velocity is relatively slow. In contrast, in solid, where molecules are constrained, ultrasound velocity is relatively high. For soft tissues, this velocity approximates 1540 m/sec but varies from 1475 to 1620 m/sec. In comparison, the velocity of ultrasound in air is 330 m/sec and 3360 m/sec in bone. Because the frequency of an ultrasound beam is determined by the properties of the emitting transducer and the velocity through soft tissue is approximately constant, wavelengths are inversely proportional to the ultrasound frequency.

Ultrasound waves transport energy through a given medium; the rate of energy transport is expressed as "power," which is usually expressed in joules per second or watts.[1] Since medical ultrasound is usually concentrated in a small area, the strength of the beam is usually expressed as power per unit area or "intensity." In most circumstances, intensity is usually expressed with respect to a standard intensity. For example, the intensity of the original ultrasound signal may be compared with the reflected signal. Since ultrasound amplitudes may vary by a factor of 10^5 or greater, amplitudes are usually expressed using a logarithmic scale. The usual unit for intensity comparisons is the decibel, which is defined as:

$$\text{Decibel (dB)} = 10 \cdot \log(I_1/I_0) \qquad \text{[Eq. 14.2]}$$

where I_1 is the intensity of the wave to be compared, and I_0 is the intensity of the reference waves.

Positive values imply a wave of greater intensity than the reference wave, and negative values indicate a lower intensity. Increasing the wave's intensity by a factor of 10 adds 10 dB to the decibel measurement, and doubling the intensity adds 3 dB.

Ultrasound Beam

Piezoelectric crystals convert between ultrasound and electrical signals. Most piezoelectric crystals that are used in clinical applications are the manufactured ceramic ferroelectrics, the most common of which are barium titanate, lead metaniobate, and lead zirconate titanate. When presented with a high-frequency electrical signal, these crystals produce ultrasound energy; conversely, when they are presented with an ultrasonic vibration, they produce an alternating current electrical signal. Commonly, a short ultrasound signal is emitted from the piezoelectric crystal, which is directed toward the areas to be imaged. This pulse duration is typically 1 to 2 sec. After ultrasound wave formation, the crystal "listens" for the returning echoes for a given period and then pauses before repeating this cycle. This cycle length is known as the pulse repetition frequency (PRF). This cycle length must be long enough to provide enough time for a signal to travel to and return from a given object of interest. Typically, the PRF varies from 1 to 10 kHz, which results in 0.1 to 1 msec between pulses. When reflected ultrasound waves return to these piezoelectric crystals, they are converted into electrical signals, which may be appropriately processed and displayed. Electronic circuits measure the time delay between the emitted and received echoes. Since the speed of ultrasound through tissue is constant, this time delay may be converted into the precise distance between the transducer and tissue. The amplitude or strength of the returning ultrasound signal provides information about the characteristics of the insonated tissue.

The 3D shape of the ultrasound beam is dependent on both the physical aspects of the ultrasound signal and the design of the transducer. An unfocused ultrasound beam may be thought of as an inverted funnel, in which the initial straight columnar area is known as the *near field* (also known as Fresnel zone), followed by the conical divergent area known as the *far field* (also known as Fraunhofer zone). The length of the near field is directly proportional to the square of the transducer diameter and is inversely proportional to the wavelength, specifically,

$$F_n = D^2/4\lambda \qquad \text{[Eq. 14.3]}$$

where F_n is the near field length, D is the diameter of the transducer, and λ is the ultrasound wavelength. Increasing the frequency of the ultrasound increases the length of the near field. In this near field, most energy is confined to a beam width no greater than the transducer diameter. Long Fresnel zones are preferred with medical ultrasonography, which may be achieved with large diameter transducers and high-frequency ultrasound. The angle of the far field convergence (θ) is directly proportional to the wavelength and inversely proportional to the diameter of the transducer and is expressed by the equation:

$$\sin\theta = 1.22\lambda/D \qquad \text{[Eq. 14.4]}$$

Further shaping of the beam geometry may be adjusted using acoustical lenses or the shaping of the piezoelectric crystal. Ideally, imaging should be performed within the near field or the focused aspect of the ultrasound beam because the ultrasound beam is most parallel with the greatest intensity and the tissue interfaces are most perpendicular to these ultrasound beams.

Attenuation, Reflection, and Scatter

Waves interact with the medium in which they travel and with one another. Interaction among waves is called *interference*. The manner in which waves interact with a medium is determined by its density and homogeneity. When a wave is propagated through an inhomogeneous medium (and all living tissue is essentially inhomogeneous), it is partly reflected, partially absorbed, and partly scattered.

Ultrasound waves are reflected when the width of the reflecting object is larger than one fourth of the ultrasound wavelength. Because the velocity of sound in soft tissue is approximately constant, shorter wavelengths are obtained by increasing the frequency of the ultrasound beam (see Eq. 14.1). Large objects may be visualized using low frequencies (ie, long wavelengths), whereas smaller objects require higher frequencies (ie, short wavelengths) for visualization. In addition, the object's ultrasonic impedance (Z) must be significantly different from the ultrasonic impedance in front of the object. The ultrasound impedance of a given medium is equal to the medium density multiplied by the ultrasound propagation velocity. Air has a low density and propagation velocity; therefore it has a low ultrasound impedance. Bone has a high density and propagation velocity; therefore it has a high ultrasound impedance. For normal incidence, the fraction of the reflected pulse compared with the incidence pulse is:

$$I_r = (Z_2 - Z_1)^2 / (Z_2 + Z_1)^2 \qquad \text{[Eq. 14.5]}$$

where I_r is intensity reflection coefficient, and Z_1 and Z_2 represent the acoustical impedance of the two media.

The greater the differences in ultrasound impedance between two objects at a given interface, the greater the ultrasound reflection. Because the ultrasound impedances of air or bone are significantly different from blood, ultrasound is strongly reflected from these interfaces, limiting the availability of ultrasound to deeper structures. This limitation of ultrasound energy to deeper structures results in ultrasound shadowing, which is discussed later in this chapter. Echocardiographic studies across lung or other gas-containing tissues or across bone are not feasible. Reflected echoes, also called *specular echoes*, are usually significantly stronger than scattered echoes. A grossly inhomogeneous medium, such as a stone in a water bucket or a cardiac valve in a blood-filled heart chamber, produces strong specular reflections at the water-stone or blood-valve interface because of the significant differences in ultrasound impedances. Furthermore, if the interface between the two objects is not perpendicular, then the reflected signal may be deflected at an angle and may not return to the transducer for imaging.

In contrast, if the objects are small, compared with the wavelength, then the ultrasound wave will be scattered. Media that are inhomogeneous at the microscopic level, such as muscle, produce more scatter than specular reflection because the differences in adjacent ultrasound impedances are low and the objects are small. These small objects will produce echoes that reflect throughout a large range of angles with only a small percentage of the original signal reaching the ultrasound transducer. Scattered ultrasound waves will combine in constructive and destructive fashions with other scattered waves, producing an interference pattern known as *speckle*. Compared with specular echoes, the returning ultrasound signal amplitude will be lower and will display as a darker signal. Although smaller objects can be visualized with higher frequencies, these higher frequencies result in greater signal attenuation, limiting the depth of ultrasound penetration.

Attenuation refers to the loss of ultrasound power as it traverses tissue. Tissue attenuation is dependent on ultrasound reflection, scattering, and absorption. The greater the ultrasound reflection and scattering, the less ultrasound energy is available for penetration and resolution of deeper structures; this effect is especially important during scanning with higher frequencies. In normal circumstances, however, absorption is the most significant factor in ultrasound attenuation.[2] Absorption occurs as a result of the oscillation of tissue caused by the transit of the ultrasound wave. These tissue oscillations result in friction with the conversion of ultrasound energy into heat. More specifically, the transit of an ultrasound wave through a medium causes molecular displacement. This molecular displacement requires the conversion of kinetic energy into potential energy as the molecules are compressed. At the time of maximal compression, the kinetic energy is maximized and the potential energy minimized. The movement of molecules from their compressed location to their original location requires conversion of this potential energy back into kinetic energy. In most cases, this energy conversion (either kinetic into potential energy or vice versa) is not 100% efficient and results in energy loss as heat.[1]

TABLE 14.1 Attenuation Coefficients

Material	*Coefficient (dB/cm/MHz)*
Water	0.002
Fat	0.66
Soft tissue	0.9
Muscle	2
Air	12
Bone	20
Lung	40

The absorption is dependent on both the material through which the ultrasound is passing and the ultrasound frequency. The degree of attenuation through a given thickness of material, x, may be described by:

$$\text{Attenuation (dB)} = a \cdot \text{freq} \cdot x \qquad \text{[Eq. 14.6]}$$

where a is the attenuation coefficient in dB per cm at 1 MHz, and freq represents the ultrasound frequency in megahertz (MHz).

Examples of attenuation coefficient values are given in Table 14.1. Although water, blood, and muscle have low ultrasound attenuation, air and bone have very high tissue ultrasound attenuation, limiting the ability of ultrasound to traverse these structures. Table 14.2 gives the distance in various tissues at which the intensity or amplitude of an ultrasound wave of 2 MHz is halved (the half-power distance).

Imaging Techniques

M Mode

The most basic form of ultrasound imaging is M-mode echocardiography. In this mode, the density and position of all tissues in the path of a narrow ultrasound beam (ie, along a single line) are displayed as a scroll on a video screen. The scrolling produces an updated, continuously changing time plot of the studied tissue section several seconds in duration. Because this is a timed *motion display* (normal cardiac tissue is always in motion), it is called *M mode*. Because only a very limited part of the heart is being observed at any one time and because the image requires considerable interpretation, M mode is not currently used as a primary imaging technique. M mode is, however, useful for the precise timing of events within the cardiac cycle and is often used in combination with CFD for the timing of abnormal flows (see "Color-Flow Doppler" section). Quantitative measurements of size, distance, and velocity are also easily performed in the M mode without the need for sophisticated analysis stations. Because M-mode images are updated 1000 times per second, they provide greater temporal resolution than two-dimensional (2D) echocardiography, thus more subtle changes in motion or dimension can be appreciated.

B Mode

The different reflectivities of various cardiac structures result in variations of the reflected ultrasound wave. The detected signals are

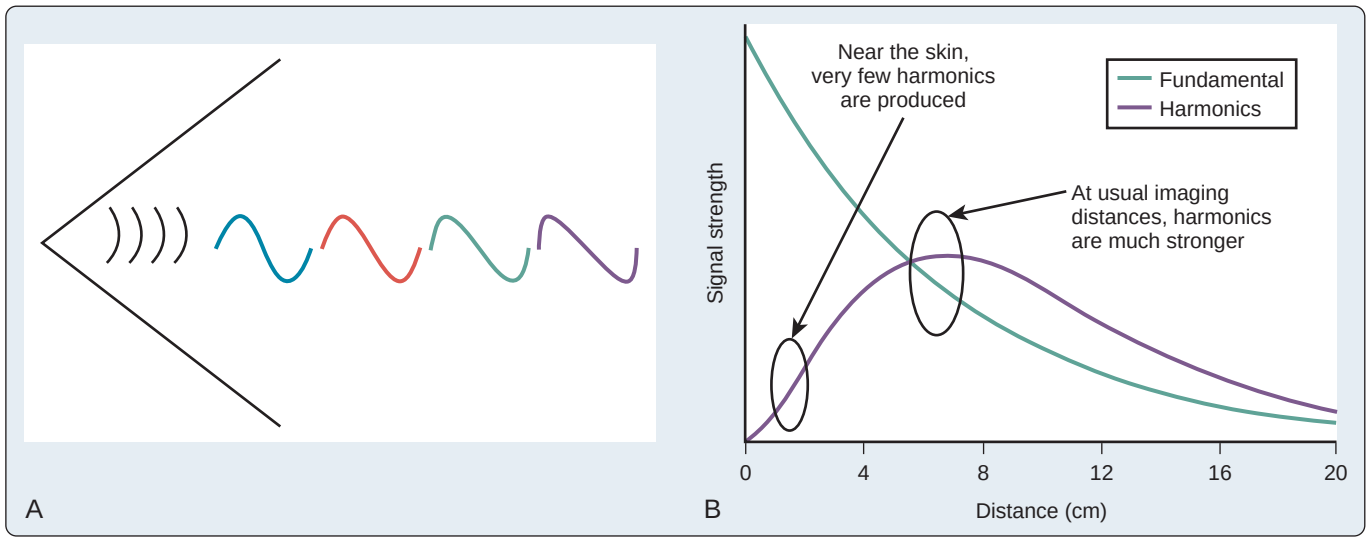

Fig. 14.2 Harmonic imaging. (A) Because the velocity of ultrasound transit is directly proportional to density, the peak amplitudes will travel slightly faster than the trough. With time, this differential velocity transit of the peak with the trough wave results in distortion of the propagated sin wave, resulting in a more peaked wave. (B) Relationship between imaging distance and strength of fundamental and harmonic frequencies is illustrated. As ultrasound pulse propagates, strength of fundamental frequency declines, whereas strength of harmonic frequency increases. At usual imaging distances for cardiac structures, strength of harmonic frequency is maximized. Note: Harmonic frequency strength is exaggerated in this schematic. Harmonic frequency signal strength is significantly lower than fundamental frequency signal strength. *(B, Used with permission. From Thomas JD, Rubin DN. Tissue harmonic imaging: why does it work?* J Am Soc Echocardiogr *1998;11:803–808.)*

TABLE 14.2 Half-Power Distances at 2 MHz

Material	*Half-Power Distance (cm)*
Water	380
Blood	15
Soft tissue (except muscle)	1–5
Muscle	0.6–1.0
Bone	0.2–0.7
Air	0.08
Lung	0.05

translated from the amplitude of the reflected signal to luminance and displayed as a brightness-mode or B-mode image. By rapid, repetitive scanning along many different radii within an area in the shape of a fan (sector), echocardiography generates a 2D image of a section of the heart. This image, which resembles an anatomic section, can be more easily interpreted than an M-mode display. Information on structures and motion in the plane of a 2D scan is updated 20 to 40 times per second. This repetitive update produces a live (real-time) image of the heart. Scanning 2D echocardiographic devices usually image the heart using an electronically steered ultrasound beam (phased-array transducer).

Harmonic Imaging

Harmonic frequency is ultrasound transmission of integer multiples of the original frequency. For example, if the fundamental frequency is 4 MHz, then the second harmonic frequency is 8 MHz, the third fundamental frequency is 12 MHz, and so on. Harmonic imaging refers to a technique of B-mode imaging in which an ultrasound signal is transmitted at a given frequency but will *listen* at one of its harmonic frequencies.[3,4] As ultrasound is transmitted through a tissue, the tissue undergoes slight compressions and expansions that correspond to the ultrasound wave, temporarily changing the local tissue density. Because the velocity of ultrasound transit is directly proportional to density, the peak amplitudes will travel slightly faster than the trough. This differential velocity transit of the peak with the trough wave results in distortion of the propagated sin wave, resulting in a more peaked wave. This peaked wave will contain frequencies of the fundamental frequency, as well as the harmonic frequencies (Fig. 14.2). Although very little distortion occurs in the near field, the amount of energy contained within these harmonics increase with ultrasound distance traversed as the ultrasound wave becomes more peaked. Eventually, the effects of attenuation will be more pronounced on these harmonic waves with a subsequent decrease in the harmonic amplitude. Because the effects of attenuation are greatest with high-frequency ultrasound, the second harmonic is usually used.

The use of tissue harmonic imaging is associated with improved B-mode imaging. Near-field scatter is common with fundamental imaging. Because the ultrasound wave has not yet been distorted, very little harmonic energy is generated in the near field, minimizing near-field scatter when harmonic imaging is used. Because higher frequencies are used, greater resolution may be obtained. Finally, with tissue harmonic imaging, side-lobe artifacts are substantially reduced and lateral resolution is increased.

Doppler Techniques

Most modern echocardiographic scanners combine Doppler capabilities with their 2D imaging capabilities. After the desired view of the heart has been obtained with 2D echocardiography, the Doppler beam, represented by a cursor, is superimposed on the 2D image. The operator positions the cursor as parallel as possible to the assumed direction of blood flow and then empirically adjusts the direction of the beam to optimize the audio and visual representations of the reflected Doppler signal. At the present time, Doppler technology can be used in at least four different ways to measure blood velocities: pulsed, high-repetition frequency, continuous-wave, and color-flow. Although each of these methods has specific applications, they are seldom concurrently available.

Doppler Effect

Information on blood-flow dynamics can be obtained by applying Doppler frequency shift analysis to echoes reflected by the moving red blood cells.[5,6] Blood-flow velocity, direction, and acceleration can be instantaneously determined. This information is different from that obtained in 2D imaging and hence complements it.

The Doppler principle as applied in echocardiography states that the frequency of ultrasound reflected by a moving target (red blood cells) will be different from the frequency of the reflected ultrasound. The magnitude and direction of the frequency shift are related to the velocity and direction of the moving target. The velocity of the target is calculated with the Doppler equation:

$$v = (cf_d)/(2f_0 \cos\theta) \qquad \text{[Eq. 14.7]}$$

where v represents the target velocity (blood-flow velocity), c is the speed of sound in tissue, f_d signifies the frequency shift, f_0 represents the frequency of the emitted ultrasound, and θ is the angle between the ultrasound beam and the direction of the target blood-flow velocity. Rearranging the terms,

$$f_d = v(2f_0 \cos\theta)/c \qquad \text{[Eq. 14.8]}$$

As is evident in Equation 14.8, the greater the velocity of the object of interest, the greater the Doppler frequency shift. In addition, the magnitude of the frequency shift is directly proportional to the initial emitted frequency (Fig. 14.3). Low-emitted frequencies produce low Doppler frequency shifts, whereas high-emitted frequencies produce high Doppler frequency shifts. This phenomenon becomes important with aliasing as discussed in the following text. Furthermore, the only ambiguity in Equation 14.7 is that the direction of the ultrasonic signal could refer to either the transmitted or the received beam. However, by convention, Doppler displays are made with reference to the received beam; thus if the blood flow and the reflected beam travel in the same direction, then the angle of incidence is zero degrees and the cosine is +1. As a result, the frequency of the reflected signal will be higher than the frequency of the emitted signal.

Equipment currently used in clinical practice displays Doppler blood-flow velocities as waveforms. The waveforms consist of a spectral analysis of velocities on the ordinate and time on the abscissa. By convention, blood flow toward the transducer is represented above the baseline. If the blood flows away from the transducer, then the angle of incidence will be 180 degrees, the cosine will equal −1, and the waveform will be displayed below the baseline. When the blood flow is perpendicular to the ultrasonic beam, the angle of incidence will be 90 or 270 degrees, the cosine of either angle will be zero, and no blood flow will be detected. Because the cosine of the angle of incidence is a variable in the Doppler equation, blood-flow velocity is measured most accurately when the ultrasound beam is parallel or antiparallel to the direction of blood flow. In clinical practice, a deviation from parallel of up to 20 degrees can be tolerated, resulting in an error of only 6% or less.

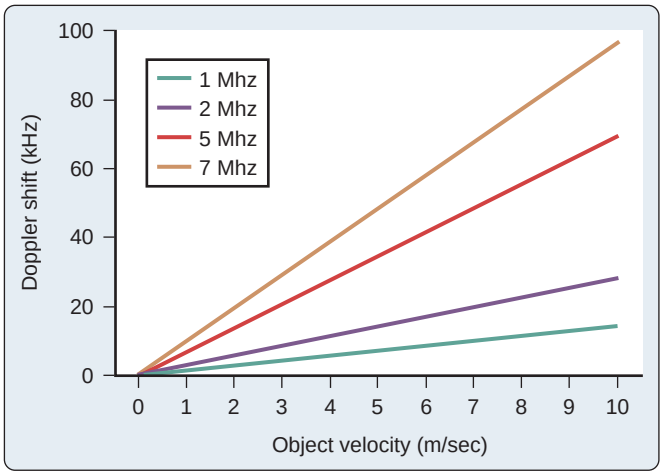

Fig. 14.3 Graph of Doppler shift frequency versus velocity for various emitted ultrasound frequencies. A lower emitted ultrasound frequency will produce a lower Doppler frequency shift for a given velocity. This lower Doppler frequency shift will allow for a higher velocity measurement before aliasing occurs.

Pulsed-Wave Doppler

In PWD, blood-flow parameters can be determined at precise locations by emitting repetitive short bursts of ultrasound at a specific frequency (PRF) and analyzing the frequency shift of the reflected echoes at an identical sampling frequency (f_s). A time delay between the emission of the ultrasound signal burst and the sampling of the reflected signal determines the depth at which the velocities are sampled; the delay is proportional to the distance between the transducer and the location of the velocity measurements. To sample at a given depth (D), sufficient time must be allowed for the signal to travel a distance of 2 × D (from the transducer to the sample volume and back). The time delay, T_d, between the emission of the signal and the reception of the reflected signal is related to D and to the speed of sound in tissues (c), by the following formula:

$$D = cT_d/2 \qquad \text{[Eq. 14.9]}$$

The operator varies the depth of sampling by varying the time delay between the emission of the ultrasonic signal and the sampling of the reflected wave. In practice, the sampling location or sample volume is represented by a small marker, which can be positioned at any point along the Doppler beam by moving it up or down the Doppler cursor. On some devices, varying the width and height of the sample volume is also possible.

The trade-off for the ability to measure flow at precise locations is that *ambiguous information* is obtained when flow velocity is very high. Information theory suggests that an unknown periodic signal must be sampled at least twice per cycle to determine even rudimentary information such as the fundamental frequency; therefore the rate of PRF of PWD must be at least twice the Doppler frequency shift produced by flow.[7] If not, the frequency shift is *undersampled*. In other words, this frequency shift is sampled so infrequently that the frequency reported by the instrument is erroneously low.[1]

A simple reference to Western movies will clearly illustrate this point. When a stagecoach gets underway, its wheel spokes are observed as rotating in the correct direction. As soon as a certain speed is attained, rotation in the reverse direction is noted because the camera frame rate is too slow to observe the motion of the wheel spokes correctly. In PWD, the ambiguity exists because the measured Doppler frequency shift (f_D) and the sampling frequency (f_s) are in the same frequency (kilohertz [kHz]) range. Ambiguity will be avoided only if the f_D is less than one half the sampling frequency:

$$f_D < f_s/2 \qquad \text{[Eq. 14.10]}$$

The expression $f_s/2$ is also known as the *Nyquist limit*. Doppler shifts above the Nyquist limit will create artifacts described as *aliasing* or *wraparound*, and blood-flow velocities will appear in a direction opposite to the conventional one (Fig. 14.4). Blood flowing with high velocity toward the transducer will result in a display of velocities above and below the baseline. The maximum velocity that can be detected without aliasing is dictated by:

$$V_m = c^2/8Rf_0 \qquad \text{[Eq. 14.11]}$$

where V_m represents the maximal velocity that can be unambiguously measured, c signifies the speed of sound in tissue, R is the range or distance from the transducer at which the measurement is to be made, and f_0 represents the frequency of emitted ultrasound.

Based on Equation 14.11, this aliasing artifact can be avoided by either minimizing the R or f_0. Decreasing the depth of the sample volume in essence increases f_s. This higher sampling frequency allows for the more accurate determination of higher Doppler frequency shifts (ie, higher velocities). Furthermore, since f_o is directly related to

f_d (see Eq. 14.7), a low-emitted ultrasound frequency will produce a lower Doppler frequency shift for a given velocity (see Fig. 14.3). This lower Doppler frequency shift will allow for a high-velocity measurement before aliasing occurs.

High-Pulse Repetition Frequency Doppler

On some instruments, PWD can be modified to a high-PRF mode. In conventional PWD, only a single burst of ultrasound is considered to be in the body at any given time; however, in high-PRF Doppler, two to five sample volumes are simultaneously presented. Information coming back to the transducer may be coming back from depths of two, three, or four times the initial sample volume depth. The returning signals can be a mix of signals that have previously been emitted and have traveled to distant gates and other signals that were just sent and returned from the first range gate.

The high-PRF mode allows increasing the sampling frequency because the scanner does not wait for the return of the information from distant gates; nonetheless, it receives information back within the specified time-gate period. Because high-sampling frequencies are used, higher velocities can be measured with this method than with PWD ; however, the exact gate from which the ultrasound signals are reflected is unknown (range ambiguity) (Box 14.2).

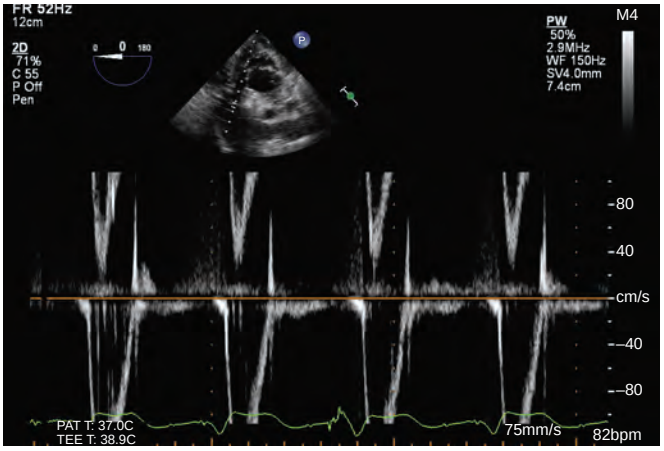

Fig. 14.4 Example of aliasing (deep transgastric view). Pulsed-wave Doppler through the aortic valve is demonstrated. Because the blood-flow velocity through the aortic valve is very high, it appears to wrap around the velocity scale when pulsed-wave Doppler is used.

Continuous-Wave Doppler

The CWD technique uses continuous, rather than discrete, pulses of ultrasound waves. Ultrasound waves are continuously being both transmitted and received by separate transducers. As a result, the region where flow dynamics are measured cannot be precisely localized. Because of the large range of depths being simultaneously insonated, a large range of frequencies is returned to the transducer. This large frequency range corresponds to a large range of blood-flow velocities. This large-velocity range is known as *spectral broadening*. Spectral broadening during CWD interrogation contrasts with the homogeneous envelope obtained with PWD (Fig. 14.5). Blood-flow velocity is, however, measured with great accuracy even at high flows, since sampling frequency is very high. CWD is particularly useful for the evaluation of patients with valvular lesions or congenital heart disease, in whom anticipated high pressure–high velocity signals are anticipated. CWD is also the preferred technique when attempting to derive hemodynamic information from Doppler signals.

Color-Flow Doppler

Advances in electronics and computer technology have allowed the development of CFD ultrasound scanners capable of displaying real-time blood flow within the heart as colors while also showing 2D images in black and white. In addition to showing the location, direction, and velocity of cardiac blood flow, the images produced by these devices allow the estimation of flow acceleration and differentiation of laminar from turbulent blood flow. CFD echocardiography is based on the principle of multigated PWD in which blood-flow velocities are sampled at many locations along many lines covering the entire imaging sector.[8] At the same time, the sector is also scanned to generate a 2D image.

A location in the heart where the scanner has detected flow toward the transducer (the top of the image sector) is assigned the color red. Flow away from the direction of the top is assigned the color blue.

BOX 14.2 PULSED-WAVE VERSUS CONTINUOUS-WAVE DOPPLER ANALYSIS

- Pulsed-wave Doppler
  - Spatial specificity
  - Ambiguity in the measurement of high velocities
- Continuous-wave Doppler
  - Ability to measure high velocities accurately
  - Spatial ambiguity

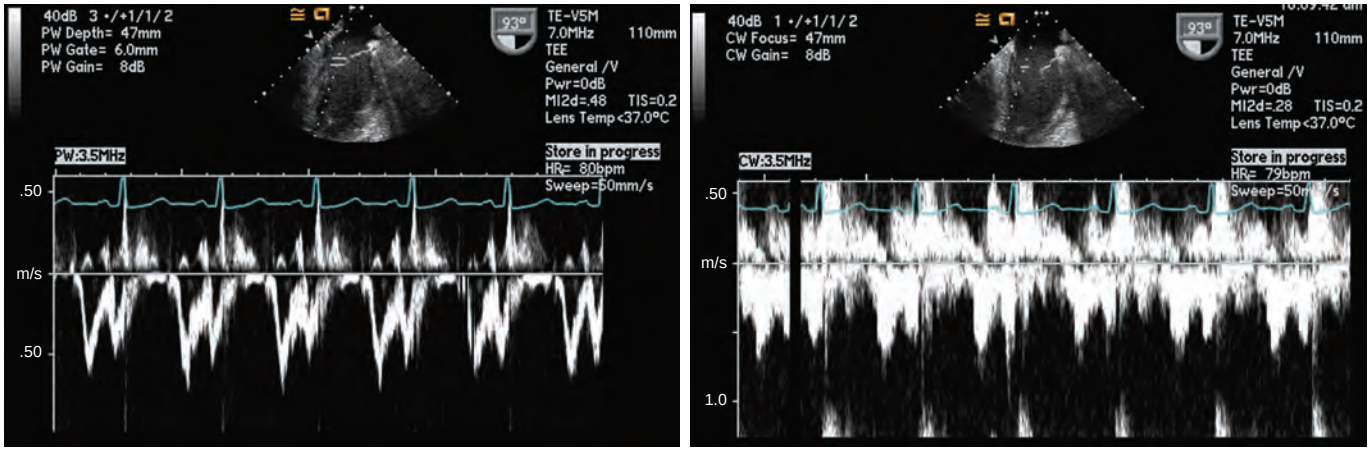

Fig. 14.5 Pulsed-wave Doppler (PWD) versus continuous wave Doppler (CWD). Both images are Doppler spectra through the mitral valve. *Left,* PWD is used. Because a specific region of interest is defined by the Doppler gate, a clean envelope of transmitral flow is displayed. *Right,* CWD is used. Because spatial specificity is lost, spectral broadening of velocities are displayed.

This color assignment is arbitrary and determined by the equipment's manufacturer and the user's color mapping. In the most common color-flow coding scheme, the faster the velocity (up to a limit), the more intense the color. Flow velocities that change by more than a preset value within a brief time interval (flow variance) may have an additional hue added to either the red or the blue. Both rapidly accelerating laminar flow (change in flow speed) and turbulent flow (change in flow direction) satisfy the criteria for rapid changes in velocity. In summary, the brightness of the red or blue colors at any location and time is usually proportional to the corresponding flow velocity, whereas the hue is proportional to the temporal rate of change of the velocity.

Contrast Echocardiography

Normally, red blood cells scatter ultrasound waves weakly, resulting in their black appearance on ultrasonic examination. Contrast echocardiography is performed by injecting nontoxic solutions containing gaseous microbubbles. These microbubbles present additional gas-liquid interfaces, which substantially increase the strength of the returning signal. This augmentation in signal strength may be used to better define endocardial borders, optimize Doppler envelope signals, and estimate myocardial perfusion.

Gramiak and colleagues[9] originally reported the use of contrast echocardiography in 1968. They described visualization of aortic valve (AV) incompetence during left-sided heart catheterization (Box 14.3). Subsequently, contrast echocardiography has been used to image intracardiac shunts,[10] valvular incompetence,[11] and pericardial effusions.[12] In addition, LV injections of hand-agitated microbubble solutions have been used to identify semiquantitative LV endocardial edges,[13] cardiac output (CO),[14] and valvular regurgitation.[15]

Contrast agents are microbubbles, consisting of a shell surrounding a gas. Initial contrast agents were agitated free air in either a saline or a blood-saline solution. These microbubbles were large and unstable; consequently, they were unable to cross the pulmonary circulation and were effective only for right-sided heart contrast. Because of their thin shell, the gas quickly leaked into the blood with resultant dissolution of the microbubble. Agents with a longer persistence were subsequently developed.

More modern contrast agents have both improved the shell surrounding the microbubble, as well as modification of the gas. The shell must inhibit the diffusion of gas into the blood and must enhance the pressure that a microbubble can tolerate before dissolving.[16] Gases with low shell diffusivity and blood saturation concentration result in a microbubble of increased survival because the gas would rapidly equilibrate with blood and the gas would tend to stay within the shell. Improvements in the shell both increase the tolerance of the microbubble to ultrasound energies and decrease the diffusion of the gas into the blood; both changes further increase the persistence of the microbubbles. At the same time, there must be an element of fragility; the microbubbles must be disrupted by ultrasound signals that produce appropriate imaging effects. The use of high–molecular-weight and less-soluble gases further increases the persistence of the contrast agents. Currently, the perfluorocarbons are the most common gases used in contrast agents. The microbubbles need to be small enough to traverse the pulmonary circulation with a predominant size particle that approaches the size of an erythrocyte. The number of larger particles needs to be minimized to reduce the risk of obstruction of pulmonary capillary flow. Because the reflected energy of contrast agents is high, attenuation of the ultrasound signal is common. This signal attenuation interferes with the visualization of distal structures.

An ultrasound signal produces compression and rarefaction (expansion) of the medium through which it travels. When this compression and rarefaction impact a microbubble, the bubble is compressed and expanded, respectively.[17] These changes result in changes in the bubble volume, causing bubble vibrations with subsequent effects on the returning ultrasound signal. These bubble pulsations may result in changes in the bubble radius by a factor of 20 or more.[18]

The acoustic properties of these microbubbles depend on the amplitude of the ultrasound signal. The amplitude of an ultrasound signal is usually defined by its mechanical index (MI), which is the peak negative pressure divided by the square root of the ultrasound frequency. Normally, when bubbles are insonated by ultrasound at their intrinsic resonant frequency, they vibrate; during the peak of the signal, they are compressed, and at the nadir of the signal, they expand. An ideal bubble would oscillation at the insonated ultrasound frequency.[19] At low ultrasound amplitudes (MI < 0.1), the microbubbles oscillate at the frequency of the insonated signal with the degree of compression being equal to the degree of expansion. This is called *linear oscillation*. With fundamental imaging, no special contrast echocardiographic signals are produced.[20] With increasing signal amplitudes (MI 0.1–0.7), the degree of expansion exceeds the degree of compression, which results in nonlinear oscillations. These nonlinear oscillations result in the creation of ultrasound waves at harmonic frequencies of the delivered ultrasound waves. Although some bubble destruction will occur at all amplitudes, further increases in ultrasound amplitude (MI 0.8–1.9) result in more compression and expansion with subsequent extensive bubble destruction. This bubble destruction, called *scintillation*, results in a brief but high output signal appearing as swirling. Because of the extensive bubble destruction, intermittent imaging must be performed to allow contrast replenishment. The role of most contrast imaging modalities is to create and display these nonlinear components while suppressing the linear echoes from tissue and tissue motion.[21]

Further improvements in image acquisition can be achieved using harmonic imaging.[18] As explained previously, nonlinear oscillations result in the creation of harmonics. It was theorized that if the receiver was tuned to receive the first harmonic of the transmitted ultrasound signal, then the signal-to-noise ratio can be improved by predominately imaging signals from the microbubbles producing these harmonics. Because tissue also produces harmonics, tissue gray-scale imaging was also enhanced. Further improvements may include subharmonic and ultraharmonic imaging, which may provide more specific contrast enhancement. Harmonic imaging with TEE improves endocardial visualization and allows partial assessment of myocardial perfusion.[22] Harmonic-powered Doppler is more sensitive for detecting basilar perfusion in the far field compared with harmonic gray-scale imaging.[23]

The first-generation agents were Albunex and Levovist. Currently, Optison (Mallinckrodt, St. Louis, MO) and Definity (DuPont Pharmaceuticals, Waltham, MA) are available for use in the United States; Levovist and SonoVue (Bracco Diagnostics, Princeton, NJ) are approved in Europe. Albunex is no longer available. Albunex used albumin encapsulation to stabilize a 4-μm air bubble that could opacify the left ventricle but did not result in good microvascular perfusion. Levovist uses an air microbubble within a fatty acid shell.

Optison is a refinement to Albunex, with the substitution of perfluoropropane within an albumin shell. Definity uses perfluoropropane within a liposome shell. SonoVue consists of hexafluoride with a

BOX 14.3 DIAGNOSTIC APPLICATIONS FOR CONTRAST ECHOCARDIOGRAPHY

- Assessment of congenital heart disease

  - Measurement of left ventricular function
  - Quantification of valvular regurgitation
  - Enhancement of color-flow Doppler signals
- Assessment of myocardial perfusion
  - Measurements of perfusion area after coronary artery bypass graft surgery
  - Assessment of quality of coronary bypass grafts and cardioplegia distribution
  - Correct assessment of the results of surgery for ventricular septal defect

phospholipid shell. New agents under development may use polymer shells whose flexibility and size can be more precisely controlled. These agents may be targeted to specific organs or vectors.

The safety of contrast echocardiography must be considered. The contrast agents, themselves, must have a high therapeutic index. Multiple large bubbles may obstruct pulmonary microcirculation. The disruption of microbubbles by high-amplitude ultrasound may rupture of capillaries and injure surrounding tissue.[24] Rare allergic and life-threatening anaphylactic or anaphylactoid reactions occur at a rate of approximately 1 per 10,000.[21] Premature ventricular contractions have been described during high-intensity triggered imaging.[25] Other investigators were not able to demonstrate an increase in premature ventricular complex occurrence during or after imaging with triggered ultrasound at an MI of 1.[26] Contraindications to the use of perflutren-containing agents included pulmonary hypertension, serious ventricular arrhythmias, severe pulmonary disease, cardiac shunting, or hypersensitivity to perflutren, blood, blood products, or albumin. If current recommendations are followed, then contrast echocardiography rarely results in significant side effects.[16]

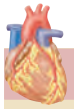
Echocardiographic Scanners

The transformation of reflected ultrasound echoes into 2D moving images is a complex process involving numerous electronic and digital manipulations. For example, a 2D echocardiographic image at 60 Hz is generated by scanning the heart every 16.7 msec or 60 times each second. The image is generated by combining these scan lines. A process called *interlacing* combines successive scans into a frame of 1/30 of a second. Because the eye cannot resolve an image lasting 1/30 of a second, microprocessors further process the frame electronically in real time to create the image of a heart moving through time. The intrinsic persistence of the display screen enhances image quality, and the end result is a fairly smooth image.

Resolution

Resolution is the ability to describe two point targets as distinct. An ultrasound image may be described by its axial, lateral, and elevational resolution (Box 14.4). *Axial resolution* is the minimum separation between two interfaces located along the same scan line in the acoustic beam, enabling them to be imaged as two different interfaces. The most precise image resolution is along this axial direction. The higher the frequency of the ultrasound signal, the greater the axial resolution, because ultrasound waves of shorter wavelengths may be used. Shorter bursts of ultrasound waves (ie, short pulse length) provide greater axial resolution. Pulse length should be no more than two or three cycles or they may slow B-mode frame rate. The range of frequencies contained within a given ultrasound transmission is referred to as the *frequency bandwidth*. Generally, the shorter the pulse of the ultrasound produced, the greater the frequency bandwidth; more low- and high-frequency information is in the same pulse. Because of the relationship between short pulse lengths and high bandwidths, high bandwidths are associated with better axial resolution. High-transducer bandwidths also allows for better resolution of deeper structures because they simultaneously have low-frequency information as well. Depth does not affect axial resolution.

Lateral resolution is the minimum separation of two targets aligned along an arc perpendicular to the ultrasound beam. The most important determinant of lateral resolution is both ultrasound beam width (or ultrasound beam focusing) and acoustic line spacing. For focusing, the narrower the beam, the better the lateral resolution. For line spacing, the closer the acoustic lines, the better the resolution. If a small object appears within the near field, it can then be accurately resolved laterally; however, if it appears within the far field, then the resolution of this small object will appear to blur because of the increase in the width of the ultrasound beam and the increased separation between ultrasound lines. Elevational resolution, or out of plane, refers to the ability to determine differences in the thickness of the imaging plane. The thickness of the ultrasound beam is a major determinant of elevational resolution. Elevational resolution is an important factor in live biplane imaging and 3D imaging. In these modes, all three resolution factors are important.



BOX 14.4 OPTIMIZATION OF RESOLUTION

- Axial
  - High ultrasound frequency
  - Short duration of ultrasound pulse
  - High-frequency bandwidth
- Lateral
  - Narrow beam width
- Elevational
  - Thickness of the ultrasound beam

Preprocessing

Ultrasound echoes are received and converted to electronic signals by the transducer. On most modern echocardiographic scanners, the analog electronic signals undergo several modifications before being digitized and eventually displayed as an image. Preprocessing describes the modifications performed on the analog and digital signal before storage.

Dynamic Range Manipulation

The intensity of echocardiographic signals spans a wide range from very weak to very strong. A high dynamic range (DR) allows the visualization of very strong and very weak signals on the same image. Very strong signals (eg, metallic valve struts) falling above the saturation level of the electronic circuitry create *white* oversaturated signals that compromise resolution. Very weak signals below the sensitivity of the instrument will not be detected and therefore not seen. The DR of the instrument is defined by the limits at which extremely strong or weak signals are eliminated; DR, within hardware limits, is under operator control (Fig. 14.6). In this manner, signals of low intensity that contain little useful information and are mostly noise can be selectively accepted or rejected.

A wide DR is needed to improve overall resolution, whereas a narrow range facilitates the discrimination between true image signals and noise. In clinical echocardiography, strong signals that arise from dense tissues (eg, cardiac valves) and weaker signals arising from soft tissues (eg, myocardium) are of interest. To give the weaker signals a greater representation in the DR, an amplifier converts the linear signal intensity scale into a logarithmic scale. Although this conversion increases the number of weaker signals detected, it also, unfortunately, amplifies noise.

Transmit Power and Overall Gain

Acoustic transmit power is proportional to the amplitude of the acoustic wave. Ultrasound systems work within acoustic safety limits to prevent heating tissue. Transmit power can be measured by the MI. Signals that are farther away can be strengthened by increasing the MI. In contrast, the overall receive gain control of an ultrasound scanner does not affect transmit power. It increases and decreases the receive intensity of the acoustic signals in a proportional manner by amplifying signals after they are received by the transducer, thus acting as a volume control.

Time-Gain Compensation

Because any wave traveling through tissues is attenuated proportionally to the traveled distance, it is necessary to compensate for the weaker echos returning from more distant objects than those from equally dense objects closer to the transducer. Depth compensation, or time-gain compensation (TGC), compensates for this difference

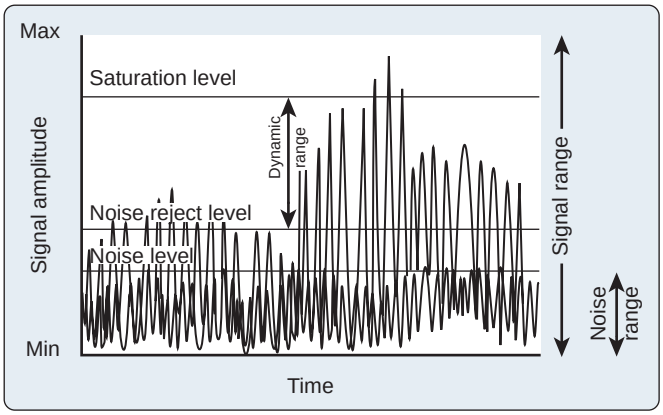


Fig. 14.6 Dynamic range of a representative echocardiographic display system. All ultrasound signals begin at zero signal level and can increase in amplitude until they reach the signal saturation level. Many of the low-intensity signals fall within the range of the background noise and are therefore obscured. All systems have a built-in system reject, which eliminates both the system noise and the low-intensity echoes that lie just above the noise level. The dynamic range of the system is between the noise reject level and the saturation level. Signals within the dynamic range appear on the image display. *(From Thys DM, Hillel Z. How it works: basic concepts in echocardiography. In: Bruijn NP, Clements F, eds.* Intraoperative Use of Echocardiography. *Philadelphia: JB Lippincott; 1991:255–318.)*

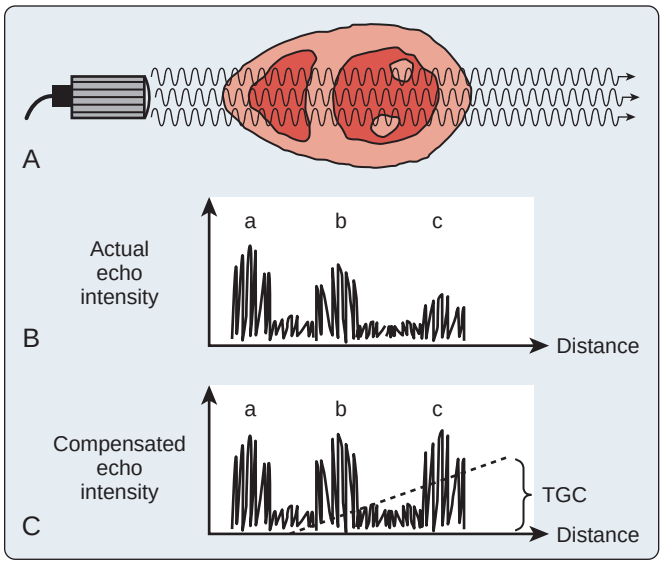

Fig. 14.7 (A) As an ultrasound beam is aimed across the heart, specular echoes are reflected at the right ventricular wall *(a)*, the septum *(b)*, and the left ventricular wall *(c)*. (B) The normal loss of echocardiographic strength is due to the decreasing intensity of the beam as it propagates through the heart. (C) Time-gain compensation *(TGC)* allows the intensity of the far-field signals to be increased selectively. *(From Thys DM, Hillel Z. How it works: basic concepts in echocardiography. In: Bruijn NP, Clements F, eds.* Intraoperative Use of Echocardiography. *Philadelphia: JB Lippincott; 1991:255–318.)*

in echo amplitudes (Fig. 14.7). Because echoes traveling from farther depths are received later, time is used to discern depth. TGC can be manually or automatically controlled.

Lateral gain control is an innovation that allows the application of gain control to selected angular blocks from one side to the other of the ultrasound image. This feature enhances the image strength of structures that are nearly parallel to the ultrasound beam (eg, the septum and lateral wall on a short-axis [SAX] view at the level of the papillary muscles). Thus lateral gain control is used to bring out imaging of the SAX view of the myocardium (Fig. 14.8).

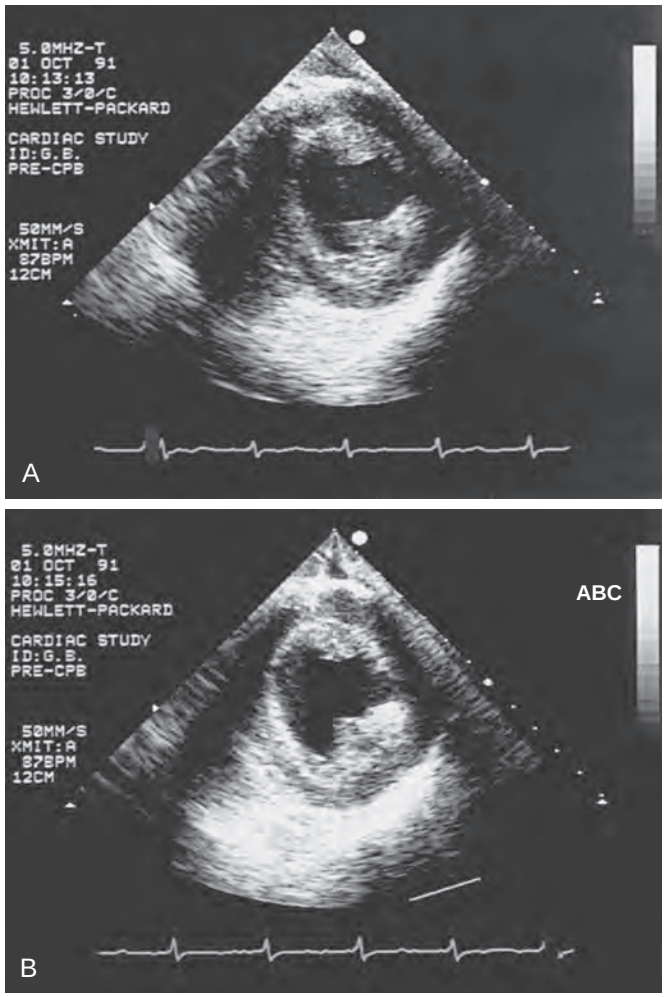

Fig. 14.8 (A) Standard two-dimensional short-axis view of the left ventricle at the level of the papillary muscles. Note that the image drops out in the septal and lateral walls (vertical portions of the wall). (B) Identical view after the application of lateral gain adjustments. The septal and lateral walls appear brighter, and less dropout is seen.

Leading-Edge Enhancement

Leading-edge enhancement, or differentiation, is another type of preprocessing used to sharpen the image. The reflected echocardiographic signal undergoes half-wave rectification and is smoothed into a signal envelope (Fig. 14.9A and B). An amplifier then differentiates the leading edge of the smoothed signal envelope to its first mathematical derivative (Fig. 14.9C), and a narrower and brighter image spot is formed (Fig. 14.9D and E). Because a 2D echocardiographic image comprises multiple radially juxtaposed scan lines, excessive edge enhancement narrows bright spots in the direction of travel of the echocardiographic beam (ie, axially but not laterally). For this reason, leading-edge enhancement is primarily performed on M-mode scans, whereas instruments with 2D-mode capability use little or no edge enhancement in the 2D mode. Therefore M-mode images often have a higher resolution than 2D images and are better suited for quantitative measurements.

Postprocessing

Digital Scan Conversion

After completing analog preprocessing, ultrasound devices digitize the image data with an analog-to-digital converter (Fig. 14.10). Further processing is performed while data are stored in the digital memory (input processing) or as they are received from the memory (output processing). The acoustic beam is swept in a polar fashion similar to

waving a flashlight. A display screen works in a rectangular format. An early step in digital processing uses a scan converter to transform the information obtained as radial sector scan lines into a rectangular (Cartesian) format for television screen display.

As an example, the digital storage of images is sketched. Computer memory stores the information of two adjacent columns in the image, for example, 128. There is also one row of memory for each of, for example, the 512 horizontal television image lines (raster lines). Therefore a typical television display of an echocardiographic image consists of 128 columns by 512 rows for a total of 65,536 picture elements or pixels. Although the monitor displays only 64 shades of gray for each pixel, for example, a 10-bit memory unit assigned to each pixel has the capacity to store 1024 degrees of brightness. Each pixel can be assigned 10 binary bits of memory for a total of 2^{10} (1024) possible storage combinations. The memory that is actually used depends on the specific system and manufacturing specifications.

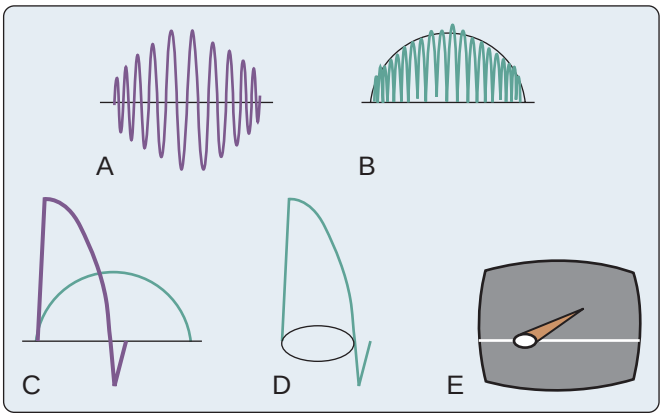

Fig. 14.9 Leading-edge enhancement techniques. (A) Radiofrequency (RF) type of echocardiographic display. (B) This video represents the average height of the upper half of the RF signal. (C) Differentiation is obtained by taking the first derivative of the video display. (D, E), Intensity modulation represents the conversion of signal amplitude to intensity, changing the signal from a spike to a dot. *(From Thys DM, Hillel Z. How it works: basic concepts in echocardiography. In: Bruijn NP, Clements F, eds.* Intraoperative Use of Echocardiography. *Philadelphia: JB Lippincott; 1991:255–318.)*

Temporal Processing

As digital data are entered into memory, they can undergo temporal averaging; that is, images can be averaged over time to change the aesthetics of the image. In the variable persistence mode, information from previous images is combined with current image data. A weighted average of the old and new data is then entered into memory as the new current data. A mechanism is built in to allow variable representation of the old data into the new image. A different input-processing option calculates the arithmetic mean of the new data and up to nine frames of existing data. The drawback is that averaging reduces temporal resolution and the ability to see quickly moving structures.

Gray-Scale Modification

The video image is generated from data retrieved from memory via the scan converter. During retrieval, data can be subjected to histogram modification or gray-ramp processing. This process redistributes the gray-level assignment of each pixel according to new values, which can bring out darker pixels and suppress brighter pixels. Manufacturers spend great efforts in creating their own ramps, which gives a signature appearance to the image. All levels of gray receive some representation, even though the original image may have been formed from only a limited range of grays.

Equipment

Because fat, bone, and air-containing lung interfere with sound-wave penetration, clear transthoracic echocardiographic views are particularly difficult to obtain in patients with obesity, emphysema, or abnormal chest wall anatomy. To avoid these problems, TEE transducers were developed. Sound waves emitted from an esophageal transducer only have to pass through the esophageal wall and the pericardium to reach the heart, improving image quality and increasing the number of echocardiographic windows. Other advantages of TEE include the stability of the transducer position and the possibility of obtaining continuous recordings of cardiac activity for extended periods.

The first TEE examination was performed in 1975. The probe used allowed only M-mode imaging and had limited control of direction. Two-dimensional TEE was first performed with a mechanical system,[27] which consisted of a vertical and a horizontal mechanical scanner connected to 3.5-MHz ultrasonic transducer contained in a 12′20′6-mm oil bag. The transducers were rotated by a single-phase commutator motor via flexible shafts. Subsequently, phased-array transducers were mounted into gastroscope housings.[28,29] With their greater flexibility and control, these probes allowed 2D scanning of the heart through many planes, and the probes became the prototypes of the currently used models.

All TEE probes share several common features. All of the currently available probes use a multifrequency transducer that is mounted on the tip of a gastroscope housing. The majority of the echocardiographic examination is performed using ultrasound between 3.5 and 7 MHz. The tip can be directed by the adjustment of knobs placed at the proximal handle. There are two knobs in most adult probes; one allows anterior and posterior movement, and the other permits side-to-side motion. Multiplane probes also include a control to rotate mechanically the echocardiographic array from 0 to 180 degrees. Thus in combination with the ability to advance and withdraw the probe and to rotate it, many echocardiographic windows are possible. Another feature common to most probes is the inclusion of a temperature sensor to warn of possible heat injury from the transducer to the esophagus.

Currently, most adult echocardiographic probes are multiplane (variable orientation of the scanning plane), whereas pediatric probes are either multiplane or biplane (transverse and longitudinal orientation, parallel to the shaft). The adult probes usually have a shaft length of 100 cm and are between 9 and 12 mm in diameter. The tips of the probes vary slightly in shape and size but are generally 1 to 2 mm wider than the shaft. The size of these probes requires the patient to weigh at least 20 kg. Depending on the manufacturer, the adult probes contain between 32 and 64 elements per scanning orientation. In general, the image quality is directly related to the number of elements used. The pediatric probes are mounted on a narrower, shorter shaft with smaller transducers. These probes may be used in patients weighing as little as 1 kg. Because of size limitations, these probes may not possess a lateral control knob. The use of the pediatric probe on all patients to decrease the risk of esophageal injury has been questioned. The answer is that the smaller probes provide less diagnostic information. The numbers of elements are reduced, the aperture is smaller, there is less control of the tip, and the smaller transducer tip does not usually make good contact in the adult esophagus. These factors combine to significantly reduce image quality.

An important feature that is often available is the ability to alter the scanning frequency. A lower frequency, such as 3.5 MHz, has greater penetration and is more suited for the transgastric (TG) view. It also increases the Doppler velocity limits. Conversely, the higher frequencies yield better resolution for detailed imaging. One of the limitations of TEE is that structures very close to the probe are seen only in a very narrow sector. Newer probes may also allow a broader near-field view. Finally, newer probes possess the ability to scan simultaneously in more than one plane. Nonmechanical matrix array probes use a diced crystal stack that can scan both laterally and elevationally. This 2D array can create a 3D ultrasound image and can also create simultaneous intersecting 2D images. This type of probe needs a beamformer capable of creating 3D reconstruction.

Image Storage

All modern echocardiographic scanners allow the operator to store or freeze a single echocardiographic image on the display screen. This feature allows the scrutiny of any unusual transient anatomic or physiologic observations. Once frozen, an image can also be subjected to some simple quantitative measurements. With the continuous motion of the cardiac structures, however, capturing the exact frame that is to be analyzed is often difficult. For this reason, techniques to acquire several consecutive frames have been developed.

Cine Memory

When activated, this mode captures a sequence of several echocardiographic images in digital memory. Because of the digital storage technique, the quality of the stored images is high. The images can be displayed again in several different ways. In one method, the frames are displayed one by one as the operator manually controls the transition from one frame to the next using a trackball. Any amount of time can be spent on a single frame. The images can also be replayed continuously in repeated endless-loop fashion at the same speed as the original recording speed or at a different speed.

Videotape

Many echocardiographic scanners are equipped with ½-inch video home system (VHS), *super* VHS (sVHS), or ¾-inch videocassette recorders (VCRs). Their advantages include low cost and their ability to record multiple cardiac cycles, facilitating the creation of a 3D image in the reviewer's mind.[30] Because VCRs store images in analog format, the quality of videotaped images is currently inferior to the real-time display, the digital cine memory replay, or digital storage. In the United States, videotape is used to record images using the National Television Standards Committee (NTSC) format. When videotape is used, resolution is limited by this NTSC format, which is not lost with digital storage.[30] Other disadvantages include the inability to randomly access parts of the current examination or previous examinations, difficulty sharing examinations with colleagues, and the degradation of videotape quality over time.[30]

Digital Storage

Digital image storage is rapidly becoming an alternative to videotape storage. Although the digital storage of echocardiographic images has increased the complexity of study storage, the American Society of Echocardiography (ASE) and others have suggested that digital storage has advantages over other modalities (Box 14.5).[31,32] These advantages include the following:

1. Reading is more efficient. With the use of VCR videotapes, the echocardiographer needs to review the entire 10 to 30 minutes of the study, which includes both important and redundant information. Using digital storage, the echocardiographer can direct his or her attention to specific clips, data may be accessed randomly, and the noncontributory segments of the study need not be viewed.
2. Because the studies are stored on a central server, the echocardiographer may read studies at any location that contains a workstation. When the storage system is properly configured, studies may be read on campus via institutional intranet connections or may be read off site.
3. Because of study centralization indexing and archiving in digital storage systems, previous studies may be rapidly accessed for comparison with a current study. The need to rummage through racks of old videotapes and search for a specific study is eliminated. This centralization of studies decreases the inefficient use of clinical staff time retrieving and loading physical media such

BOX 14.5 ADVANTAGES OF DIGITAL ECHOCARDIOGRAPHIC STORAGE[31,32]

1. More efficient reading
2. Ability to read studies in a variety of locations
3. Easy comparison with previous studies
4. Easier quantification
5. Ability to include images with reports to referring physicians
6. High image quality
7. No image degradation over time
8. Uses less storage space than VCRs do
9. Integration of the images and reports within the hospital's electronic medical record
10. More robust research
11. Easy implementation of a clinical performance improvement program
12. Improved overall accuracy and reproducibility
13. Greater facilitation of medical education
14. Decreases in medicolegal risk

as VCR videotapes or digital media. Because these older studies are more easily available, unnecessary duplication of procedures is decreased and the delivery of optimal patient care increases.

4. Since the Digital Imaging and Communications in Medicine (DICOM) file header contains information about the acquisition of the study, spatial, temporal, and velocity calibrations are included with each image, and quantification may be rapidly accomplished within the analysis program without special tools.
5. More convenient communication with the referring physician may be facilitated because the study images may be included easily with the report.
6. The standard resolution of VHS images is equivalent to 480 × 320 pixels, whereas the standard resolution of sVHS is equivalent to 560 × 480 pixels. Digital images provide a resolution of 800 × 600 pixels or higher, which are exactly as they are recorded by the ultrasound machine. No degradation occurs during the transfer of images from the ultrasound machine to the digital storage systems, as will occur with videotape transfer.
7. Over time, videotape degrades. A magnetic realignment of the VCR tape occurs with resultant degradation of image quality. Digital echocardiographic storage provides a more stable image quality.
8. The physical storage of VCRs requires significant space, which is usually a premium in either a hospital or an office environment.
9. The echocardiographic reports may be incorporated within the hospital's electronic medical record.
10. Because the highest quality images are available, more robust research may be performed. Communication with core laboratories is simplified.
11. A clinical quality-assurance program may be easily implemented, within which echocardiograms can be re-reviewed randomly on a regular basis. If consultation is necessary, then sharing studies with colleagues both from within and outside of the institution can be easily accomplished over digital networks.
12. Because physicians may be directed to the important aspects of the echocardiographic examination, of echocardiographic examinations provide improved accuracy and reproducibility.
13. Because moving images can be easily incorporated into presentations, facilitation of medical education is greater.
14. Since studies may be easily and reliably retrieved, medicolegal risk is reduced.

Because of these advantages, the ASE has unequivocally recommended that all examinations should be digitally captured and stored.[31] The increased efficiency of digital reading of echocardiographic studies has been demonstrated by Mathewson and associates,[33] who timed study acquisition and analysis during approximately 750 pediatric echocardiograms. As a group, the digitally captured images contained more hemodynamic measurements and thus required more time for acquisition. The average times for study acquisition were 26.0 ± 8.9 minutes for videotape and 28.4 ± 11.5 minutes for the single-beat digital method. In contrast, interpretation of these studies was more rapid using digital methods, with an average interpretation time of 6.5 ± 3.7 minutes for the videotape compared with 4.6 ± 3.9 minutes for the digital method.

Image Terminology

Image Creation

A single static echocardiographic image is rendered by a number of dots or pixels on a screen. The image resolution is defined by the number of columns and rows of pixels displayed, which is typically 800 and 600, respectively, for medical ultrasound. Each pixel of the image is described by its red, green, and blue components and is represented by three bytes of data; each of these bytes contain a number from 0 to 255, which represents the level of the pixels' primary colors. If 256 levels are possible for each of these three primary colors, then a total of 16.8 million colors (256^3) may be represented. A video clip consists of a series of sequentially displayed static images. Most echocardiographic video clips have approximately 30 frames per second. If no methods of compression are used, then the storage requirements for digital storage of echocardiographic clips become huge. A single image would require 921,600 bytes of data (640 columns × 480 rows × 3 bytes per pixel). If a 30 frame-per-second temporal resolution is used, then an uncompressed 10-minute examination would require 16,588,800,000 bytes or 15.4 gigabytes (GB) of storage.

Clinical Compression

Because of these space requirements, clinical examinations must be subject to compression. The two major categories of compression are clinical and digital. During the performance of echocardiographic examinations, many cardiac cycles may be obtained during image acquisition. During standard analog storage of examinations using VCR technologies, the videotape is allowed to run continuously, capturing the entire examination. With clinical compression, short clips are stored to represent each relevant echocardiographic view. Typically, either several seconds or several cardiac cycles are recorded, which may be played back in a loop when displayed for interpretation.

Does clinical compression effect the interpretation of echocardiographic examinations? Haluska and colleagues[34] reported high concordance between videotaped and digital echocardiographic interpretations of adult echocardiographic examinations. Most observed discordances were minor, with lesser values being reported with the digital method. For example, degrees of mitral regurgitation (MR) were reported to be milder by the digital method compared with video presentation. Most major discordances were cases of assessment of AV and mitral valve (MV) thickening and the degree of MR; the authors hypothesized that the major discordances were caused by undersampling and not image quality. The routine acquisition of longer video clips may not necessarily increase the accuracy of digital echocardiographic readings. Shah and associates[35] evaluated 102 patients with regurgitant valvular disease, recording findings on videotape, as well as digitally using one, two, and three cardiac cycles. They observed substantial agreement when the videotape and one-cycle digital presentations were compared. There were no increases in agreement when two or three cardiac cycles were presented digitally.

Digital Compression

There are two basic types of digital image compression: lossless and lossy. Lossless compression reduces the file size by replacing identical values in a given image data set with the single value and the number of repetitions. This type of digital compression allows for exact reconstruction of the data set and does not result in a loss of data. Because no data are lost, there is no degradation of image quality. The creation of a lossless data set requires substantial processing power and may affect

the speed of file manipulations. Lossless compression may allow for a threefold reduction in file size. In contrast, lossy compression reduces the image size by permanently eliminating nonessential image information. Although the goal of lossy compression is image compression without the loss of image quality, excessive lossy compression may result in degradation of image quality. Lossy compression may provide a 20-fold reduction in image size.

In a comparison of quantitative measurements of sVHS and digital Moving Pictures Expert Group 1 (MPEG-1)–derived images, Garcia and colleagues[36] demonstrated excellent agreement among linear, area, and Doppler measurements. The MPEG-1 measurements were reproducible and provided a higher quality, compared with the sVHS images. Other studies have confirmed the diagnostic quality of images subjected to MPEG-1 compression.[37,38] Harris and associates[39] compared the image quality of sVHS recording with MPEG-2 compressions, analyzing 80 matched examination interpretations among four echocardiographers. They reported an overall concordance rate of 94%. Most of the reported discrepancies (4% total) were minor. They concluded that MPEG-2 compression offers excellent concordance with sVHS image review. Similar high-quality compression may be seen with newer compression schemes such as MPEG-4.[40]

Digital Imaging and Communications in Medicine Standard

With the increased use of medical imaging, standardized formats for image storage were developed to allow for the uniform acquisition, storage, and distribution of examinations. In 1983, the American College of Radiology (ACR) and the National Electrical Manufacturers Association (NEMA) formed a joint committee to create a standard format for storing and transmitting medical images, which was published in 1985.* This original protocol was limited to single-frame grayscale images and required highly specific nonstandard hardware for information transfer and storage. Images were stored in a proprietary format; consequently, image viewing was difficult. Subsequently, this format has been developed further and renamed DICOM.[41] Its current version may be found on the NEMA website; version PS3 is being used.*

Each DICOM file has both header and image data. The header data may contain a variety of patient demographic information, acquisition parameters, and image dimensions. Informational object definitions specify the source of the data, supply the rules that determine which data elements are required and which are optional, and define the valid methods of data manipulation. In the case of echocardiography, 2D, color, and Doppler echocardiographic techniques are all supported. Calibration information for linear, temporal, and velocity data are available. Information may be exchanged using a variety of methods.

Image Acquisition, Transmission, Analysis, and Storage

Image Acquisition

Most modern ultrasonography machines have the ability to store electronic studies in a DICOM-compatible format for transmission to the Picture Archiving and Communication System (PACS), as well as modality worklist capability. This modality worklist capability enables a piece of imaging equipment to obtain details of patients and scheduled examinations electronically from the DICOM worklist server. Because of the need for image transmission, each ultrasound machine must be properly configured before its introduction into clinical service. The machine must be assigned an appropriate Application Entry (AE) Title and Internet protocol (IP) address, which will uniquely identify the machine to the network. The IP address of the gateway, through which the machine is expected to communicate, must be entered, as well as the IP addresses of both the PACS and DICOM worklist servers.

Before performing an examination, the patient must be properly identified. If a modality worklist capability is present on the ultrasound machine, then the patient information will already have been prepopulated on the ultrasound machine. The minimum examination should consist of all 28 ASE/SCA (Society of Cardiovascular Anesthesiologists) recommended standard multiplane TEE views with the appropriate Doppler and color-Doppler spectra.[42,43] Most of these views are saved as video clips, and the Doppler images are saved as static images. When available, appropriate 3D images should be obtained as well. Calibration information for off-line analysis (eg, length, time, velocity) is automatically stored for 2D and Doppler spectrum. Because of the size of the data set, this calibration information and the ability to perform off-line data manipulation of 3D data set are not usually available. Because electrocardiographic monitoring should be used, clips of a fixed number of cardiac cycles may be specified and automatically saved. Because electrocautery artifacts may interfere with cycle determination, a fixed time (eg, 1 to 2 seconds) may be alternatively specified. Although dependent on the number and duration of video clips and images stored, the usual echocardiographic examination is between 50 and 100 MB. After the conclusion of the study, all examination information may be sent via the local area network (LAN) to the PACS server.

Study Transmission

Normally, echocardiographic studies are initially stored on the internal hard drive of the ultrasound machine. These studies will normally be retained until deleted by the end user. Because studies stored on these machines are not accessible via a global PACS, they must be transferred centrally. Although studies may be copied onto removable media, such as digital videodisks (DVDs), compact disks (CDs), universal serial bus (USB) devices, or magnetooptical devices and manually transferred to a server ("sneaker-netted"), transmission via a LAN is most efficient.

LAN transmission speed will limit the speed of information exchange. Although older LANs may provide 10 megabits per second (Mbps) connectivity, a minimum of 100 Mbps is usually necessary between the ultrasound machines and the PACS server. A connection speed of 100 Mbps to 1 GB per second (Gbps) may be necessary to connect the PACS station to the review stations (Table 14.3). In addition to transmission speed, network architecture (eg, interconnectivity of gateways, bridges, switches, servers) has an important role in the performance of a network. Most ultrasound devices will support a network switch with autonegotiate features, allowing for the rapid transmission of information. Some older devices may only support lower speeds of communications and/or less efficient duplex modes and may not function properly with a switch set for autonegotiate functionality. Several network connections may need to be left at a fixed setting to allow communication with these older devices.

Image Storage: Picture Archiving and Communication System Server

After the creation of a study entry by the DICOM worklist server, an acquisition number is assigned by the worklist server. As discussed earlier, this information is sent to the ultrasound machine but may

TABLE 14.3 Transmission Time Requirement for a 50-MB Study

Speed of Connectivity	*Study Download Time*
28.8 kbps modem	3.9 hours
112 Kbps ISDN	1 hour
768 Kbps DSL or cable modem	8.6 minutes
1.54 Mbps T1 (trunk) line	4.4 minutes
10 Mbps Ethernet	40 seconds
100 Mbps Ethernet	4 seconds
1 Gbps Ethernet	0.4 seconds

DSL, Digital subscriber line; *Gbps,* gigabytes per second; *ISDN,* integrated services digital network; *Kbps,* kilobytes per second; *Mbps,* megabits per second.

also be sent to the PACS server. The important demographic information is stored, as well as the details of the expected echocardiographic examination. When completed, the study is sent from the ultrasound machine to the PACS server. Typically, the study will be stored on the PACS server for a short period (days) before being sent to long-term storage. In many cases, these data will also be mirrored to an off-site disaster recovery server and storage as well. The more recent studies (typically 6 months to a few years old) are usually stored on redundant arrays of independent disks (RAIDs) for rapid retrieval of data, whereas the older studies (older than a few years) may be stored on less expensive and slower media such as DVDs, digital linear tape, or advanced intelligent tape. With the decreasing price of RAID storage, a greater number of studies may be stored on this fast-access medium.

Study Distribution and Analysis

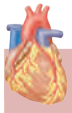
Dedicated Workstations

The need for study analysis is heavily dependent on physician work flow. In the typical cardiac anesthesia practice, the vast majority of studies are performed, interpreted, and reported by the physician at the time of the examination. In contrast, most outpatient echocardiographic studies are performed by a technician and sent to digital storage. They are then later recalled by the cardiologist for review, analysis, interpretation, and report generation. Nonetheless, most digital storage solutions will provide dedicated workstations for image review, analysis, and report generation capabilities, and anesthesia providers have the option to use these resources. Typically, these workstations will have fast connections with the PACS server, allowing for rapid transmission of a particular study to a workstation for analysis. Usually, multiple studies can be displayed for comparison. Image configurations may be adjusted by the user, and farther off-line image adjustments (eg, brightness, contrast) can usually be made. Clip playback speeds can be easily controlled, including the ability to start or stop and step through a study. Because calibration information has been incorporated with the study, off-line calculations may be performed. Images or clips can be selected for exportation as standard image or video files for incorporation into teaching materials. Reporting software may be offered as an option for these image analysis workstations. Measurements and qualitative descriptions may be entered for both generation of a study report and population of a structured query language (SQL) database, which may be used for performance improvement or research.

Off-Site Distribution

Echocardiographic images may be distributed off site as well. Mirroring the recently obtained studies on a separate server to handle all off-site distribution of studies (Web server) is usually the most efficient. The distribution of studies is limited by two basic constraints: security and communication. Most off-site distribution of medical images uses an Internet browser application to both retrieve studies from the PACS and display these studies for the user. An open-access system through the public Internet may present challenges vis-à-vis the Health Insurance Portability and Accountability Act (HIPAA) privacy regulation. Security of this medical information must be ensured by either a log-in system, allowing for auditing of access to patient information, or a virtual personal network (VPN), which is a method of providing remote access to an institutional LAN.

As discussed earlier, individual studies may be 50 to 100 MB in size. If high-speed network connectivity is available (such as 1 Gbp), then a 50-MB study may be transmitted to a workstation in less than 1 second (see Table 14.3). This high-speed connectivity is, however, not usually available to a user outside of the institutional LAN. If studies are to be accessed outside of an institution, the Internet must be used to download and view these studies; transmission speed may limit the speed of study display. An old-technology dial-up modem may require almost 4 hours to download a 50-MB study, whereas a 1.54-Mbps T1 line may require approximately 5 minutes. Because of these transmission speed issues, studies must be compressed before off-site study transmission. Using one of the lossy compression routines is most common. Although there is generally some image degradation, image quality may still be reasonable for some diagnostic work. Because these compression routines are used and the actual DICOM image file is not sent, calibration information is lost; consequently, off-line image measurements and calculation may be problematic.



BOX 14.6 COMPLICATIONS FROM INTRAOPERATIVE TRANSESOPHAGEAL ECHOCARDIOGRAPHY

- Injury from direct trauma to the airway and esophagus
  - Esophageal bleeding, burning, tearing
  - Dysphagia
  - Laryngeal discomfort
  - Bacteremia
  - Vocal cord paralysis
- Indirect effects
  - Hemodynamic and pulmonary effects of airway manipulation
  - Distraction from patient care

Complications

Complications resulting from intraoperative TEE can be separated into two groups: injury from direct trauma to the airway and esophagus and indirect effects of TEE (Box 14.6). In the first group, potential complications include esophageal bleeding, burning, tearing, dysphagia, and laryngeal discomfort. Many of these complications could result from pressure exerted by the tip of the probe on the esophagus and the airway. Although maximum flexion of the probe will not result in pressure above 17 mm Hg in most patients, occasionally, even in the absence of esophageal disease, pressures greater than 60 mm Hg will result.[44] To look more closely at the effects on the esophagus, animal autopsy studies have been performed. In dogs as small as 5 kg on cardiopulmonary bypass (CPB) with full heparinization, no evidence of macroscopic or microscopic injury to the esophageal mucosa was noted after 6 hours of maximally flexed probe positioning.[45]

Further confirmation of the low incidence of esophageal injury from TEE is apparent in the few case reports of complications. In a study of 10,000 TEE examinations, there was one case of hypopharyngeal perforation (0.01%), two cases of cervical esophageal perforation (0.02%), and no cases of gastric perforation (0%).[46] Kallmeyer and colleagues[47] reported overall incidences of TEE-associated morbidity and mortality of 0.2% and 0%, respectively. The most common TEE-associated complication was severe odynophagia, which occurred in 0.1% of the study population, dental injury (0.03%), endotracheal tube malpositioning (0.03%), upper gastrointestinal hemorrhage (0.03%), and esophageal perforation (0.01%). Piercy and associates[48] reported a gastrointestinal complication rate of approximate 0.1%, with a great frequency of injuries among patients older than 70 years and among women. Lennon and colleagues[49] reported a 1.2% incidence of upper gastrointestinal complications consistent with TEE injury among 516 patients undergoing cardiac surgery with TEE. In this study, 0.38% of the patients exhibited signs of complications early, whereas the remainder exhibited signs later. If resistance is met while advancing the probe, then the procedure should be aborted to avoid potentially lethal complications.

Another possible complication of esophageal trauma is bacteremia. Studies have shown that the incidences of positive blood cultures in patients undergoing upper gastrointestinal endoscopy and those undergoing TEE are 4% to 13%[50,51] and 0% to 17%,[52–54] respectively. Although bacteremia may occur, it does not always cause endocarditis. Antibiotic prophylaxis in accordance with the American Heart Association (AHA) guidelines is not routinely recommended but is optional in patients with prosthetic or abnormal valves or in patients who are otherwise at high risk for endocarditis.[55]

In one of the earliest studies using TEE, transient vocal cord paralysis was reported in two patients undergoing neurosurgery in the sitting position with the head maximally flexed and the presence of an armored endotracheal tube.[56] This complication was believed to be attributable to the pressure the TEE probe exerted against the larynx. Since this initial report, no further problems of this kind have been reported with the use of newer equipment.

The second group of complications that result from TEE includes hemodynamic and pulmonary effects of airway manipulation and, particularly for new TEE operators, distraction from patient care. Fortunately, in the anesthetized patient, hemodynamic consequences to esophageal placement of the probe are rare, and no studies specifically address this issue. More important for the anesthesiologist are the problems of distraction from patient care. Although these reports have not appeared in the literature, the authors have heard of several endotracheal tube disconnections that went unnoticed to the point of desaturation during TEE examination. Additionally, instances during which severe hemodynamic abnormalities have been missed because of a fascination with the images or the controls of the echocardiograph machine have been reported. Clearly, new echocardiographic operators should enlist the assistance of an associate to watch the patient during the echocardiographic examination. This second anesthesiologist will become unnecessary after sufficient experience is gained. Ensuring that all respiratory and hemodynamic alarms are activated during the echocardiographic examination is also important. One report that appeared in the literature recounted an incident during which an esophageal stethoscope was inadvertently pushed into the patient's stomach during TEE; it was noticed to be missing only when the patient developed a small bowel obstruction.[57]

Safety Guidelines and Contraindications

To ensure the continued safety of TEE, the following recommendations are made. The probe should be inspected before each insertion for cleanliness and structural integrity. If possible, the electrical isolation should also be checked. The probe should be inserted gently; if resistance is met, then the procedure should be aborted. Minimal transducer energy should be used, and the image should be frozen when not in use. Finally, when not imaging, the probe should be left in the neutral, unlocked position to avoid prolonged pressure on the esophageal mucosa.

Absolute contraindications to TEE in intubated patients include esophageal stricture, diverticula, tumor, recent suture lines, and known esophageal interruption. Relative contraindications include symptomatic hiatal hernia, esophagitis, coagulopathy, esophageal varices, and unexplained upper gastrointestinal bleeding. Notably, despite these relative contraindications, TEE has been used in patients undergoing hepatic transplantation without reported sequelae.[58,59]

Credentialing

The observance of guidelines for training, credentialing, certifying, and recertifying medical professionals has become increasingly common in the current era. Although there have been warnings[60] and objections[61] to anesthesiologists making diagnoses and aiding in surgical decision making, there is no inherent reason that an anesthesiologist cannot provide this valuable service to the patient.

In 1990, a task force from the American College of Physicians, the American College of Cardiology (ACC), and the AHA created initial general guidelines for echocardiography.[62] The ASE also provided recommendations for general training in echocardiography and has introduced a self-assessment test for measuring proficiency. These organizations have recommended the establishment of three levels of performance with a minimum number of cases for each level: level 1, an introduction and understanding of the indications (120 2D and 60 Doppler cases); level 2, independent performance and interpretation (240 2D and 180 Doppler cases); and level 3, laboratory direction and training (590 2D and 530 Doppler cases).[61,63] However, these guidelines are limited because they are not based on objective data or achievement. Furthermore, because different individuals learn at different rates, meeting these guidelines does not ensure competence nor does failure to meet these guidelines preclude competence.

Proficiency in echocardiography can be more efficiently achieved in a limited setting (ie, the perioperative period) with fewer clinical applications (eg, interpreting wall motion, global function, MR severity) than in a setting that introduces every aspect of echocardiography. The American Society of Anesthesiologists (ASA) and the SCA have worked together to create a document on practice parameters for perioperative TEE.[64,65] The SCA then created a Task Force on Certification for Perioperative TEE to develop a process that acknowledges basic competence and offers the opportunity to demonstrate advanced competence as outlined by the SCA/ASA practice parameters. In 1998, the National Board of Echocardiography was formed. Currently, perioperative transesophageal echocardiography examination (PTEeXAM) has two levels of board certification: basic and advanced. The basic level is limited to "… non-diagnostic monitoring within the customary practice of anesthesiology."[†] In contrast, the advanced track allows the diplomate to "… utilize the full diagnostic potential of perioperative TEE including direction of the surgical decision-making process."[‡] Both certifications require (1) holding a valid license to practice medicine; (2) board certification in an approved medical specialty, such as anesthesiology; and (3) training and/or experience in the perioperative care of surgical patients with cardiovascular disease. The basic track requires the study of 150 echocardiographic examinations (50 of these examinations require the presence of a supervising physician) and the passing of either the basic or advanced PTEeXAM; the advanced track requires the study of 300 echocardiographic examinations (150 of these examinations require the presence of a supervising physician) and the passing of the advanced PTEeXAM.

Training and Quality Assurance

TEE training should begin with a dedicated training period. This training is most easily accomplished during a cardiac anesthesia fellowship but can be completed by postgraduate physicians as well. The subject can be approached through a combination of tutorials, scientific review courses, self-instruction with teaching videos, interactive learning programs, and participation in echocardiographic reading sessions.[66,67] Frequently, a symbiotic relationship with the cardiology division can be established within which anesthesiologists can teach the fundamentals of airway management, surgical unit physiologic considerations, and the use of local anesthetics while learning the principles of echocardiography from the cardiologists.

In 2006, the ASE and SCA suggested guidelines to ensure quality improvement in perioperative TEE.[68] At the very least, each echocardiogram should be recorded in a standardized fashion and accompanied by a written report for inclusion in the patient's chart after a discussion with the anesthesia and surgical teams. Although images may also be copied and included in the chart, the ASE has unequivocally recommended that all examinations should be digitally captured and stored.[31] Careful records of any complications should be maintained. To ensure that the proper images are being obtained and that the interpretations are correct, the studies should be periodically reviewed. Components of this review should include the documentation of the indications and consent, the appropriate use of the system technology and controls, the adequacy and presentation of the imaging planes, and an assessment of whether the written report is supported by the documented images.[68] This review is another opportunity in which the relationship between cardiology and anesthesiology can be productive.

Practice Parameters

In 2010, the ASA and the SCA Task Force on Transesophageal Echocardiography updated the 1996 practice guidelines for the use of perioperative TEE.[64,65] The major change in these guidelines recommend that perioperative TEE should be used in all adult patients, without contraindications for TEE, undergoing cardiac or thoracic aortic procedures. A complete TEE examination should be performed in all patients with the following intent: (1) to confirm and refine the preoperative diagnosis, (2) to detect new or unsuspected pathologic conditions, (3) to adjust the anesthetic and surgical plan accordingly, and (4) to assess the results of the surgical intervention.

For patients in the catheterization laboratory, the use of TEE may be beneficial. Especially in the setting of catheter-based valve replacement and repair and transcatheter intracardiac procedures, both consultants and ASA members agree that TEE should be used. In the setting of noncardiac surgery, TEE may be beneficial in patients with known or suspected cardiovascular pathologic conditions, which could potentially lead to severe hemodynamic, pulmonary, or neurologic compromise. In life-threatening situations of circulatory instability, TEE remains indicated. A similar viewpoint is taken by the consultants and ASA members in regards to critically ill patients. TEE should be used to obtain diagnostic information that is expected to alter management, especially in the intensive care unit, when the quality of transthoracic images is poor or when other diagnostic modalities are not obtainable in a timely manner.

A study published by Minhaj and colleagues[69] found that in 30% of patients, the routine use of TEE during cardiac surgery revealed a previously undiagnosed cardiac pathologic condition, leading to a change in surgical management in 25% of patients studied. Eltzchig and associates[70] were able to confirm these findings in a significantly larger cohort showing that the perioperative use of TEE may improve outcome. This group reported that 7% of 12,566 consecutive TEE examinations directly influenced surgical decision making. Combined procedures (coronary artery bypass graft [CABG], valve procedures) were most commonly influenced by perioperative TEE. In 0.05% of the examinations, the surgical procedure was actually cancelled as a direct result of the intraoperative TEE examination.

Practice guidelines are systematically developed recommendations that assist the practitioner and patient in making decisions about health care. These recommendations may be adopted, modified, or rejected according to clinical needs and constraints. Practice guidelines are not intended as standards or absolute requirements, and their use cannot guarantee any specific outcome. Practice guidelines are subject to revisions from time to time as medical knowledge, technology, and technique evolve. Guidelines are supported by analysis of the current literature and by synthesis of expert opinion, open-forum commentary, and clinical feasibility data.

Technique of Probe Passage

Anesthesiologists may need to insert TEE probes in awake or anesthetized patients. Awake insertions are identical in technique to awake upper gastrointestinal endoscopy and should be performed when the patient has an empty stomach. Using a bite block is also important. Probe insertion usually requires topical oral and pharyngeal anesthesia and moderate sedation. The probe is well lubricated, and the function of the directional controls is tested before insertion. The vast majority of patients are able to assist the probe's passage through the pharynx with a swallowing action. The presence of a TEE probe, however, would complicate airway management during anesthetic induction. Thus most anesthesiologists introduce TEE probes in anesthetized patients after tracheal intubation. To improve image quality, evacuating the stomach via suction before probe insertion is also useful.

The passage of a TEE probe through the oral and pharyngeal cavities in anesthetized patients may be challenging at times. The usual technique is to place the well-lubricated probe in the posterior portion of the oropharynx with the transducer element pointing inferiorly and anteriorly. The remainder of the probe may be stabilized by looping the controls and the proximal portion of the probe over the operator's neck and shoulder. The operator's left hand then elevates the mandible by inserting the thumb behind the teeth, grasping the submandibular region with the fingers, and then gently lifting. The probe is then advanced against a slight but even resistance, until a loss of resistance is detected as the tip of the probe passes the inferior constrictor muscle of the pharynx, which usually occurs 10 cm past the lips in neonates to 20 cm past the lips in adults. Further manipulation of the probe is performed under echocardiographic guidance.

Difficult TEE probe insertion may be caused by the probe tip abutting the pyriform sinuses, vallecula, posterior tongue, or an esophageal diverticulum. Overinflation of the endotracheal tube cuff could also obstruct passage of the probe. Maneuvers that might aid the passage of the probe include changing the neck position, realigning the TEE probe, and applying additional jaw thrust by elevating the angles of the mandible. The probe may also be passed with the assistance of laryngoscopy. The probe should never be forced past an obstruction. This could result in airway trauma or esophageal perforation.

Comprehensive Intraoperative Multiplane Transesophageal Echocardiographic Examination

Over the last 3 decades, perioperative TEE has become more recognized as a valuable hemodynamic monitor and diagnostic tool. In 1993, the ASE established the Council for Intraoperative Echocardiography to address issues related to the rapidly increasing utility of TEE in the perioperative period and its important impact on anesthesia and surgical decision making. In 1997, the board members of the Council, along with the SCA, decided to create the *ASE/SCA Guidelines for Performing a Comprehensive Intraoperative Multiplane Examination*,[42] which included the collective endorsement of a standard recommended set of 20 anatomically directed cross-sectional views and the corresponding nomenclature. As implied in the original manuscript published in 1999,[42] these guidelines were established to:

1. Facilitate training in intraoperative TEE by providing a framework in which to develop the necessary knowledge and skills.
2. Enhance and improve the technical quality and completeness of individual studies.
3. Facilitate the communication of intraoperative echocardiographic data among centers to provide a basis for multicenter investigations.
4. Standardize the description of intraoperative echocardiographic data to encourage the industrial development of efficient and rapidly acquiring labeling, storage, and analysis systems.

In 2014, the ASE and SCA updated their recommendations for performing a comprehensive TEE examination that includes 28 recommended views.[43] This document was created with the appreciation of the expanding role of TEE not only intraoperatively, but also in the intensive care unit, interventional laboratory, and outpatient setting. The increasing use of TEE was also recognized for its potential as a diagnostic tool to monitor cardiac performance and as an imaging guide for interventional procedures. Consequently, cardiac surgeons, anesthesiologists, cardiac interventionalists, and clinical cardiologists have all increased their appreciation for TEE as a tool for diagnosing cardiac pathologic conditions, monitoring cardiac performance, and guiding interventional procedures.

The guidelines for the intraoperative TEE examination were not intended to be all-encompassing but rather to serve as a framework for a systematic and complete examination of cardiac and great vessel anatomy of the normal patient and to serve as a baseline for later comparison.[42,43] Although the updated recommendations for performing a comprehensive TEE examination present a suggested protocol of image acquisition, the authors of the document realized that the order

and number of views may differ for various indications. Thus a more thorough intraoperative TEE examination, including the delineation of intracardiac and extracardiac anatomy, a description of congenital heart defects, and qualitative and quantitative Doppler analysis, is recommended and warranted in appropriate patients. Ideally, a complete intraoperative TEE examination not only provides information relevant to the particular diagnosis in question, but it also identifies unanticipated findings that may have a significant impact on perioperative management (ie, patent foramen ovale [PFO], atrial thrombus, severe aortic atherosclerosis).

Multiplane Transesophageal Echocardiographic Probe Manipulation: Descriptive Terms and Technique

The process of obtaining a comprehensive intraoperative multiplane TEE examination begins with a fundamental understanding of the terminology and technique for probe manipulation (Fig. 14.11). Efficient probe manipulation minimizes esophageal injury and facilitates the process of acquiring and sweeping through 2D image planes. Horizontal imaging planes are obtained by moving the TEE probe up and down (proximal and distal) in the esophagus at various depths relative to the incisors (*upper esophageal [UE]*: 20–25 cm; *midesophageal [ME]*: 30–40 cm; *TG*: 40–45 cm; *deep TG*: 45–50 cm). Vertical planes are obtained by manually turning the probe to the patient's left or right. Further alignment of the imaging plane can be obtained by manually rotating one of the two control wheels on the probe handle, which flexes the probe tip to the left or right direction or in the anterior or posterior plane. Multiplane probes may further facilitate interrogation of complex anatomic structures, such as the MV, by allowing up to 180 degrees of axial rotation of the imaging plane without manual probe manipulation.

Comprehensive Intraoperative Transesophageal Echocardiographic Examination: Imaging Planes and Structural Analysis

Left and Right Ventricles

The left ventricle should be examined carefully for global and regional function using multiple transducer planes, depths, and rotational and angular orientations (Fig. 14.12). Although a 17-segment model for assessing regional ventricular function has been developed (Fig. 14.13), the original comprehensive intraoperative TEE examination proposed a regional assessment scheme that required a systematic approach to evaluate each of the 16 individual LV segments: 6 basal, 6 mid, and 4 apical (see Fig. 14.13).[42,43,71] Analysis of segmental function is based on a qualitative visual assessment that includes the following grading system of both LV wall thickness and motion (endocardial border excursion) during systole: 1 = normal (>30% thickening); 2 = mild hypokinesis (10% and 30% thickening); 3 = severe hypokinesis (<10% thickening); 4 = akinesis (no thickening); 5 = dyskinesis (paradoxic motion). The recently recommended ME five-chamber view enables visualization of the septal and lateral walls (slightly anterior) of the left ventricle at 0 to 20 degrees from its base to the apex, along with the left ventricular outflow tract (LVOT), right ventricle and both atria (Table 14.4; see Fig. 14.12 and Video 14.1). Slight TEE probe advancement eliminates the LVOT from the image window and permits the development of the *ME four-chamber* view (see Fig. 14.12, Table 14.4, and Video 14.2), demonstrating a slightly more mid-to-inferior plane. TEE probe rotation to approximately 80 to 100 degrees develops the ME *two-chamber* view (see Fig. 14.12, Table 14.4, and Video 14.3), which removes the right-sided chambers from the imaging window but enables visualization of the inferior and anterior LV walls at the basal, mid, and apical levels segments. The *ME long-axis (LAX)* view at 120 to 160 degrees (see Fig. 14.12, Table 14.4, and Video 14.4) allows evaluation of the remaining anteroseptal and inferolateral (posterior) LV segments. Because the left ventricle is usually oriented inferiorly to the true horizontal plane, slight retroflexion of the probe tip may be required to minimize LV foreshortening. The *TG midpapillary SAX* view *(TG mid-SAX)* at 0 to 20 degrees (see Fig. 14.12, Table 14.4, and Video 14.5) is the most commonly used view for monitoring LV function, because it allows a midpapillary assessment of the LV segments supplied by the corresponding coronary arteries (right coronary artery, left circumflex, and left anterior descending [LAD]). This view also enables qualitative and quantitative evaluation of pericardial effusions. Advancing or withdrawing the probe at the TG depth enables LV evaluation at the respective newly recommended *TG apical SAX* and basal levels (*TG basal SAX*) (see Fig. 14.12, Table 14.4, and Videos 14.6 and 14.7), respectively. Further evaluation of the left ventricle can be obtained at the midpapillary TG depth by rotating the probe forward to the *TG two-chamber* view (80 to 100 degrees) (see Fig. 14.12, Table 14.4, and Video 14.8) and *TG LAX* (90 to 120 degrees) (see Fig. 14.12, Table 14.4, and Video 14.9). Global LV function requires assessment of dilatation (>6 cm at end-diastole), hypertrophy (>1.2 cm at end-diastole), and contractility. A more extensive quantitative evaluation of ventricular performance can be acquired by planimetry measurements of end-diastolic and end-systolic areas from which ejection fraction (EF), ventricular volumes, CO, and mean circumferential shortening can be calculated, which are discussed in greater detail in the following text.

Right ventricular (RV) regional and global function can be assessed from the *ME five-chamber* and *four-chamber* views (see Fig. 14.12, Table 14.4, and Videos 14.1 and 14.2), which allows visualization of the septal and free walls. Although a formal segmental scheme has not been developed for the RV free wall, regional assessment of the septum can be performed. Turning the probe to the right and advancing slightly from the ME depth allows visualization of the tricuspid valve (TV), coronary sinus (CS), and RV apex. Rotating the probe between 60 and

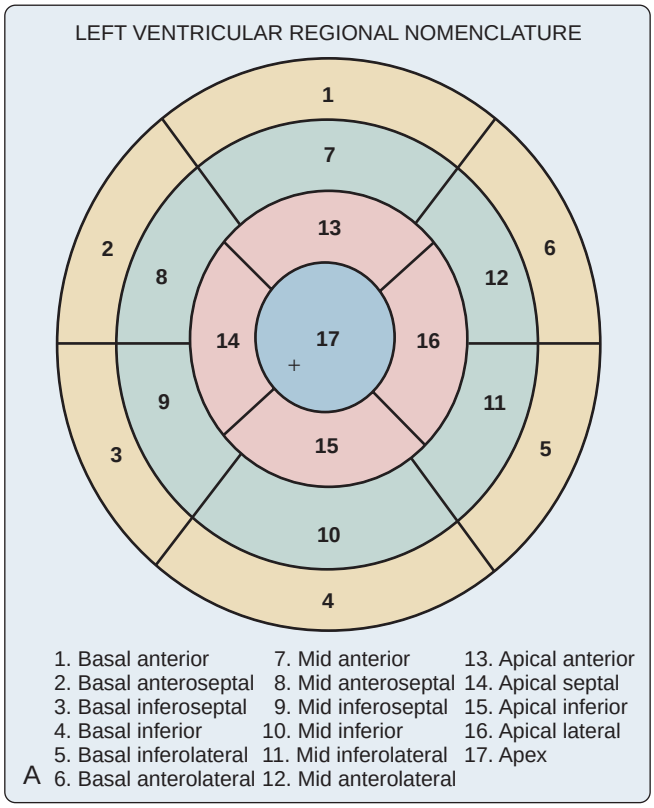
90 degrees reveals the *ME RV inflow-outflow* view (see Fig. 14.12, Table 14.4, and Video 14.10), in which the right atrium (RA), TV, inferior RV free wall, right ventricular outflow tract (RVOT), pulmonic valve (PV), and main pulmonary artery (PA) can be viewed wrapping around the centrally oriented AV. This view often allows optimal Doppler beam alignment to evaluate the TV and can also be helpful for directing PA catheter floating and positioning. The same right-sided structures can also be visualized from a different perspective by advancing the probe to the TG depth to obtain the newly recommended *TG RV inflow-outflow* view (see Fig. 14.12, Table 14.4, and Video 14.11). The *TG midpapillary SAX* view (see Fig. 14.12, Table 14.4, and Video 14.5) displays the crescent-shaped, thinner-walled right ventricle to the left of the left ventricle. Slightly withdrawing the probe reveals the right ventricle at a more basal level along with the PV in the newly recommended TG RV basal view (see Fig. 14.12, Table 14.4, and Video 14.12). The *TG RV inflow* view (see Fig. 14.12, Table 14.4, and Video 14.13) is developed by turning the probe to the right to center the right ventricle at this depth and rotating the multiplane angle forward to 100 to 120 degrees, thereby revealing the inferior RV free wall. Slight anteflexion, advancement, and rotation of the probe back toward 0 degrees can often reveal the RVOT and PV. Despite the asymmetric shape of the right ventricle, global function can still be assessed from the *ME five-chamber* and *four-chamber*, *TG midpapillary* and *RV basal SAX*, *ME RV inflow-outflow*, and *TG RV inflow* views using a quantitative evaluation scheme similar to that previously delineated for the left ventricle. Qualitative echocardiographic findings consistent with a diagnosis of global RV dysfunction include dilatation and hypertrophy, flattened or leftward shift of the atrial and ventricular septum, tricuspid regurgitation (TR), and a dilated CS. The more detailed discussion of RV evaluation appears later in this chapter.

Mitral Valve

The echocardiographic evaluation of the MV requires a thorough assessment of its leaflets (anterior and posterior), annulus, and the subvalvular apparatus (chordae tendineae, papillary muscles, and adjacent LV walls) to locate lesions and to define the cause and severity of the pathophysiologic condition. The mitral leaflets can be further divided into posterior leaflet scallops: lateral (P1), middle (P2), and medial (P3) that correspond with respective anterior leaflet sections: lateral third (A1), middle third (A2), and medial third (A3). The leaflets are



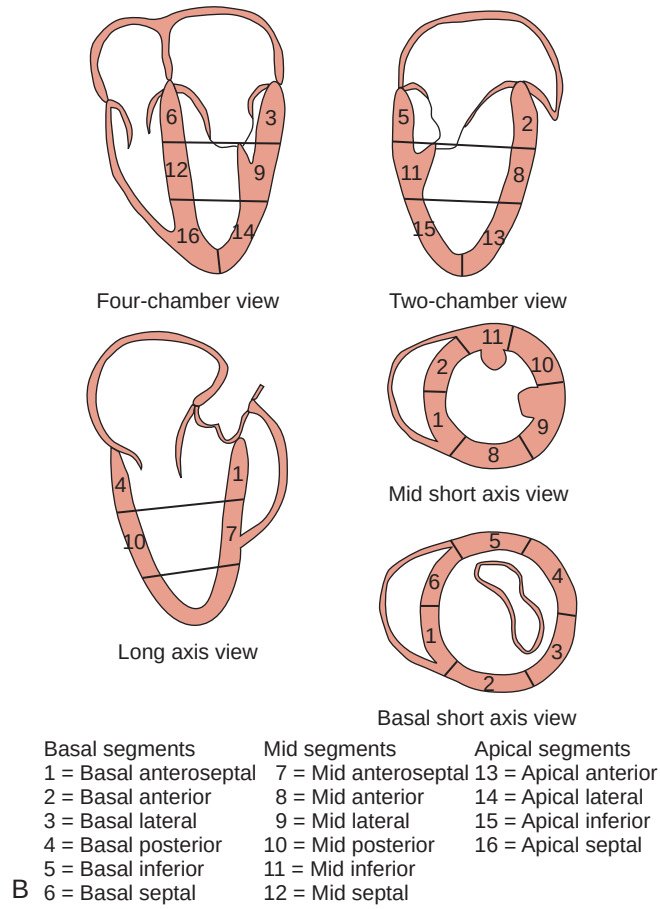


Fig. 14.13 Left ventricular segmental nomenclature. (A) 17 segments. (B) 16 segments.

united at the anterolateral and posteromedial commissures. The *ME four-chamber* view (see Fig. 14.12, Table 14.4, and Video 14.2) displays the larger appearing anterior leaflet (A2,3) to the left of the posterior leaflet (P2,1), whereas the *ME five-chamber* view reveals more of A1 and P1. Anteflexing the probe provides imaging of the anterolateral aspect of the MV, whereas gradual advancement of the probe and retroflexion shift the image plane to the posteromedial aspect of MV. Maintaining the probe at the ME depth and rotating the multiplane angle forward to 60 to 70 degrees develops the *ME mitral commissural* view (see Fig. 14.12, Table 14.4, and Video 14.14), in which A2 is flanked by P1 on the right and P3 on the left, giving A2 the appearance of a "trap-door" as it moves in and out of the imaging plane throughout the cardiac cycle. Farther forward rotation of the probe to 80 to 100 degrees develops the *ME two-chamber* view (see Fig. 14.12, Table 14.4, and Video 14.3), revealing P3 to the left and A1 on the right. Final forward probe rotation to 120 to 160 degrees reveals the *ME LAX* view (see Fig. 14.12, Table 14.4, and Video 14.4), which images P2 on the left and A2 on the right. The *TG basal SAX* view (see Fig. 14.12, Table 14.4, and Video 14.7) enables visualization of both MV leaflets ("fish-mouth view") if the probe is anteflexed and withdrawn slightly from the midpapillary level of the left ventricle. In this view, the posteromedial commissure is in the upper left, the anterolateral commissure is in the lower right, the posterior leaflet is to the right, and the anterior leaflet is to the left of the displayed image. Rotation of the probe to 80 to 100 degrees develops the *TG two-chamber* view (see Fig. 14.12, Table 14.4, and Video 14.8) that is especially useful for evaluating the chordae tendinea and corresponding papillary muscles. Further functional evaluation of the MV requires a quantitative Doppler evaluation (PWD, CWD, and CFD) of transmitral and pulmonary venous flow for assessing MR, stenotic lesions, and LV diastolic function.

Aortic Valve, Aortic Root, and Left Ventricular Outflow

The three cusps of the semilunar AV are best visualized simultaneously in the *ME AV SAX* view (see Fig. 14.12, Table 14.4, and Video 14.15), which is obtained by rotating the probe forward to 30 to 60 degrees. The noncoronary cusp is superior, lying adjacent to the atrial septum; the right cusp is inferior; and the left cusp lies to the right, pointing in the direction of the left atrial appendage (LAA). This view permits planimetry of the AV orifice, evaluation of congenital anomalies of the AV (eg, bicuspid AV), and qualitative assessment of aortic insufficiency (AI) when CFD is used. Withdrawing the probe slightly through the sinuses of Valsalva allows for imaging the right coronary artery inferiorly, and the left main coronary branching into the LAD coronary artery and left circumflex. The *ME AV LAX* view (see Fig. 14.12, Table 14.4, and Video 14.16) can be obtained at the same depth while rotating the probe to 120 to 160 degrees, allowing for visualization of the LVOT, AV annulus, and leaflets (right and either noncoronary or left), sinuses of Valsalva, sinotubular junction, and proximal ascending aorta. This view is particularly useful for evaluating AI with CFD, systolic anterior motion of the MV, and proximal aortic pathologic conditions (eg, dissections, aneurysms). The same structures can be viewed from a different perspective in the *ME five-chamber* view at 0 to 20 degrees. Rotating the probe back to 90 to 120 degrees and advancing into the stomach to TG level develops the *TG LAX* view (see Fig. 14.12, Table 14.4, and Video 14.9). In this view, the LVOT and AV are oriented to the right and inferiorly in the displayed image, thereby providing an optimal window for parallel Doppler beam alignment for the assessment of flows and pressure gradients (aortic stenosis [AS], hypertrophic obstructive cardiomyopathy). Rotating the probe back farther to 0 to 20 degrees, advancing deep into the stomach, and anteflexing the tip so that it lies adjacent to the LV apex, allows for the development of the *deep TG LAX* view, now referred to as the *deep TG five-chamber* view (see Fig. 14.12, Table 14.4, and Video 14.17), which also provides optimal Doppler beam alignment for measuring transaortic valve and LVOT flow velocities and may provide an additional window for assessing flows through muscular ventricular septal defects and LV apical pathologic conditions (thrombus, aneurysms).

Tricuspid Valve

The echocardiographic evaluation of the TV requires a thorough assessment of its three leaflets (anterior, posterior, and septal), annulus, chordae tendinea, papillary muscles, and the corresponding RV walls. In the *ME five-chamber* view, the septal TV leaflet is displayed on the right side and the anterior leaflet is usually on the left side of the annulus. Advancing the probe slightly reveals the *ME four-chamber* view (see Fig. 14.12, Table 14.4, and Video 14.2), with the septal TV leaflet on the right side and the posterior TV leaflet usually on the left side of the annulus. Rotating the multiplane angle to 50 to 70 degrees develops the *ME RV inflow-outflow* view (see Fig. 14.12, Table 14.4, and Video 14.10), which displays the posterior TV leaflet on the left side of the image and the anterior TV leaflet on the right side of the image adjacent to the AV. Slightly turning the probe rightward from the *ME bicaval* view permits the development of the newly recommended *ME-modified bicaval TV* view (see Fig. 14.12, Table 14.4, and Video 14.18) with the anterior leaflet on the right and the posterior leaflet on the left. The ME-modified bicaval view often provides better alignment of a CWD beam with a TR jet for estimating pulmonary artery pressures (PAPs). The *TG RV inflow* view (see Fig. 14.12, Table 14.4, and Video 14.13) is obtained by advancing the probe into the stomach and rotating to 100 to 120 degrees. This view is ideal for visualizing the chordae tendinea and papillary muscles in the right ventricle. Rotating back to the *TG mid-SAX* at 0 to 20 degrees and slightly withdrawing the probe to obtain the *TG RV basal* view provides a cross-sectional, SAX view of the TV, displaying the anterior leaflet in the far field, the posterior leaflet to the left in the near field, and the septal leaflet on the right side of the image. A more extensive quantitative analysis of TV pathophysiologic condition requires the use of Doppler echocardiography (PWD, CWD, and CFD) by aligning the beam parallel to transtricuspid flow in the *ME four-chamber* view, *ME RV inflow-outflow* view, or *ME-modified bicaval* view.

Pulmonic Valve and Pulmonary Artery

The PV is a trileaflet, semilunar valve. The *ME AV SAX* view (see Fig. 14.12, Table 14.4, and Video 14.15) displays the transition between the RVOT and PV. Rotating the probe back toward 0 degrees and withdrawing slightly develops the *ME ascending aortic SAX* view (see Fig. 14.12, Table 14.4, and Video 14.19) displaying the transition between the PV and the main PA and its bifurcation. Although the right PA is usually easy to visualize by turning the probe to the right, the left PA is often obscured by the interposing, air-filled, left mainstem bronchus. This view can be used in the Doppler echocardiographic assessment of a PV pathophysiologic condition because of the parallel alignment of the beam relative to the flow and can also be used to locate pulmonary emboli. The *ME RV inflow-outflow* view (see Fig. 14.12, Table 14.4, and Video 14.10) can also be used to assess the PV and main PA, which lie on the right side of the image adjacent to the AV, although the newly recommended *TG RV inflow-outflow* view (see Fig. 14.12, Table 14.4, and Video 14.11) with the PV on the right side of the screen and the more reliable *upper esophageal (UE) aortic arch SAX* view (see Fig. 14.12, Table 14.4, and Video 14.20), which displays the PV oriented to the left of the cross-sectional view of the aortic arch and usually provides a more parallel Doppler beam orientation through for the evaluation of pulmonic regurgitation or stenosis. Withdrawing the probe slightly in the *deep TG five-chamber* view (see Fig. 14.12, Table 14.4, and Video 14.17), in combination with slight anteflexion and turning to the right, can often allow visualization of the RVOT and PV to the left in the far field and provide an alternative imaging plane for Doppler echocardiographic evaluation in patients with subpulmonic and PV pathologic conditions.

Left Atrium, Left Atrial Appendage, Pulmonary Veins, and Atrial Septum

The left atrium is the closest cardiac structure to the TEE probe when positioned in the esophagus. Consequently, the left atrium is usually easily displayed in the superior aspect of the 2D image sector. The *ME five-chamber* and *four-chamber* views (see Fig. 14.12, Table 14.4, and Videos 14.1 and 14.2) display the left atrium almost in its entirety with the LAA oriented to its superior and lateral aspects when the probe is slightly withdrawn. The muscular ridges of the pectinate muscles within the LAA should not be confused with thrombi. A slightly farther withdrawal of the probe, turning it to the left, and rotating the array to approximately 90 degrees, develops the newly defined *UE left pulmonary vein view* (see Fig. 14.12, Table 14.4, and Video 14.21), which allows the left upper pulmonary vein (LUPV) to be imaged as it enters the left atrium from the anterior-to-posterior direction and separated from the lateral border of the LAA by the *warfarin ridge*. In contrast with the LUPV, which is usually optimally aligned for parallel Doppler beam alignment, the left lower pulmonary vein (LLPV) enters the left atrium just below the LUPV in a lateral-to-medial direction and is more perpendicularly aligned. Pulmonary venous Doppler-flow velocity profiles are useful for the qualitative and quantitative assessment of LV diastolic function. Turning the probe to the right at this depth reveals the newly defined *UE right pulmonary* view (see Fig. 14.12, Table 14.4, and Video 14.21), and a slight advancement and rotation of the array to 0 degrees permits visualization of the newly defined *ME right pulmonary vein* view (see Fig. 14.12, Table 14.4, and Video 14.22), which both reveal the right upper pulmonary vein (RUPV) entering the left atrium in an anterior-to-posterior direction and the right PA or superior vena cava (SVC), respectively. The right lower pulmonary vein (RLPV) can sometimes be visualized as it enters perpendicular to the LAX of the left atrium by slightly advancing the probe. The interatrial septum (IAS), consisting of thicker limbus regions flanking the thin fossa ovalis, can also be imaged in the *ME four-chamber* view (see Fig. 14.12, Table 14.4, and Video 14.2). Benign lipomatous hypertrophy of the IAS must be distinguished from pathologic lesions such as atrial myxomas. The patency of the IAS and the presence of a PFO or congenital atrial septal defects (ASDs) should be assessed with Doppler echocardiography and intravenous injections of agitated saline. Advancing and rotating the probe to 80 to 100 degrees develops the *ME two-chamber* view (see Fig. 14.12, Table 14.4, and Video 14.3), which allows for further imaging of the left atrium from left to right. The LAA and LUPV can be seen by turning the probe slightly to the left to develop the newly defined *ME LAA* view (see Fig. 14.12, Table 14.4, and Video 14.23). Rotating the probe to the right at this level and adjusting the multiplane angle to 80 to 110 degrees will develop the *ME bicaval* view (Fig. 14.12 and Table 14.4; see Video 14.24), which delineates the SVC entering the RA to the right of the image and the inferior vena cava (IVC) entering from the left. The IAS can be seen in the middle of the image separating the left and right atria. The RUPV and the RLPV can usually be seen if the probe is turned farther to the right just beyond the point at which the LAX of the SVC can no longer be visualized. This transition of images can also be used in conjunction with Doppler echocardiography to identify sinus venosus ASDs and anomalous pulmonary venous return.

Right Atrium and Coronary Sinus

The RA can be most easily visualized in the *ME five-chamber* and *ME four-chamber* views (see Fig. 14.12, Table 14.4, and Videos 14.1 and 14.2) by turning the probe to the patient's right side, as well as in the *ME RV inflow-outflow* view (see Fig. 14.12, Table 14.4, and Video 14.10). In these views, the entire RA can be visualized for size, overall function, and the presence of masses (thrombi, tumors). Rotating the multiplane angle to 80 to 110 degrees develops the *ME bicaval* view (see Fig. 14.12, Table 14.4, and Video 14.24), which displays the RA and its internal structures (Eustachian valve, Chiari network, crista terminalis). The SVC can be imaged entering the RA on the right, superior to the right atrial appendage, and the IVC enters the RA on the left of the display. Advancing and turning the probe to the right will allow for a qualitative evaluation of the intrahepatic segment of the IVC and hepatic veins. At the TG depth, both the *TG RV inflow-outflow* and *TG RV inflow* views may provide more optimal imaging windows for visualizing the RA and collateral structures. Pacemaker electrodes and central venous catheters for hemodynamic monitoring or CPB can be easily imaged in this view.

The CS lies posteriorly in the atrioventricular groove, emptying into the RA at the inferior extent of the atrial septum. The CS can be viewed in LAX entering the RA just superior to the tricuspid annulus by advancing and slightly retroflexing the probe from *ME four-chamber* view (see Fig. 14.12, Table 14.4, and Video 14.2). The CS can be imaged cross sectionally in the SAX in the *ME two-chamber* view (see Fig. 14.12, Table 14.4, and Video 14.3) in the upper left of the display. Turning the probe to the left in this view often allows visualization of the CS in the LAX as it traverses the atrioventricular groove. The CS and thebesian valve can also be visualized in the *ME-modified bicaval* view (see Fig. 14.12, Table 14.4, and Video 14.18) on the upper left of the image as it enters the RA at an obtuse angle. Echocardiographic visualization of the CS can be useful for directing the placement of CS catheters used for CPB.

Thoracic Aorta

The proximal and midascending thoracic aorta can be visualized in the SAX in the *ME ascending aortic SAX* view (see Fig. 14.12, Table 14.4, and Video 14.19). Advancing and withdrawing the probe should enable visualization of the thoracic aorta from the sinotubular junction to a point 4- to 6-cm superior to the AV and allow an inspection for aneurysms and dissections. Rotating the multiplane angle to 100 to 150 degrees develops the *ME ascending aortic LAX* view (see Fig. 14.12, Table 14.4, and Video 14.25), which optimally displays the parallel anterior and posterior walls for measuring proximal and midascending aortic diameters. This display can also be obtained from the *ME AV LAX* view (see Table 14.4, Fig. 14.6, and Video 14.6) by slightly withdrawing and turning the probe to the left.

TEE imaging of the aortic arch is often obscured by the interposing, air-filled trachea. The most optimal views of the aortic arch are obtained by withdrawing the probe from the *ME ascending aortic SAX* view at 0 degrees (see Fig. 14.12, Table 14.4, and Video 14.19) and rotating to the left to obtain the *UE aortic arch LAX* view (see Fig. 14.12, Table 14.4, and Video 14.26), which displays the proximal arch followed by the mid-arch, the great vessels (brachiocephalic, left carotid artery, and left subclavian artery), and the distal arch before it joins the proximal descending thoracic aorta imaged in cross section. Alternatively, rotating the probe to 90 degrees develops the *UE aortic arch SAX* view (see Fig. 14.12, Table 14.4, and Video 14.20). Turning the probe to the left in this view delineates the transition of the distal arch with the proximal descending thoracic aorta. Turning the probe to the right and slightly withdrawing it will allow for the mid-arch and great vessels to be imaged on the right side of the screen, followed by the distal ascending aorta when the probe is subsequently advanced and rotated forward to the 120-degree *ME ascending aortic LAX* view (see Fig. 14.12, Table 14.4, and Video 14.25). Epiaortic aortic scanning may be particularly useful for assessing the extent of ascending aortic and arch pathologic conditions (ie, aneurysms, dissection, atherosclerosis) to determine cross-clamping and cannulation sites for CPB.

A SAX image of the descending thoracic aorta is obtained by turning the probe leftward from the *ME four-chamber* view to produce the *descending aortic SAX* view (see Fig. 14.12, Table 14.4, and Video 14.27). Rotating the multiplane angle of the probe from 0 to 90 to 110 degrees produces an LAX image, the *descending aortic LAX* view (see Fig. 14.12, Table 14.4, and Video 14.28). The descending thoracic aorta should be interrogated in its entirety, beginning at the distal aortic arch, by continually advancing the probe and turning slightly to the left until the celiac and superior mesenteric arteries are visualized branching tangentially from the anterior surface of abdominal aorta when the probe is in the stomach. A thorough examination of the descending thoracic aorta may be necessary to evaluate the distal extent of an aneurysm or dissection. In addition, the *descending aortic SAX* and *LAX* views can be useful for confirming appropriate intraaortic balloon positioning.

Anatomic Variants and Artifacts

Anatomic variants may be confused as pathologic conditions. Ultrasound-based artifacts are imaging defects related to the physics of ultrasound, leading to the generation or alteration of structures.

Anatomic Variants

Right Atrium

The RA is a common source of normal anatomic variations; many of these structures are embryologic remnants, which may be confused with thrombi or masses. The Eustachian valve is formed in utero and directs oxygenated blood from the IVC toward the PFO. If this structure fails to regress into adulthood, then it can be most commonly visualized in an ME bicaval view as a variable-length, thin structure emanating from the junction of the IVC and RA (see Fig. 14.14 and Video 14.29). Although the Eustachian valve may be misinterpreted as a thrombus, it may be a source of infective endocarditis or associated with increased incidence of a PFO.[72,73] A sinus venosus remnant also emanating from the IVC-RA junction is the Chiari network (see Fig. 14.15 and Video 14.30). In contrast with the Eustachian valve, the Chiari network is a highly mobile and fenestrated structure and is strongly associated with a PFO and atrial septal aneurysms.[72]

The crista terminalis is a fibromuscular ridge located at the SVC-RA junction, separating the smooth posterior from the anterior trabeculated RA segment including the RA appendage; this structure may be seen best in the ME bicaval view (see Fig. 14.16 and Video 14.31). This ridge of tissue may vary in size. When the crista terminalis is large, it may appear as a pedunculated mass and misinterpreted as a thrombus or tumor. Lipomatous hypertrophy of the IAS may be appreciated in the ME bicaval view (see Fig. 14.17 and Video 14.32). This lipomatous hypertrophy is a collection of adipose tissue in the IAS that spares the thin fossa ovalis (septum primum), creating a classical "dumb-bell" shape. The enlarged septum may be misdiagnosed as a cardiac tumor such as an atrial myxoma. Another cause of enlarged atrial septum is hematoma infiltrating the fibrous skeleton of the heart after valvular surgery.

The ME-modified bicaval view is often used to identify the CS on the left side of the screen and is particularly useful for CS catheter placement. Some patients may possess a small valve called the thebesian valve that allows blood returning from the coronary venous circulation to enter the RA (see Fig. 14.18 and Video 14.33). This valve may interfere with the placement of the CS retrograde cardioplegia catheters.

A persistent left superior vena cava (PLSVC) is a congenital anomaly of the thoracic venous system. Instead of drainage into the left innominate vein and subsequently into the right SVC, the left arm and neck drain into a PLSVC with continuation into the CS. This variation may

be suspected echocardiographically as a dilated CS entering the RA (see Fig. 14.19 and Video 14.34). In this setting, the CS often measures greater than 1 centimeter in diameter. In an ME four-chamber view, the dilated CS may be observed to the right of the left atrium. Diagnosis of a PLSVC may be confirmed via contrast (agitated saline) injection into a left arm vein.[74]

Right Ventricle

The right ventricle, similar to the right atrium, has a smooth inflow and a trabeculated free wall and apex. When hypertrophied, the trabeculations may become large and confused with thrombus. In addition to the trabeculations, several muscular bands encircle the right ventricle. The moderator band is most prominent and is easily identified echocardiographically in multiple RV views (see Fig. 14.20 and Video 14.35). This muscular band, which contains the right bundle branch, connects the RV free wall to the interventricular septum (IVS) and may be identified in the four-chamber view as a muscular structure attached to either the RV free wall or septum.[75]

Left Atrium

The left superior pulmonary vein is separated from the LAA by a small ridge of tissue commonly visualized in the ME two-chamber view (see Fig. 14.21 and Video 14.36). This ridge, termed the *ligament of Marshall*, is commonly known as the *Coumadin ridge* because of its history of being misdiagnosed as an atrial clot with subsequent inappropriate use of anticoagulation therapy. Its appearance echocardiographically is variable but may extend into the left atrium and be confused with an atrial thrombus.

Left Ventricle

Although smoother than the RV endocardial surface, the left ventricle is also trabeculated. With hypertrophy, these trabeculations may be mistaken for intracavitary thrombus. Although less commonly identified and finer in size, the left ventricle may have intracavitary bands similar to the moderator band of the right ventricle. These bands, termed *false tendons*, typically have little clinical significance and are often identified near the apex of the left ventricle in an *ME four-chamber* view (see Fig. 14.22 and Video 14.37).

Aortic Valve

A few normal AV anatomic variants may lead to misdiagnoses of endocarditis, cardiac masses, or thrombus. Nodules of Arantius may be identified as thickened central areas on the AV leaflets (see Fig. 14.23 and Video 14.38). Although clinically insignificant, they may become hypertrophied and confused with cardiac masses. Lambl excrescences are thin projections of fibrous tissue that are covered by a layer of endothelial cells, extending most commonly from the AV and identified echocardiographically upon valve closure (see Fig. 14.24 and Video 14.39). In an ME AV LAX view, they are most often identified as thin mobile structures, extending into the aortic lumen from the AV leaflets. They are clinically insignificant; however, they may rarely develop larger *fronds* that may embolize and create clinically significant cerebral sequelae that requires anticoagulation or resection.[76] Papillary

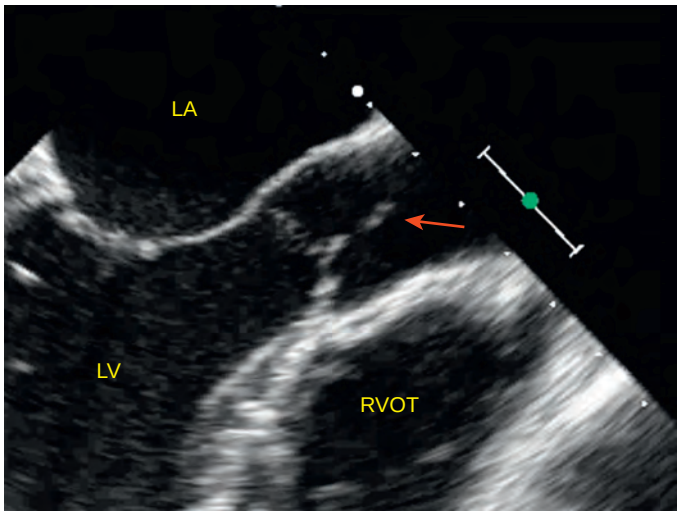

Fig. 14.24 Midesophageal long-axis view. The *red arrow* indicates a Lambl excrescence, the long filamentous mobile structure emanating from the aortic valve closure. *LA,* Left atrium; *LV,* left ventricle; *RVOT,* right ventricular outflow tract. (Video clip available online.)

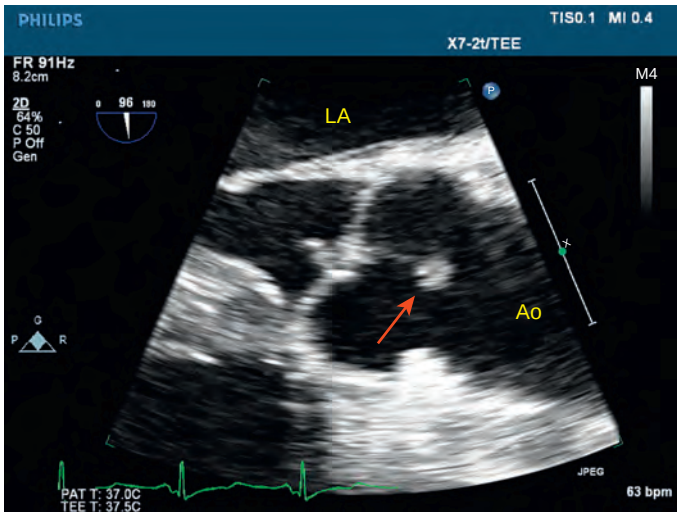

Fig. 14.25 Midesophageal aortic valve long-axis view. The *red arrow* indicates a papillary fibroelastoma, a pedunculated and mobile mass attached to the aortic valve. *LA,* Left atrium; *Ao,* ascending aorta. (Video clip available online.)

fibroelastomas, benign tumors, are thicker or larger than Lambl excrescences and carry a significantly higher rate of thromboembolism. These mobile pedunculated masses are also often identified along the line of valve closure; however, they are identified as a mass on a *stalk,* as opposed to the linear adherent structure of a Lambl excrescence (see Fig. 14.25 and Video 14.40). As a result of an increased embolism risk, they require surgical resection.[77] Finally, if the AV cups are imaged en face, the normally thin aortic cusp may appear as a mass on the valve attributable to this imaging artifact (see Fig. 14.26 and Video 14.41).[78]

Pericardium

The pericardium is a saclike structure that surrounds the cardiac structures, as well as the great vessels entering and leaving the heart. The pericardium has areas of reflections where it is folded on itself, creating sinuses. Generally, this is not apparent echocardiographically until a small amount of pericardial fluid collects, creating an echo-free space within the reflections. The transverse sinus is located posterior to the ascending aorta and anterior to the left atrium, most commonly

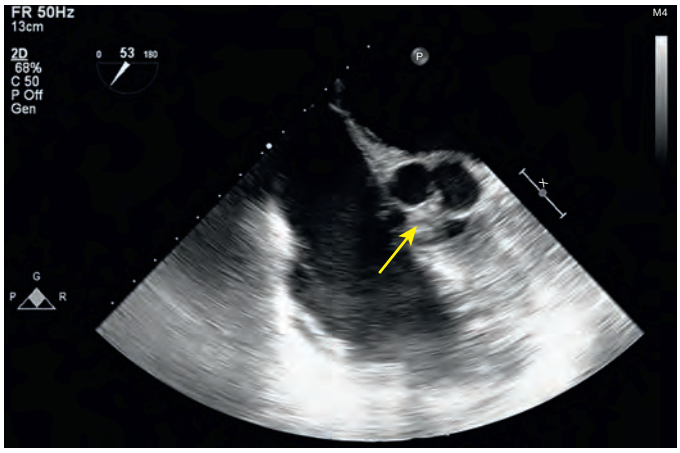

Fig. 14.26 Midesophageal aortic valve short-axis (off angle) view. The right coronary cusp of the aortic valve *(yellow arrow)* is imaged en face, so it appears as a mass. Other views through the aortic valve are normal.

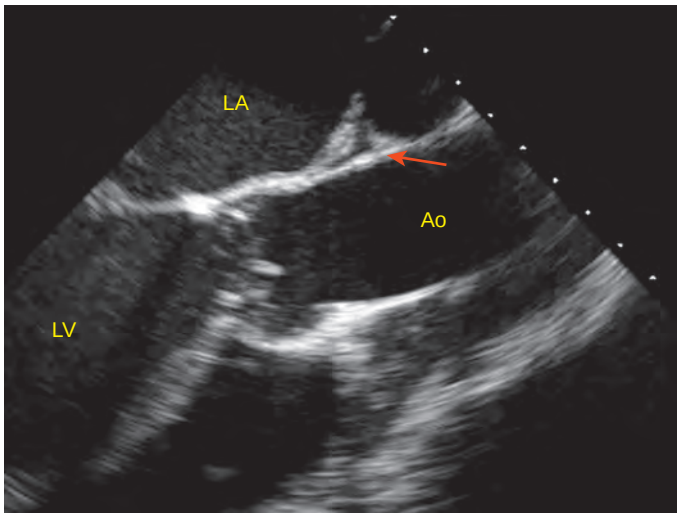

Fig. 14.27 Midesophageal long-axis view. The *red arrow* indicates the transverse sinus, a small echolucent area between the ascending aorta and the left atrium *(LA)* in a patient with a trivial pericardial effusion. *LV,* Left ventricle; *Ao,* ascending aorta. (Video clip available online.)

identified in the ME LAX view as an echolucent area and occasionally containing some fat pieces (see Fig. 14.27 and Video 14.42). The echolucent area may be confused with a cardiac abscess. Another pericardial reflection, the oblique sinus, may be observed when pericardial fluid collects, leading to an echocardiographic lucent area posterior to the left atrium and pulmonary veins.

Imaging Artifacts

Imaging artifacts may result in brightness errors or factual errors. Acoustic shadowing results in a loss of ultrasound energy with a resultant dark image distant to the object that is causing the shadowing. Acoustic impedance is a function of the density of tissue and the speed of ultrasound in that tissue; the greater the difference in the acoustic impedance, the greater the reflected signals. Acoustic shadowing occurs when a large difference in acoustic impedance at a given interface occurs. When ultrasound reaches structures with an acoustic impedance significantly different than water (eg, calcium prosthetic valves, air), a large amount of ultrasound is reflected back toward the ultrasound probe, leaving little to no ultrasound to penetrate deeper structures (see Fig. 14.28 and Video 14.43). The result is a highly echogenic structure with echolucent shadows distant to the structure. Alternate views must be used to image the shadowed structure. Attenuation

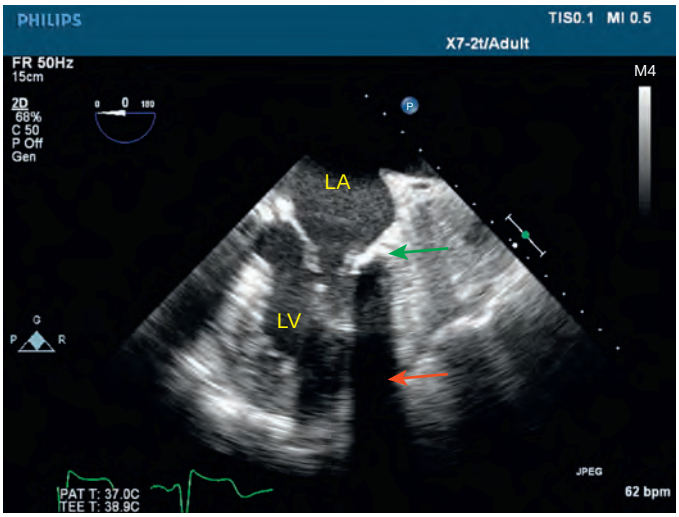

Fig. 14.28 Midesophageal five-chamber view with slight left probe rotation. The *green arrow* indicates a heavily calcified posterior leaflet of the mitral valve, whereas the *red arrow* indicates the area of distal acoustic shadowing, secondary to the more proximal highly reflective calcium. *LA,* Left atrium; *LV,* left ventricle. (Video clip available online.)

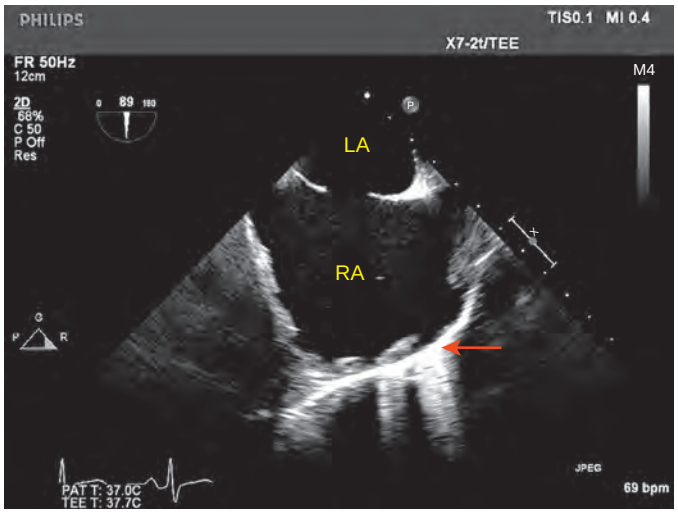

Fig. 14.29 Midesophageal bicaval view of a patient with a secundum atrial septal defect. The large right atrium allows more ultrasound energy to penetrate deeper, causing enhancement of the deeper pericardium *(red arrow). LA,* Left atrium; *RA,* right atrium. (Video clip available online.)

refers to the loss of ultrasound energy with resultant darker images. As ultrasound energy propagates, some of the energy will be lost from reflection, absorption, or refraction and not available for reflection back to the ultrasound probe. This attenuation results in objects that are more distant from the probe becoming progressively darker. The degree of attenuation may be controlled by adjusting the ultrasound frequency. Although lower frequencies result in a lower resolution, attenuation is also decreased, allowing for insonation of more distant structures.

To produce ultrasound signals, the piezoelectric crystals vibrate at a high frequency. Although the vibrations of the crystals are a necessary component of ultrasound wave generation, they may interfere with image formation close to the transducer, resulting in near-field clutter. This artifact is commonly seen during epiaortic ultrasonography when a phase-array probe is held on the anterior surface of the ascending aorta. The near-field clutter limits the anterior wall imaging. This clutter may be eliminated by using an echolucent spacer between the transducer and the object of interest; as a result, the objects are physically removed from the very near field of the transducer.

Alternatively, other imaging artifacts may result in bright images. If a superficial structure is either a weak reflector or has reduced attenuation, then ultrasound energy will not be reflected back to the transducer; therefore more ultrasound energy is available for more distant structures. This increased energy availability results in a bright display of deeper structures (Fig. 14.29; see Video 14.44). Gain or TGC may be used to optimize the image. Noise plays a role in ultrasound imaging. Excessive gain settings not only increase the brightness of the returning signals but also the brightness of any noise in the system. This amplification of returning noise leads to excessive areas of brightness where little to no signal is expected (Fig. 14.30; see Video 14.45). Electrocautery is another common source of noise in the surgical unit.

Ultrasonic imaging requires a direct line of propagation to and from the target. The depth of the target is determined by the time it takes for the ultrasound signal to return to the ultrasound transducer. A strong specular reflector, such as a prosthetic valve, may cause some ultrasound to reflect at an angle, rather than back toward the probe. If the ultrasound subsequently reflects off another object and then toward the ultrasound probe, then an artifact will be displayed. Termed *multipath*, the increased time to reflect back to the ultrasound probe will be interpreted by the machine as being along the same path as the first target, however deeper in position (Fig. 14.31). This imaging

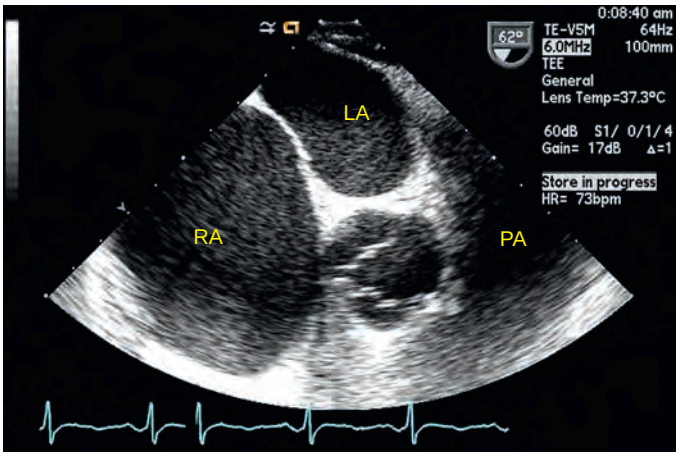

Fig. 14.30 Midesophageal right ventricular inflow-outflow view of patient with severe right atrial enlargement. Note the excessive gain, causing a "washed-out" appearance of myocardial tissue, as well as echogenicity of blood-filled chambers that should typically be echolucent. This artifact can cause the misdiagnosis of spontaneous echocardiographic contrast and the risk of thrombus formation. *LA,* Left atrium; *PA,* pulmonary artery; *RA,* right atrium. (Video clip available online.)

artifact therefore produces an artifactual area of echogenicity that is not truly present.

If a pencil is inserted into a cup of water and viewed at an oblique angle, then it will appear bent because of light refraction. Ultrasound refraction is similar to multipath; however, the ultrasound beam bends when passing through an object at an oblique angle. If this refracted ultrasound reflects off another object and returns to the probe, then the ultrasound machine will display the object as if it were along the originally delivered ultrasound pathway (Fig. 14.32).

When a structure is imaged, the ultrasound pulse is reflected once by the structure back to the ultrasound probe. Reverberation, ringing, and mirror artifact occur when the ultrasound is trapped, causing a to-and-fro reflection within the object. If the object is thin, such as bronchial rings or aortic calcifications, then the trap will be thin and the back-and-forth reflection will result in multiple reflections returning to the ultrasound probe. These multiple reflections, termed *ringing*, will appear as a bright flashlight artifact extending from the structure

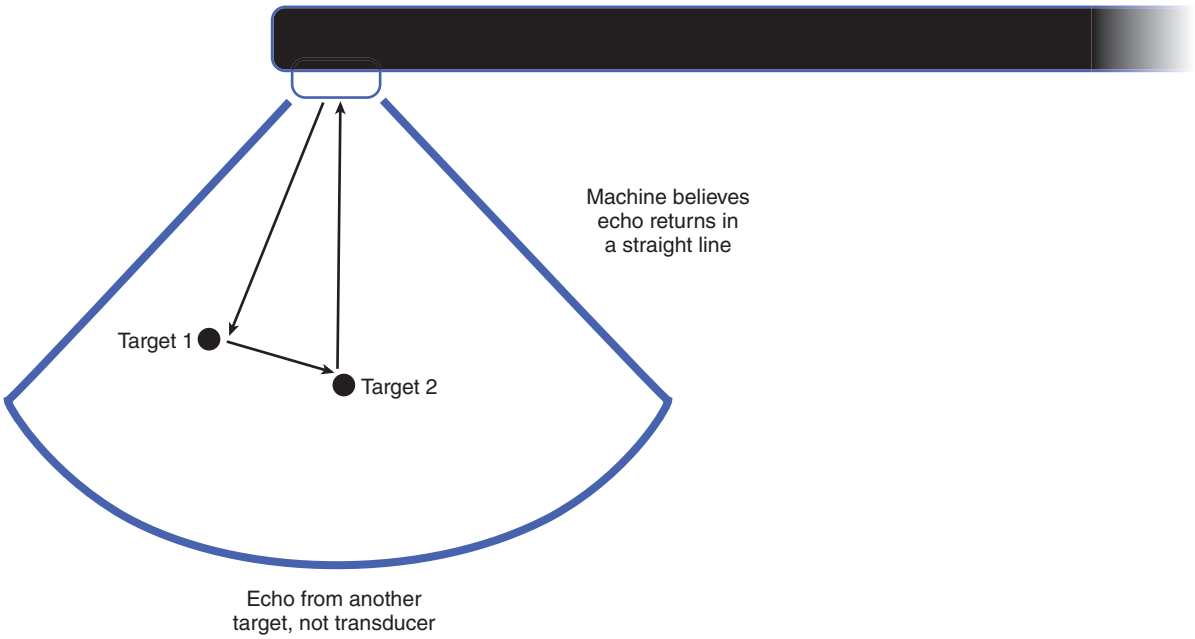

Fig. 14.31 Multipath artifacts involve ultrasound energy reflecting between two objects before returning to the ultrasound probe. The delay in the ultrasound returning to the machine causes the software to interpret and display the reflected energy deeper along the initial ultrasound path.

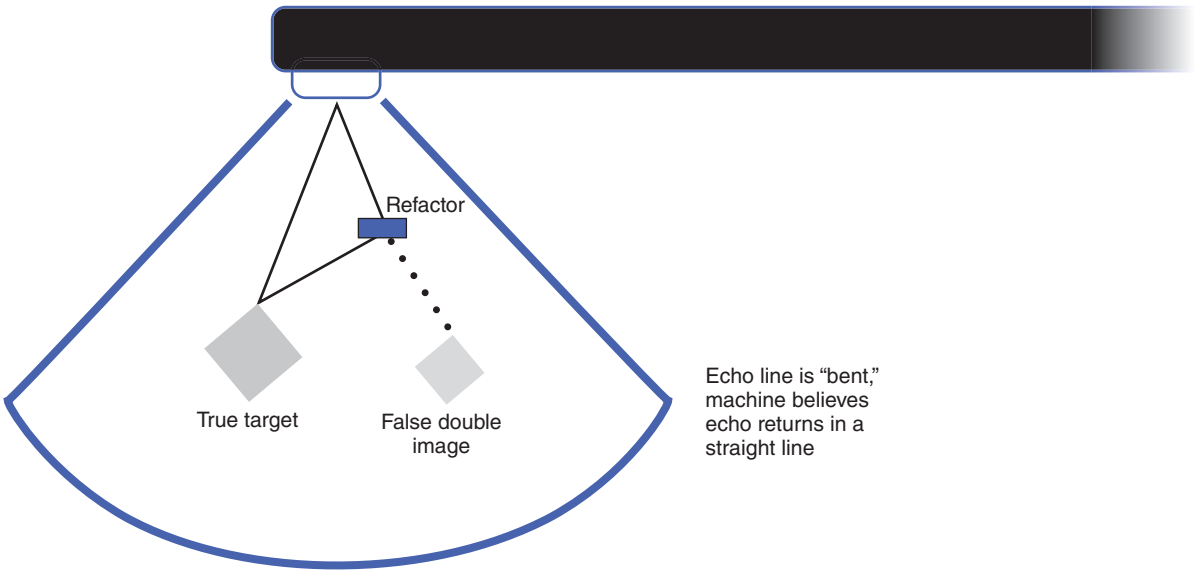

Fig. 14.32 Refraction artifacts involve ultrasound waves being bent as they are transmitted through the object at an oblique angle. In this example, some of the off-axis ultrasound energy is refracted toward the probe, leading to the generation of an artifact image along another angled pathway.

with impairment of imaging deeper to the structure (Fig. 14.33; see Video 14.46). If the trap is larger, such as the two sides of the aortic wall, then the ringing between the walls delays the ultrasound returning to the probe, yielding a second image of the aortic walls distal to the first returned signals. Termed *mirror artifact*, the displayed image will contain a duplicate structure distal to the properly displayed structure, such as a "double-barrel aorta" (Fig. 14.34). In addition to the anatomic structures, the surface of the ultrasound probe itself may act as a trap, creating both ringing and mirror artifacts.

The ultrasound machine software assumes that the transmitted and reflected ultrasound waves are propagated linearly and originate from the center of the probe. This assumption is not entirely true. The ultrasound signal is actually emitted as multiple radiation lobes at various angles from the probe's aperture with the energy summed in constructive and destructive patterns. The main beam contains the largest constructive pattern with decreasing intensity in the side lobes with increased angle of production; therefore most of the imaging occurs from the stronger central main lobe (Fig. 14.35). A strong reflector in the territory of the weaker side lobe may return to the probe; however, the software will inappropriately display the structure within the intended main lobe display area, which is termed *side-lobe artifact*. These side-lobe artifacts often occur within a generally echolucent area. For example, a side-lobe artifact of a central venous catheter may be displayed within the echolucent ascending aorta and misinterpreted as an aortic dissection. As the beam oscillates to display a single frame, multiple side-lobe artifacts may yield an imaging artifact with a curved

appearance (Fig. 14.36). Grating lobes are a type of side lobe when the ultrasound elements are spaced larger than one half of the wavelength, leading to larger angular lobes. This artifact is not usually encountered because ultrasound manufacturers ensure the spacing is appropriate for the typical wavelengths used.

An object may appear in an incorrect location because of range ambiguity. After initiating an ultrasound pulse, the machine spends time "listening" for the returning ultrasound signal. If a prior ultrasound signal returns from a deep structure while listening from a subsequent ultrasound pulse, then the signal may be interpreted as being in a significantly more shallow location (Fig. 14.37).

Clinical Applications

Left Ventricular Assessment

Assessment of Left Ventricular Size

Measurements of LV size may be performed using M-mode or 2D or 3D measurements[79] (Table 14.5). When performing measurements of internal linear diameters, measurements should be taken perpendicular to the LV LAX at or immediately below the level of the MV leaflet tips. M-mode measurements allow for a high temporal resolution that provides reproducible measurements; however, measurements may only be performed in a single axis and are commonly off axis. Two-dimensional measurements of ventricular diameter provide additional information concerning axis alignment, thereby increasing the accuracy of the measurements. This 2D measurement is only representative if the left ventricle is normally shaped.

Early in the development of echocardiography, Feigenbaum and colleagues[80] compared echocardiographic and angiographic volumes to show that M-mode echocardiographic measurements were related to actual ventricular size by cubing single M-mode echocardiographic dimensions and comparing them with their angiographic equivalents. Although reasonably good correlations were obtained, they never intended to use M-mode ventricular diameters for the actual, clinical measurements of ventricular volumes.

LV volume measurements may be with biplane disk summary or area-length measurements using 2D echocardiography or using 3D data sets. Because volume estimations of LV volume from linear measurements assume a fixed geometry LV shape, volume calculations from linear measurements (such as the Teichholz and Quinones methods) are no longer recommended for clinical use in the 2015 ASE guidelines.[79] Since the biplane disk summation method (modified Simpson method) corrects for shape distortions, it is currently the recommended method of 2D volume measurements. With biplane disk summation, the total LV volume is calculated from the summation of a stack of elliptical disks. The height of each disk is calculated as a fraction of the LV LAX, based on the longer of the two lengths from the two- and four-chamber views. The cross-sectional area (CSA) of the disk is based on the diameters obtained, and the volume of the disk is estimated. The volume is obtained by the summation of these values (Fig. 14.38). In contrast, the area-length method assumes a bullet-shaped ventricle; this assumption is not always accurate. Both of these 2D methods may be limited by apex foreshortening, which decreases the accuracy of the measurement.

Although these approximations result in an acceptable calculation of LV volumes in the elliptically shaped normal left ventricle, it is not accurate for the pathologic ventricle. Additionally, the placement of the 2D plane can be subject to positioning errors, which may lead to chamber foreshortening that can lead to measurement errors even in a normally configured left ventricle. Measurements using 3D data sets are not restricted by geometric assumptions nor are they effected by ventricular foreshortening (Fig. 14.39). Studies comparing LV volumes

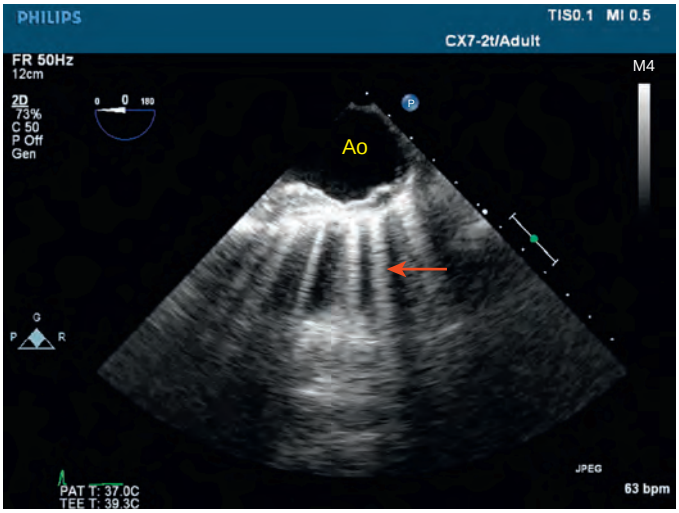

Fig. 14.33 Descending aortic short-axis view in a patient with grade IV atheromatous disease. Note the ringing artifact with bright "flashlight beams" extending from the aortic wall *(red arrow)*. *Ao,* Descending aorta. (Video clip available online.)

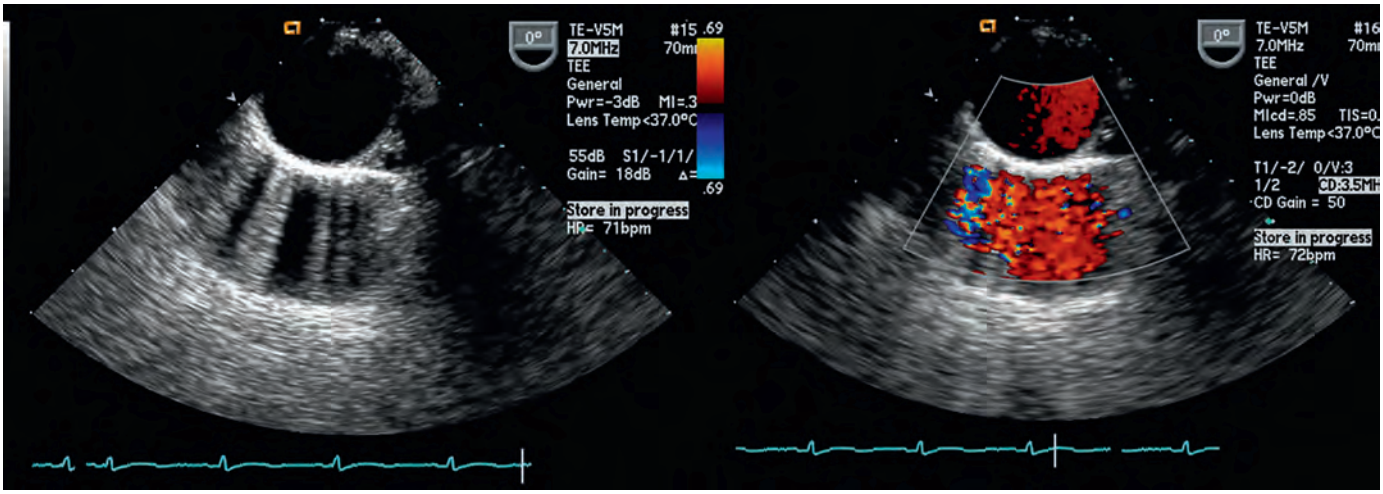

Fig. 14.34 Mirroring artifact; descending aortic short-axis view. The descending aorta is best imaged at the top of the figure. Because ultrasound waves are trapped within the aortic wall, a secondary image appears deeper to the original image. When color-flow Doppler is added to the image on the right, flow appears in both the top original image and in the mirror image.

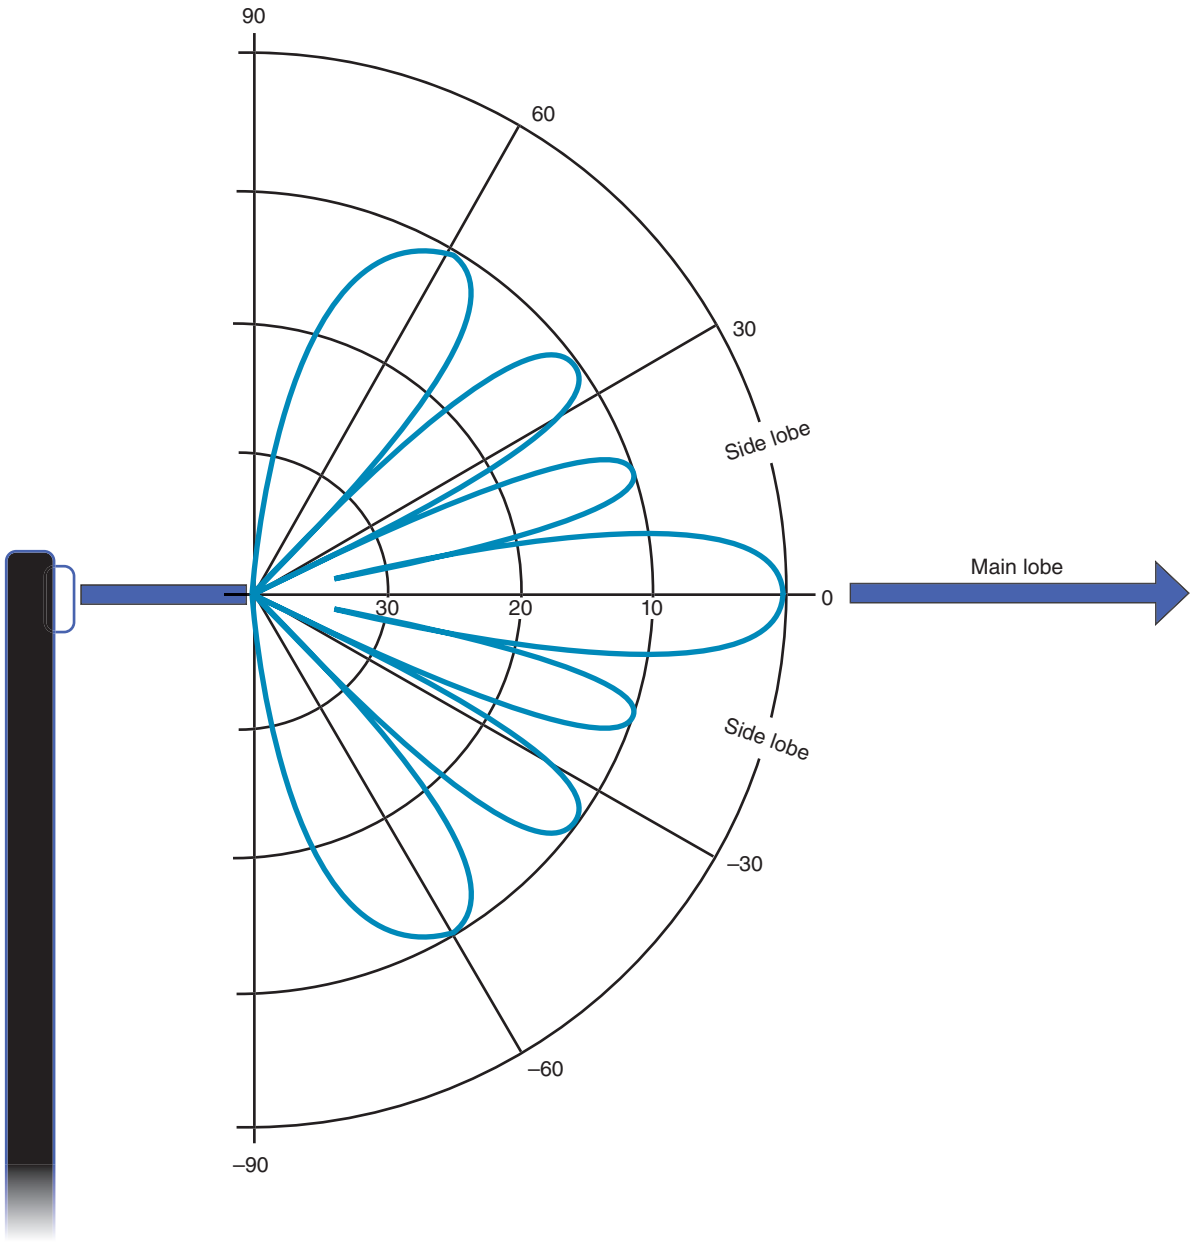

Fig. 14.35 Ultrasound energy is actually emitted as multiple radiation lobes at various angles from the probe's aperture with the energy summed in constructive and destructive patterns. The main beam is the largest constructive pattern, and the side lobes decrease in intensity with increased angle of production. Although weak in intensity, these side lobes may be the source of artifacts if they encounter strong reflectors.

and mass measured by 3D echocardiography, 2D echocardiography, and magnetic resonance imaging (MRI), which is the gold standard, showed significantly better correlation between 3D echocardiography and MRI than between 2D echocardiography and MRI.[81–83] Jenkins and associates[84] compared LV measurements obtained by 2D and 3D echocardiography with MRI-derived measurements in 110 patients.[84] Three-dimensional measurements were performed both online using tracing and offline using edge detection. Although all echocardiographic measurements underestimated LV volumes, they found that the EF estimates were similar. The correlation between MRI and online 3D echocardiography was better than 2D echocardiography; however, the off-line 3D echocardiography provided the best correlation with MRI-derived volumes.

Left Ventricular Preload by End-Diastolic Dimensions

Although preload is often estimated by measuring left-sided heart filling pressures (pulmonary capillary wedge pressure [PCWP], left atrial pressure [LAP], or left ventricular end-diastolic pressure [LVEDP]) in conventional hemodynamics, measuring LV end-diastolic dimensions or calculating LVEDPs can determine preload in echocardiography. In M-mode echocardiography, a single ventricular diameter is obtained, whereas one or multiple tomographic cuts are recorded in

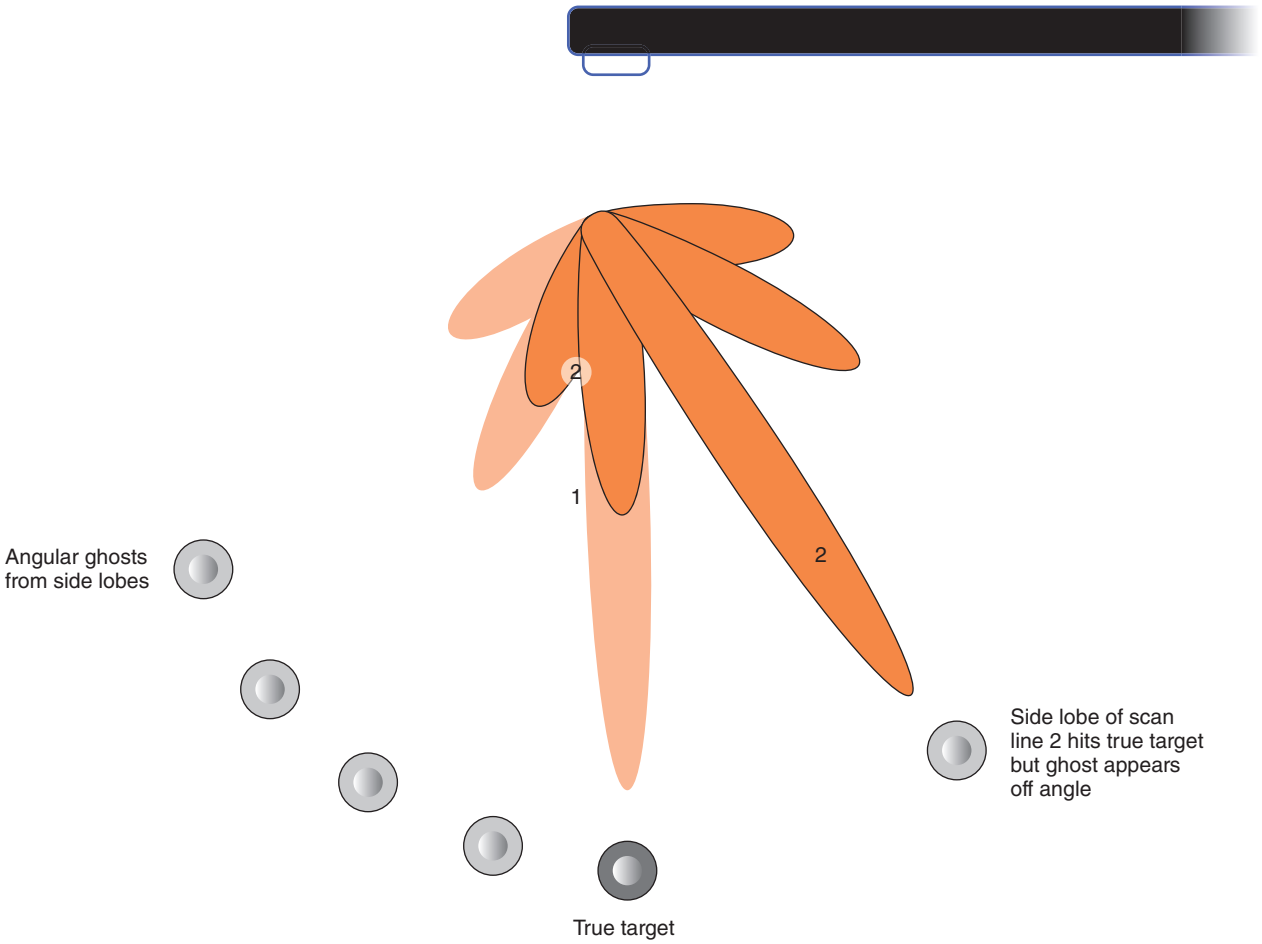

Fig. 14.36 Multiple side-lobe artifacts may yield an imaging artifact with a curved appearance attributable to the beam oscillating to generate a single frame and multiple artifacts displayed next to each other.

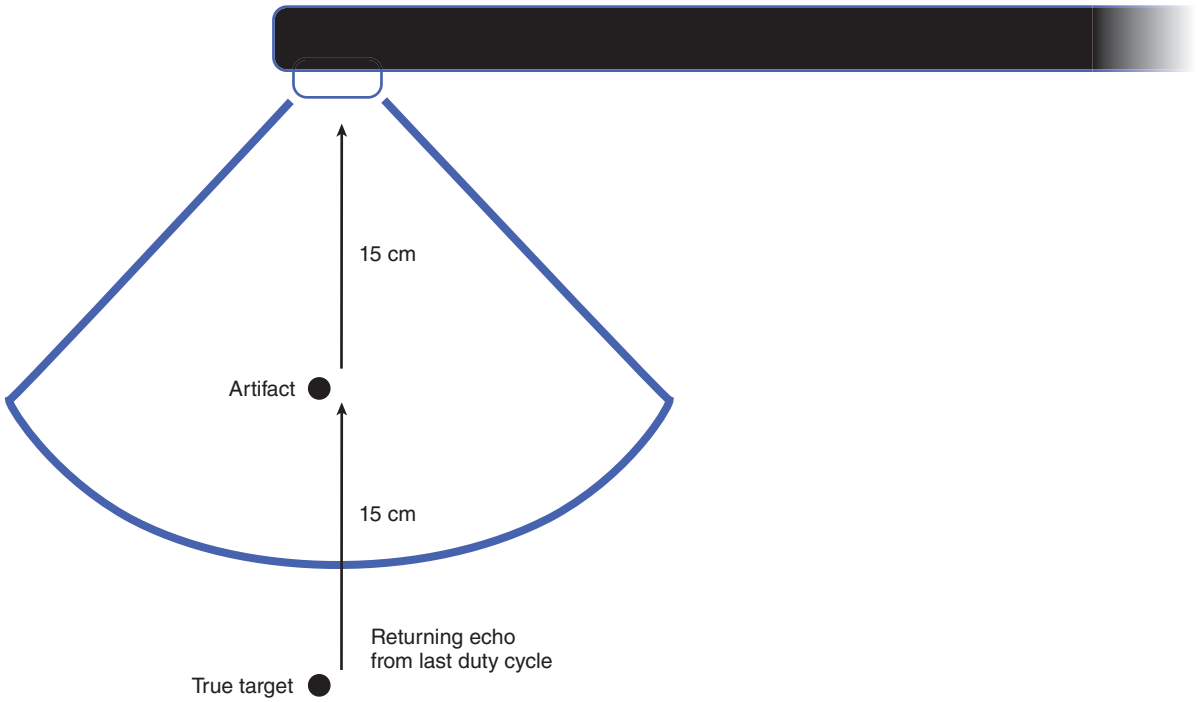

Fig. 14.37 Termed *ranged ambiguity*, a prior ultrasound signal returning from a deep structure, while listening from a subsequent ultrasound pulse, may cause the ultrasound machine to display the artifact in a significantly more shallow location.

TABLE 14.5 Normal Value for Two-Dimensional Left Ventricle Size and Function

	Male	*Female*
	Mean ± SD	*Mean ± SD*
LV Internal Diameters		
Diastolic (mm)	50.2 ± 4.1	45.0 ± 3.6
Systolic (mm)	32.4 ± 3.7	28.2 ± 3.3
LV Volumes (Biplane)		
LV EDV (mL)	106 ± 22	76 ± 15
LV ESV (mL)	41 ± 10	28 ± 7
LV Volumes Normalized by BSA		
LV EDV (mL/m^2)	54 ± 10	45 ± 8
LV ESV (mL/m^2)	21 ± 5	16 ± 4
LV EF (Biplane)	62 ± 5	64 ± 5

BSA, Body surface area; *EDV,* end-diastolic volume; *EF,* ejection fraction; *ESV,* end-systolic volume; *LV,* left ventricle; *SD,* standard deviation.

Adapted from Lang RM, Badano LP, Mor-Avi V, et al. Recommendations for cardiac chamber quantification by echocardiography in adults: an update from the American Society of Echocardiography and the European Association of Cardiovascular Imaging. *J Am Soc Echocardiogr*. 2015;28:1–39.

2D echocardiography. It has been proposed that end-diastolic dimensions provide a better index of preload than the PCWP. When PCWP and end-diastolic volume (EDV), derived from SAX areas at the level of the papillary muscles, were compared as predictors of cardiac index (CI) in patients undergoing CABG surgery, a strong correlation was observed between end-diastolic area (EDA) or EDV and CI, whereas no significant correlation was found between PCWP and CI.[85]

In a study of 32 patients during cardiovascular surgery, Beaupre and colleagues[86] compared SAX area changes with simultaneous PCWP changes obtained from PA catheters. Estimates of stroke volume (SV) derived from SAX area changes were consistent with thermodilution data in 91% of patients. In contrast, EDA changes correlated with PCWP changes in only 23% of patients. Because LV compliance changes dramatically during cardiovascular surgery, PCWP is an inadequate guide to LV preload. Clements and associates[87] studied 14 patients during resection of abdominal aortic aneurysms. At multiple times during surgery, echocardiograms and first-pass radionuclide studies were recorded simultaneously. The correlation between echocardiographic and radionuclide estimates was excellent; however, virtually no correlation was observed between estimates from either of these techniques and PAPs. Thus TEE (but not the PAC) provides the anesthesiologist with a direct, quantitative method to assess LV preload and ejection. However, if severe regional wall motion abnormalities (RWMAs) are present, then information from a single cross section may not be adequate for estimating these parameters.

TEE is often limited to a single SAX view at the level of the papillary muscles. Some evidence suggests that SAX EDAs measured at this level correlate reasonably well with measurements obtained by on-heart echocardiography and with EDVs measured simultaneously using radionuclides. However, findings by Urbanowicz and colleagues[88] were in disagreement with these conclusions. Using a combined radionuclide and thermodilution technique, these investigators found that the correlation coefficient between the left ventricular end-diastolic area (LVEDA) by TEE and the LVEDV was only 0.74. In addition, they noted discordant changes in four of nine patients. Overall, it has been shown that despite variable loading conditions, changes in LV SAX area reflect changes in LV pressure or compliance factors. There are two main echocardiographic signs of decreased preload:

1. Decrease in EDA (<5.5 cm^2/m^2) invariably reflects hypovolemia. It is, however, difficult to set an upper limit of EDA below which hypovolemia can be confirmed. This is particularly true in patients with impaired contractility where a compensatory baseline increase in preload makes the echocardiographic diagnosis of hypovolemia difficult.
2. Obliteration of the end-systolic area (the "kissing ventricle sign") that accompanies the decrease in EDA in severe hypovolemia.

Left Ventricular Mass

LV geometry can be classified into four distinct patterns based on wall thickness, cavity size, and mass: normal, concentric hypertrophy, eccentric hypertrophy, and concentric remodeling (Fig. 14.40).[89–91] Concentric hypertrophy results from pressure overload states such as AS and hypertension and results in an increase in wall thickness and muscle mass of the left ventricle without LV dilation. Eccentric hypertrophy results from volume overload states such as aortic or MR and leads to an increase in muscle mass with LV dilation. Thus both pressure and volume overload states can result in increased left ventricular mass (LVM). The differentiation of patients with increased LVM into concentric versus eccentric hypertrophy requires calculation of relative wall thickness (Eq. 14.12 and Table 14.6). Concentric remodeling refers to a state of increased wall thickness without an increase in overall muscle mass and is generally a precursor to concentric hypertrophy. These entities are distinct from the asymmetric hypertrophy that is found in disorders such as hypertrophic obstructive cardiomyopathy in which only the septal portion of the left ventricle becomes hypertrophic.

LVM equals the product of LV wall volume and the density of the myocardium (1.04 g/mL). LV myocardial wall volume is assessed by subtracting intracavitary LV volume from the volume enclosed by the epicardium.[92] Relative wall thickness is a parameter based on wall thickness and cavity size at end-diastole. It is calculated via the following formula[93]:

$$\text{Relative wall thickness} = [2 \times (\text{ILWTd})]/(\text{LVIDd}) \qquad \text{[Eq. 14.12]}$$

where ILWTd is inferolateral wall thickness diameter at end-diastole (cm), and LVIDd represents LV internal diameter at end-diastole (cm).

A relative wall thickness greater than 0.42 is considered elevated. A patient with normal LVM but increased relative wall thickness would be categorized as concentric remodeling.

ASE guidelines[93] recommend the estimation of LVM based on the geometric assumption of the left ventricle as the shape of an American football (a prolate ellipsoid with a major : minor axis ratio of 2 : 1) and uses linear measurements of the LV SAX dimensions using either 2-D or M-mode measurements.[92] The ASE-recommended linear formula[93] uses ILWTd, anteroseptal wall thickness at end-diastole (ASWTd), and LVIDd (all measured in centimeters):

$$\text{LVM (g)} = 0.8 \times (1.04[(\text{LVIDd} + \text{ILWTd} + \text{ASWTd})^3 - (\text{LVIDd})^3]) + 0.6 \qquad \text{[Eq. 14.13]}$$

The calculations necessary for determining LVM are incorporated into many echocardiographic software systems. This formula requires precise identification of the endocardial surfaces, because even small errors are magnified when cubed in the formula. Although the ASE convention has been to measure the distance between the leading edges of the structures, refinements in image processing now allow improved image resolution for measurement of the actual visualized thicknesses and to measure chamber dimensions from endocardium to endocardium.[93] Trabeculations and spaces should be excluded from the endocardial border. M-mode measurements are limited by the beam orientation being frequently off-axis; 2D echocardiographic images are more precise and thus are the standard mode of calculation. The ASE recommends measuring ILWTd and ASWTd from the standard TG mid-SAX view (Fig. 14.41A).[93] LVIDd is best measured from either the ME two-chamber view (Fig. 14.41B) or the TG two-chamber view (Fig. 14.41C), depending on which image is of higher quality.[93] LVIDd is measured at the junction of the basal and middle thirds of the left ventricle (just above the tips of the papillary muscles) on a line perpendicular to the LAX of the ventricle. When unable to obtain these views in a way that adequately shows the true major and minor axes of the left ventricle, LVIDd can be measured from the TG mid-SAX view, measuring from endocardium to endocardium (see Fig. 14.41A).

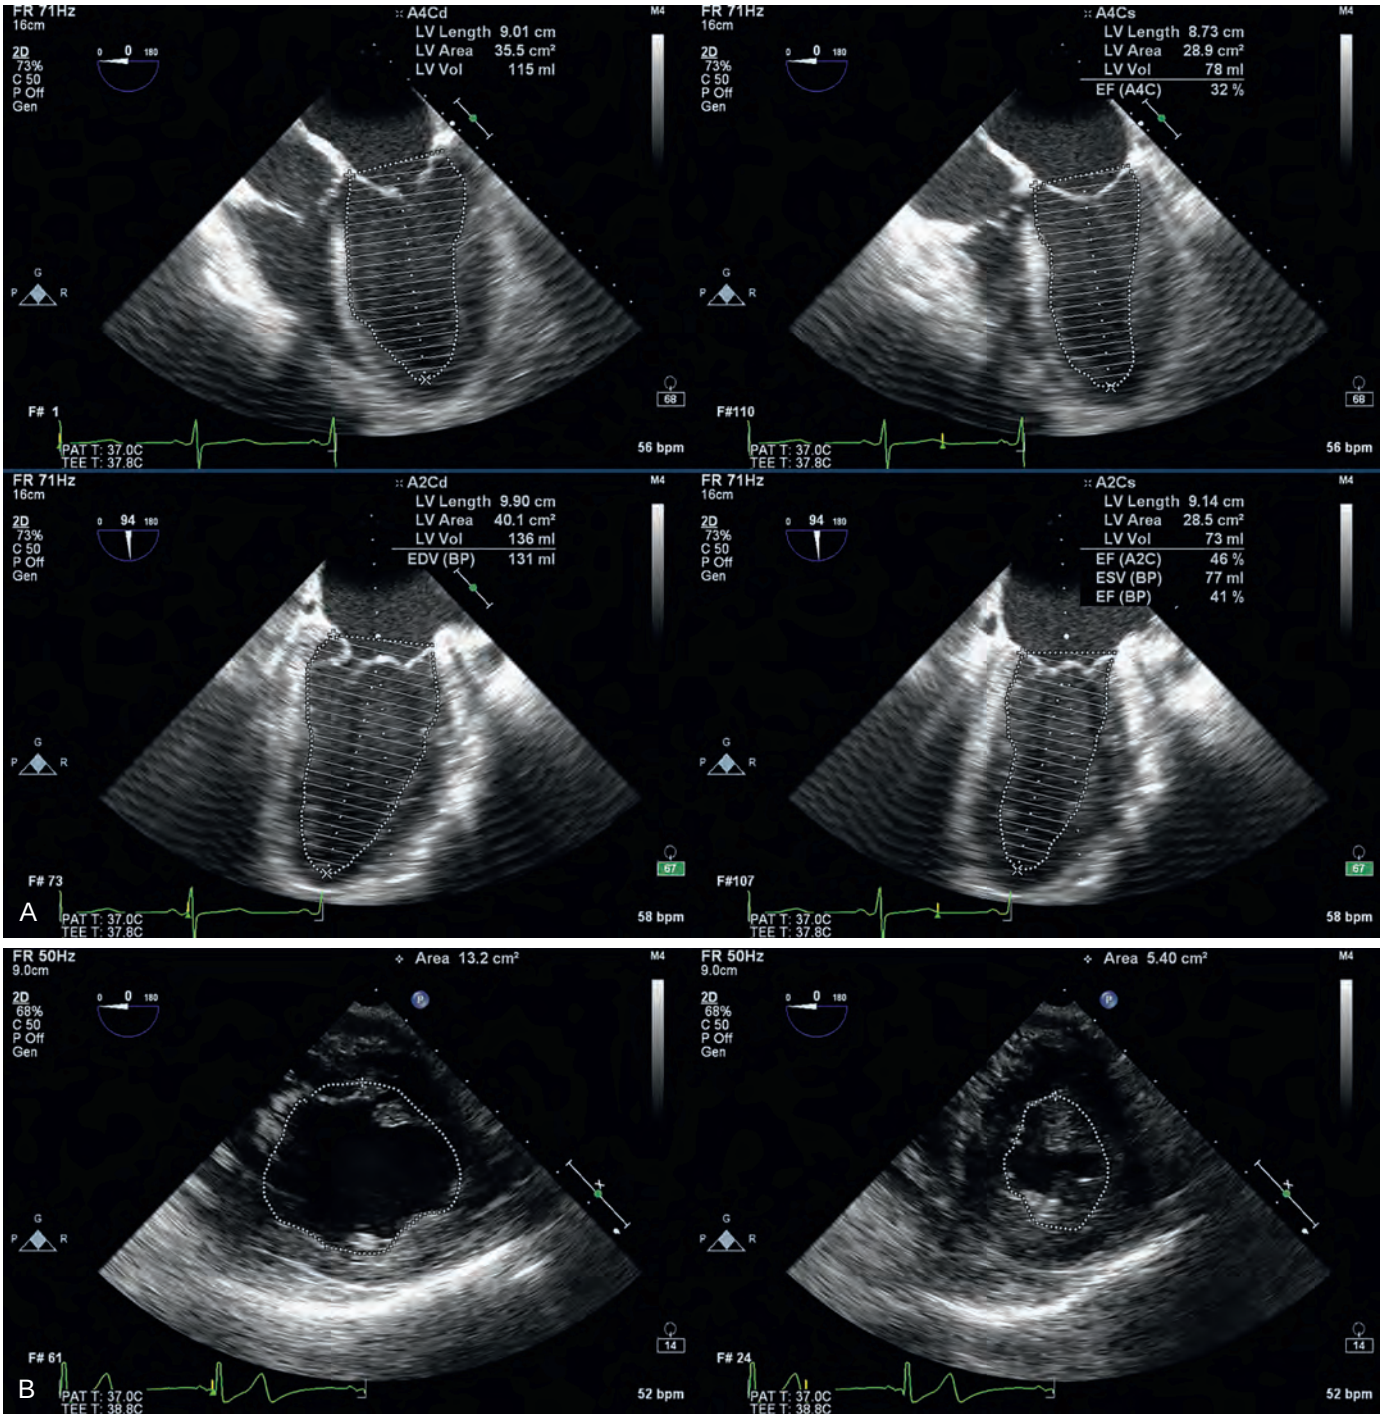

Fig. 14.38 (A) Measurement of left ventricular *(LV)* volume by modified Simpson method. *(Top row)* Midesophageal four-chamber view. *(Second row)* The orthogonal mid esophageal two-chamber view. The column on the left is diastole, and the column on the right is systole. With biplane disk summation, the total LV volume is calculated from the summation of a stack of elliptical disks. The height of each disk is calculated as a fraction of the LV long-axis view, based on the longer of the two lengths from the two- and four-chamber views. The cross-sectional area of the disk is based on the diameters obtained, and the volume of the disk is estimated. The volume is obtained by the summation of these values. (B) Measurement of fractional area change in the transgastric midpapillary view. The left ventricular area during diastole and systole are determined. The fractional area change is calculated by subtracting the systolic area from the diastolic area and then dividing that number by the diastolic area.

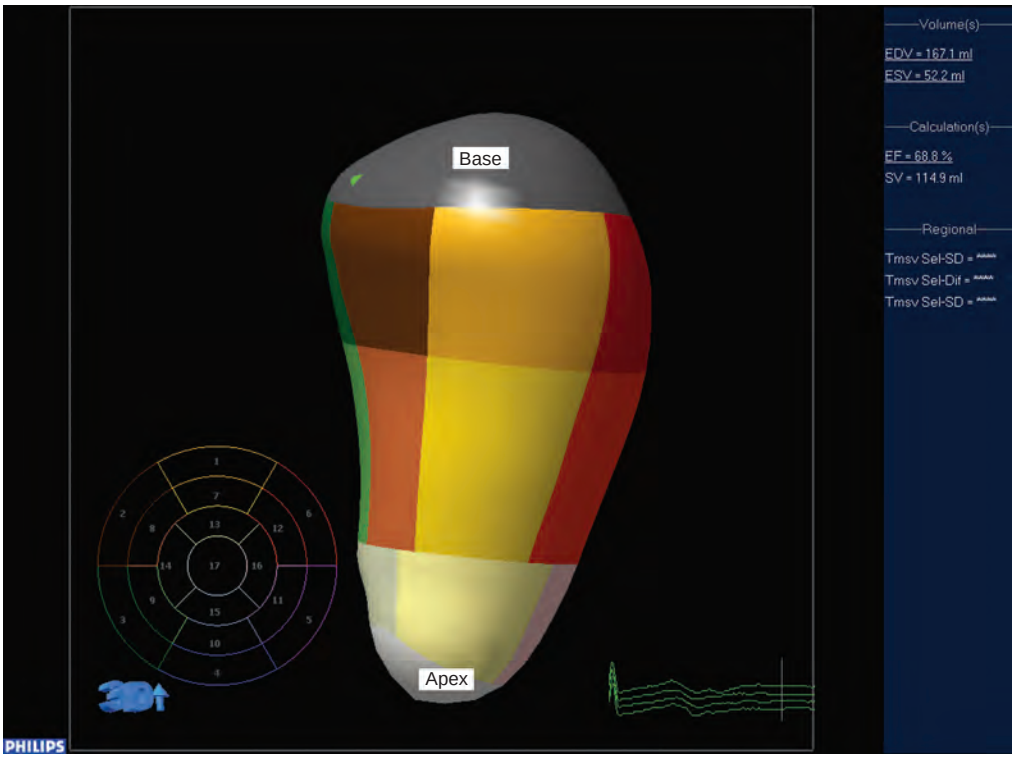

Fig. 14.39 Measurement of left ventricular volume by three-dimensional reconstruction.

Reference values as recommended by ASE are provided in Table 14.7. However, it must be noted that LVM values obtained using TEE are greater by an average of 6 g/m^2 because of minor differences found in inferolateral wall thickness on TEE.[94]

Left Ventricular Systolic Function

The echocardiographic assessment of global and regional LV function consists of 2D, 3D, or Doppler evaluation of cardiac structures. Using echocardiography, contractility has most frequently been estimated with ejection-phase indices. A wide array of ejection-phase indices have been described, but all require that end-diastolic and end-systolic dimensions be measured. In M-mode echocardiography, these dimensions will often be simple, linear, internal dimensions of the LV cavity. The ratio:

$$FS = (LVIDd - LVIDs)/LVIDD \qquad [Eq.\ 14.14]$$

where LVIDd, representing LV internal diastolic dimension, and LVIDs, representing LV internal systolic dimension, will yield fractional shortening (FS), a basic ejection-phase index of contractility. This one-dimensional method for measuring LV systolic function is not accurate with significant RWMAs.

With 2D echocardiography, multiple tomographic cuts can be obtained and used to calculate ventricular volumes using a variety of formulas such as modified Simpson formula (see Fig. 14.38A).[95] Using the ventricular volumes, EF can be calculated using the standard formula:

$$EF = (LVEDV - LVESV)/LVEDV \qquad [Eq.\ 14.15]$$

where LVEDV is LV end-diastolic volume, and LVESV is LV end-systolic volume.

EF less than 52 in men or less than 54 in women is suggestive of abnormal LV systolic function.[79]

During intraoperative TEE, it is most convenient to monitor a single, SAX view at the level of the midpapillary muscles. Once the end-diastolic and end-systolic endocardial areas have been delineated with the help of tracing software, contractility may be estimated using the fractional area of contraction (FAC) or the ejection fraction area (EFA) (see Fig. 14.38B):

$$FAC = (LVEDA - LVESA)/LVEDA \qquad [Eq.\ 14.16]$$

where LVEDA is LV end-diastolic area, and LVESA is LV end-systolic area.

Conventional TEE methods cannot discriminate the effects of load on contractility (ie, impaired contractility and falsely high EF in severe MR or intact contractility and falsely low EF in severe AS). Additionally, all conventional echocardiographic methods examine only a single LV diameter or tomographic plane at a time. Taking into consideration the frequent LV foreshortening that occurs in the ME tomographic planes or the presence of segmental abnormalities (particularly in patients with coronary artery disease [CAD]), realizing why true representation of global LV function is not always feasible with these methods is easy.

The 2015 ASE guidelines recommend the calculation of EF from EDV and end-systolic volume (ESV) estimates using either 2D (using the modified Simpson method) or 3D echocardiography (see Fig. 14.39).[79] If the endocardium cannot be well visualized, then contrast may be used. Three-dimensional and tissue Doppler measurements of LV function are discussed in Chapter 15.

Left Ventricular Diastolic Function

Evaluation of diastolic function requires the assessment of the LV pressure-volume relationship during diastole filling. This relationship can only be measured hemodynamically. Echocardiographic assessment of diastolic function attempts to evaluate diastolic filling by evaluating patterns and time of flow, such as from the left atrium into the left ventricle or from pulmonary veins into the left atrium. The primary determination of flow is the pressure differences in the two chambers.[96] The early diastolic pressure difference between the left atrium and the left ventricle primarily reflects the rate of LV relaxation. Thus if filling is delayed, then impaired relaxation is usually present. It is important to remember that other factors, such as chamber and myocardial compliance, LV loading conditions, ventricular interaction, and pericardial constraint, can also influence rates of LV filling.

The evaluation of diastolic function may be evaluated using LA size, Doppler analysis of MV inflow and pulmonary vein flow, color M-mode propagation velocities, and tissue Doppler analysis of the MV annulus.[97–100]

Indices for Evaluation

Left Atrial Size

LA size is most accurately measured in the ME two- and four-chamber views.[79] Although the Doppler velocity and time-interval measurements reflect filling pressures at the time of analysis, LA size measurements reflect cumulative effects over time.[99] LV enlargement may occur in the absence of diastolic dysfunction. If LA enlargement is present, then this measurement must be used in conjunction with other indices of LV diastolic function to interpret its significance.

Transmitral Doppler Analysis

Transmitral Doppler spectrum may be measured using PWD. Typically, the PWD gate is positioned at the tip of the MV leaflets in an ME four-chamber view.[99] Normally, transmitral spectrum consists of an early diastolic phase (E wave) and a late diastolic component associated with atrial contraction (A wave) (Fig. 14.42A). The velocity sweep speeds of 25 to 50 mm/sec should be initially used to evaluate respiratory variations in flow that may occur with pulmonary or pericardial disease, after which it may be increased to 100 mm/sec. The peak E- and A-wave velocities, A-wave duration, and E-wave deceleration time (DT) should be determined. The E-wave DT is measured from the peak of the E wave until the actual or extrapolated intersection with zero. In addition, the isovolemic relaxation time (IVRT) may be measured by placing a CWD cursor in the LVOT to simultaneously measure aortic ejection and ventricular inflow. Normal values are listed in Table 14.8. Generally, with increasing age, E-wave velocity and E/A ratio decrease and A-wave velocity and DT increase.

Mitral E-wave velocities are primarily determined by early diastolic LA-LV pressure gradient, which is primarily influenced by both LA preload and LV relaxation.[101] The A-wave velocity is affected by LV compliance and LA contractile function.[99] Finally, the E-wave DT is

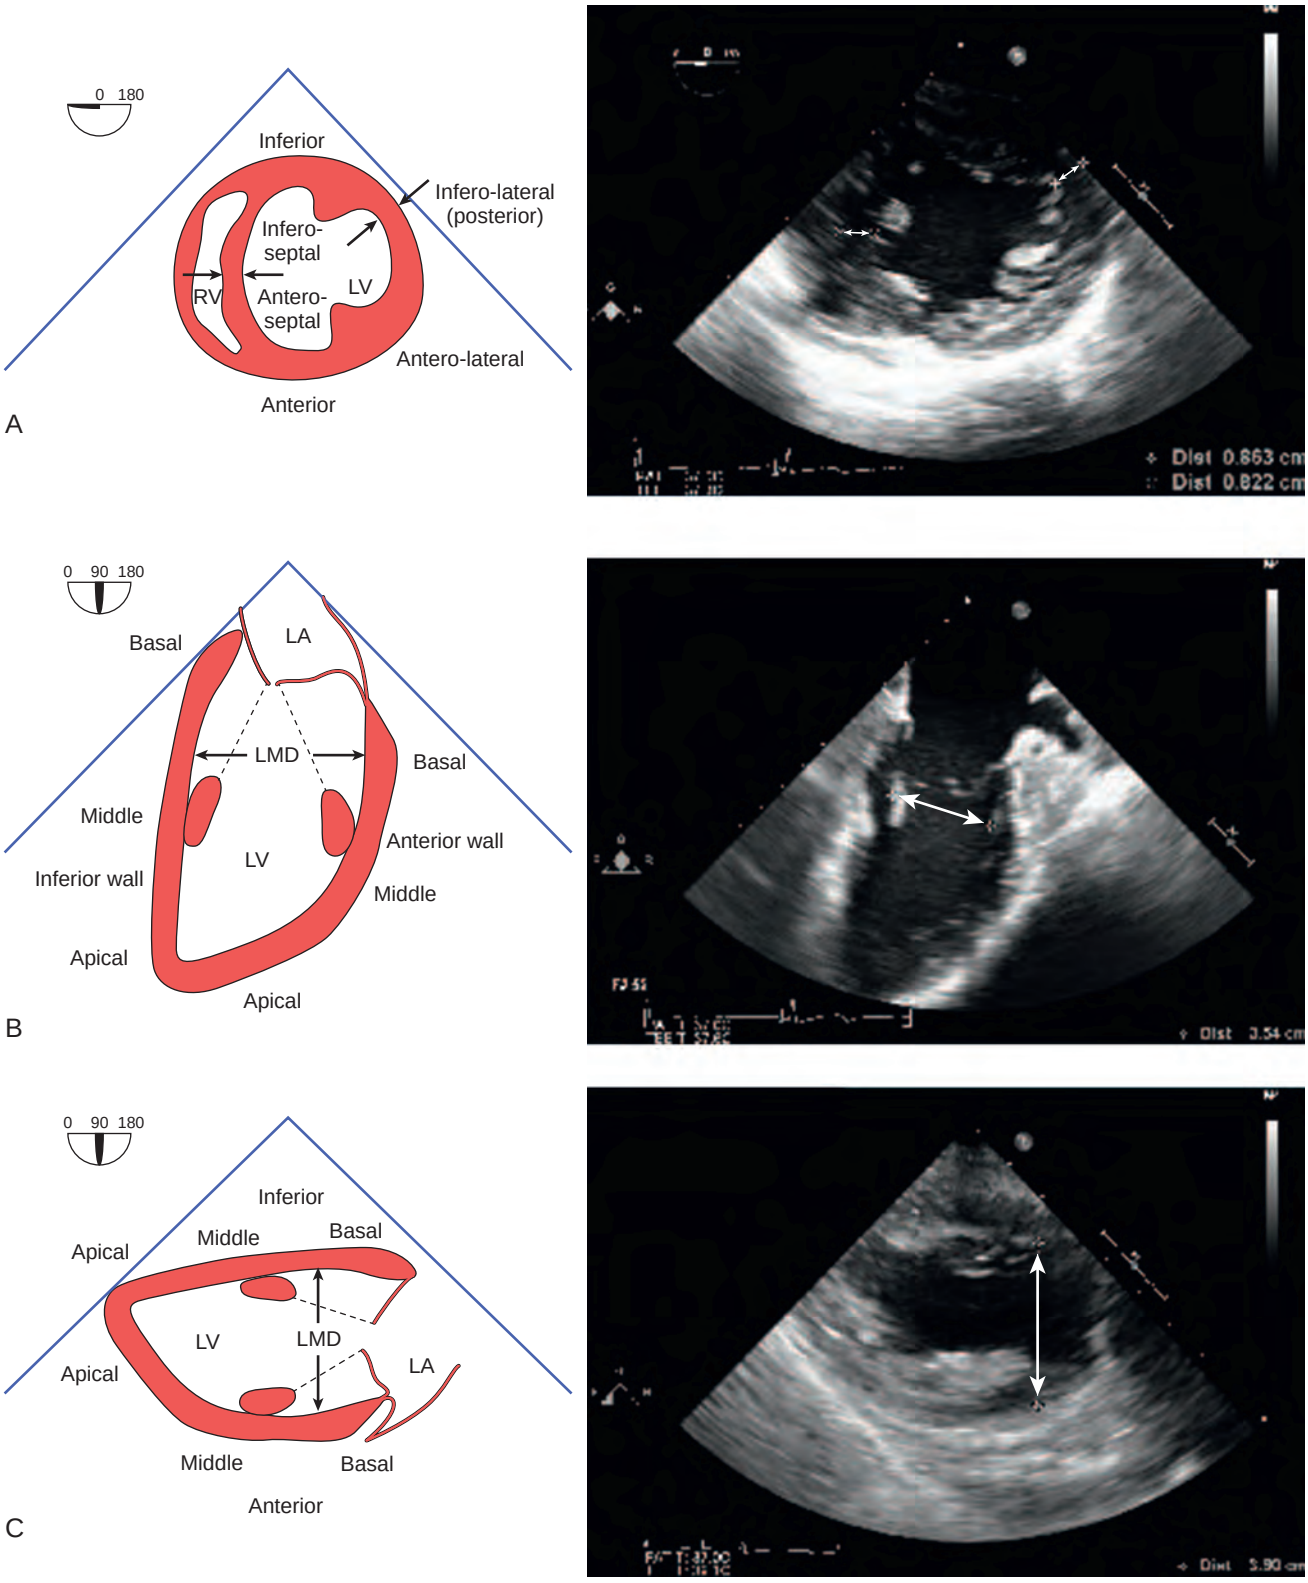

Fig. 14.41 Transesophageal echocardiographic images used in the calculation of left ventricular mass. (A) Transgastric midpapillary short-axis view showing the recommended measurements of the inferolateral wall thickness diameter at end-diastole (ILWTd) and anteroseptal wall thicknesses at end-diastole (ASWTd). (B) Midesophageal two-chamber view shows the measurement of the left ventricular internal diameter at end-diastole (LVIDd). (C) Transgastric 2-chamber view shows the measurement of the left ventricular internal diameter at end-diastole (LVIDd). Using the formula: Left ventricular mass (g) = $0.8 \times (1.04[(\text{LVIDd} + \text{ILWTd} + \text{ASWTd})^3 - (\text{LVIDd})^3]) + 0.6$. The left ventricular mass of this patient equals 84.6 grams. *LA,* Left atrium; *LV,* left ventricle; *LMD,* left ventricular diameter; *RV,* right ventricle. *(Permission pending from Weiner M, Kahn RA, Evans AS. Fig. 14.42 Transmitral flow and diastolic dysfunction. (A) Normal transmitral spectrum consists of an early diastolic phase (E wave) and a late diastolic component associated with atrial contraction (A wave). The E-wave velocity is usually larger than the A-wave velocity. (B) Delayed relaxation. With delayed relaxation, the A wave becomes smaller than the E wave. (C) Pseudonormalization. With worsening diastolic dysfunction, left atrial pressure increases with a concomitant increase in the E-wave velocity. Although there is an increase in the E-wave deceleration time, differentiation of the pseudonormalization pattern from normal is dependent on additional indices of diastolic function. (D) With the restrictive pattern, the E wave becomes dominant with a very rapid deceleration time.

influenced by LV relaxation, LV diastolic pressures after MV opening, and LV compliance. With normal diastolic function, the E/A of MV inflow ratio is between 0.8 and 1.5, with an E-wave DT greater than 140 milliseconds. With impaired relaxation, the A-wave velocity increases, and the E/A ratio becomes less than 0.8 (Fig. 14.42B). The E-wave DT is usually longer than 200 milliseconds. Further worsening in diastolic function results in increases in LAP. This increased LAP increases the E-wave velocity. This increased E-wave velocity results in a *pseudonormalization* of the E/A ratio (Fig. 14.42C). Further progression to restrictive cardiomyopathy results in the rapid increase in ventricular pressure during early diastole with resultant shortened early diastolic filling. This is characterized by an E/A wave ratio greater than 1.5 and an E-wave DT less than 140 milliseconds (Fig. 14.42D).

Pulmonary Venous Flow Analysis

The pulmonary veins may be imaged from a number of views as described earlier. The location of the vein may be optimized by CFD. Ideally, a 2- to 3-mm PWD sample volume is placed more than 0.5 cm

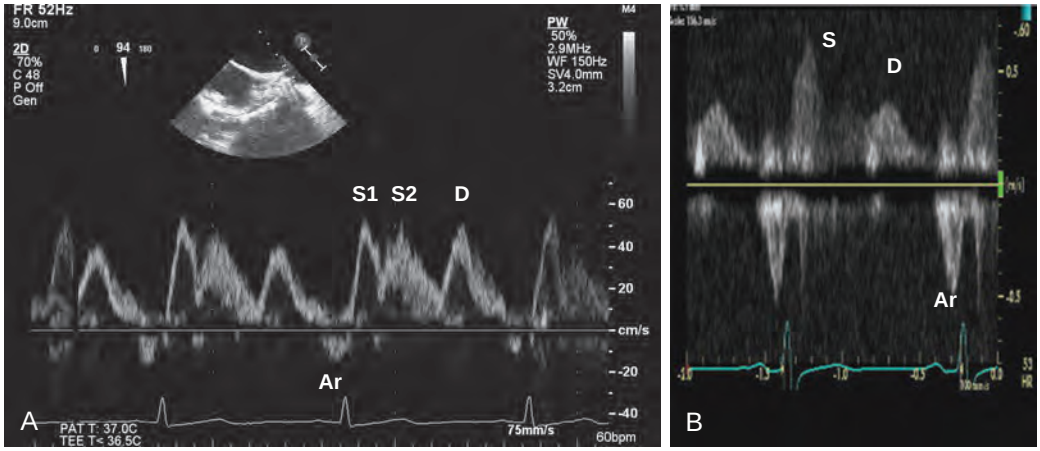

Fig. 14.43 Pulmonary venous tracing. (A) The normal pulmonary venous tracing is characterized by flow into the left atrium (toward the transducer) during both systole *(S)* and diastole *(D)* with a small flow reversal during atrial systole. The systolic component, which occurs immediately after the QRS complex, consists both of an *S1* and *S2* component. The S1 component represents the suction effect during atrial relaxation, whereas the S2 component represents flow as a result of right ventricular systole. Flow during diastole *(D)* is normally less than systolic flow. Atrial contraction produces an atrial reversal wave *(Ar)* immediately before ventricular systole. (B) With worsening left ventricular diastolic function, there is an increase in atrial Ar velocity and duration. The mitral inflow spectrum from a transthoracic ultrasound is demonstrated on the left, and the pulmonary venous spectrum is on the right. Pulmonary venous Ar velocity is significantly increased at 50 cm/sec and its prolonged duration is at >200 milliseconds in comparison with mitral A (late diastolic) velocity. *(B, Reproduced with permission from Nagueh SF, Appleton CP, Gillebert TC, et al. Recommendations for the evaluation of left ventricular diastolic function by echocardiography.* J Am Soc Echocardiogr. *2009;22:107–133.)*

into the pulmonary vein, ensuring that the direction of pulmonary blood flow is parallel to the Doppler beam. The normal pulmonary venous tracing consists of a large positive systolic wave (ie, flow toward the left atrium), a smaller diastolic wave, and a negative atrial wave (Fig. 14.43A). The systolic wave may have both S1 and S2 components. The S1 component is associated with a *suction* effect of LA relaxation, whereas the S2 component is related to the pushing of blood by the right ventricle across the pulmonary circulation.[102] The peak systolic and diastolic velocities should be measured, as well as the atrial reversal velocity and duration. If both S1 and S2 components of the pulmonary systolic flows are present, then the S2 velocity should be used for calculations because S1 is related to atrial relaxation. After measuring of the transmitral Doppler spectrum, the difference between the atrial reversal duration and the A-wave duration should be calculated. The atrial systole component of the pulmonary venous flow (ie, atrial reversal) velocity is usually less than 35 cm/sec, and its duration is usually less than the transmitral E-wave duration.

As summarized by Nagueh and associates,[99] "S1 velocity is primarily influenced by changes in LA pressure and LA contraction and relaxation, whereas S2 is related to SV and pulse-wave propagation in the PA tree. D velocity is influenced by changes in LV filling and compliance and changes in parallel with mitral E velocity. Pulmonary venous Ar [atrial reversal wave] velocity and duration are influenced by LV late diastolic pressures, atrial preload, and LA contractility. A decrease in LA compliance and an increase in LA pressure decrease the S velocity and increase the D velocity, resulting in an S/D ratio <1, a systolic filling fraction <40%, and a shortening of the DT of D velocity, usually <150 ms. With increased LVEDP, Ar velocity and duration increase, as well as the time difference between Ar duration and mitral A-wave duration." Increases in LAP results in a blunting of the systolic component

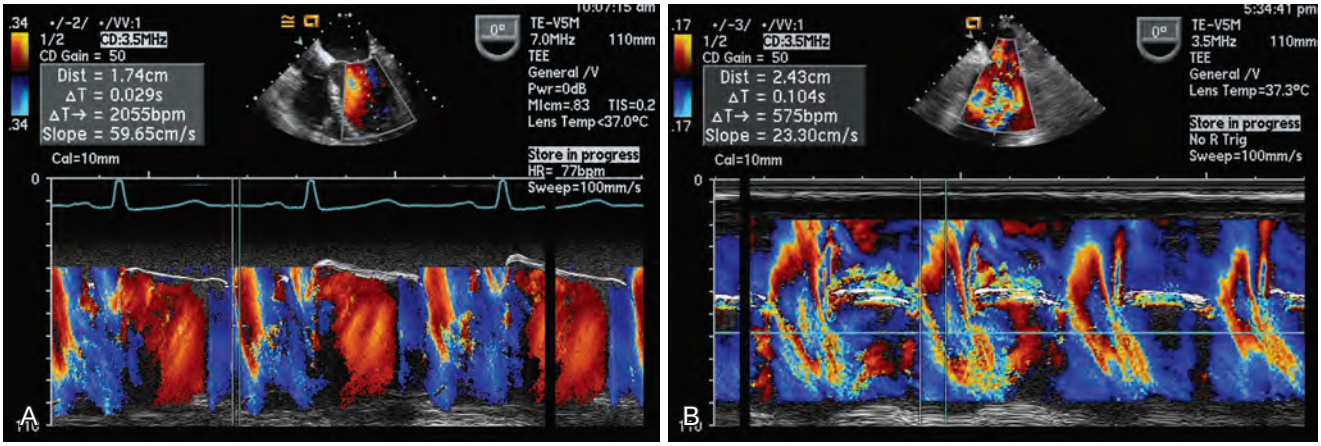

Fig. 14.44 Color M-mode propagation velocity. (A) Normal. The color M-mode slope of the left ventricular inflow is greater than 50 cm/sec. (B) With decreased diastolic function, the M-mode propagation slope is decreased.

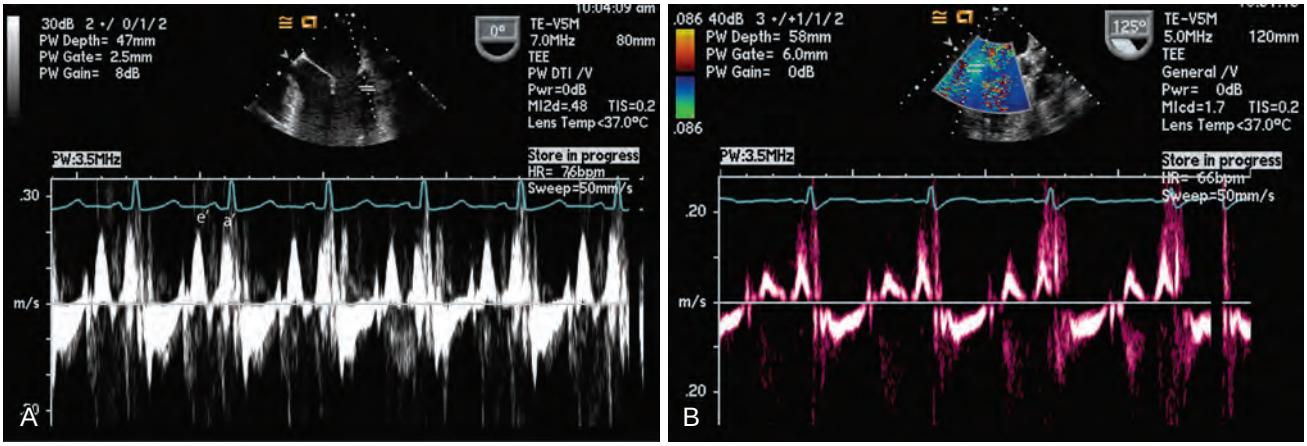

Fig. 14.45 Tissue Doppler measurements. (A) Normal tissue Doppler spectrum. e′ is both greater than a′ and more than 8 cm/sec. (B) With worsening left ventricular diastolic function, the e velocity decreases.

of pulmonary venous flow, compared with diastolic pulmonary venous flow. With greater increases in LVEDP, the atrial reversal wave velocity exceeds 35 cm/sec and the duration becomes greater than 30 milliseconds compared with the transmitral E-wave duration (Fig. 14.43B).

Color M-Mode Flow Propagation Velocity

Mitral-apical propagation velocity (V_p) may be measured using color M-mode imaging. A clear view of LV inflow is obtained. CFD mapping is superimposed on the LV inflow, and the color mapping is adjusted to a displayed and aliased signal in the center of the ventricular inflow.[103] The M-mode scan line is displayed extending through the MV leaflet opening to the LV apex. V_p is determined by measuring the slope of the aliasing velocity from the mitral inflow to approximately 4 cm into the LV cavity during early systole (Fig. 14.44A). A V_p greater than 50 cm/sec is considered normal.[99] This early filling wave is driven by the pressure gradient between the LV base and apex, which represents a suction force attributable to LV restoring forces and relaxation. A decrease in V_p serves as a semiquantitative marker of LV diastolic dysfunction (Fig. 14.44B). In most cases of diastolic dysfunction, other indices of diastolic function are present; if these indices are inconclusive, then V_p may provide useful information concerning the estimation of LVEDP.

Tissue Doppler

Spectral Doppler is usually used to determine blood-flow velocities. Because these velocities are relatively high and the amplitude of the Doppler signal is low, high amplitude–low velocity ultrasound signals are usually ignored. In contrast, during tissue Doppler examination, the primary interest is in the high amplitude–low velocity ultrasound signals created by the myocardium; low amplitude–high velocity signals are ignored. DTI of the MV annulus may be used to judge diastolic function.[104] Most modern ultrasound machines have presets optimized for tissue Doppler analysis that include the high amplitude–low velocity signals that are normally excluded. The sample volume should be positioned with 1 cm of the septal and lateral annular insertion points and should cover the longitudinal excursion of the mitral annulus in both systole and diastole.[99] Normally, this DTI wave consists of two diastolic components: one in early diastole (e′) and one in late diastole (a′) (Fig. 14.45). Measurements should be taken at both points and the results averaged. The septal e′ wave is generally lower than the lateral e′-wave velocity. The peak e′- and a′-wave velocities should be determined, and both the e′/a′ and E/e′ ratios should be calculated. These two signals are in the opposite direction of MV inflow. The major determinants of e′-wave velocity are LV relaxation, preload, systolic function, and LV minimal pressure. These indices may not be accurate with heavy annular calcification, mitral stenosis (MS), prosthetic MVs or annuli, or constrictive pericarditis. Because preload has minimal effect on e′-wave velocity, the E/e′ ratio is useful to correct for E-wave velocities in the presence of diastolic dysfunction. Normal values for these parameters are listed in Table 14.8. Septal E/e′ ratios less than 8 and septal e′-wave velocities greater than 8 cm/sec usually indicate

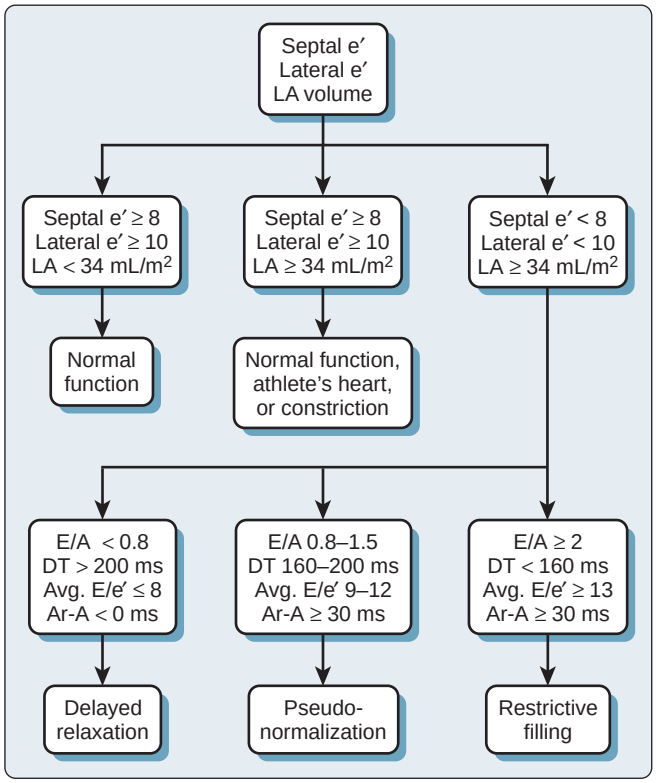

Fig. 14.46 Classification of diastolic dysfunction. *A*, Late diastolic transmitral velocity; *Ar-A*, difference between pulmonary venous atrial reversal duration and transmitral A-wave duration; *DT*, E-wave deceleration time; *E*, early diastolic transmitral velocity; *e′*, early diastolic tissue Doppler velocity; *LA*, left atrial.

normal LV filling pressures, whereas septal E/e′ ratios greater than 16 and septal e′-wave velocities less than 8 cm/sec (lateral e′-wave velocity less than 8.5 cm) usually indicate increased LV filling pressures.[97,99]

Classification of Diastolic Dysfunction

There are three primary stages of diastolic dysfunction: impaired relaxation, pseudonormalization, and restrictive cardiomyopathy, which may be classified using the indices presented in Fig. 14.46.[99] In patients with mild diastolic dysfunction (impaired relaxation), the mitral E/A ratio is less than 0.8, DT is more than 200 milliseconds, IVRT is 100 milliseconds or longer, systolic is greater than diastolic pulmonary venous flow, annular e′-wave velocity is less than 8 cm/sec, and the E/e′ ratio is less than 8. In most of these cases, the LAP is not elevated. With the progression to moderate diastolic dysfunction, the increase in LV filling pressures is mild to moderate. With these increases in LAP, the early diastolic LA-LV pressure gradient increases, which results in a pseudonormalization of the E/A ratio (0.8 to 1.5). This ratio may decrease by more than 50% with Valsalva. Other supporting data for the diagnosis of moderate diastolic dysfunction include an increase of the E/e′ ratio from 9 to 12, e′ less than 8 cm/sec, a pulmonary venous atrial reversal wave velocity greater than 30 cm/sec, the diastolic pulmonary venous blood-flow velocity greater than the systolic velocity, and the difference between pulmonary venous atrial reversal duration and transmitral A-wave (Ar-A) duration of 30 milliseconds or longer. Finally, severe diastolic dysfunction (restrictive LV filling) may be diagnosed with an E/A ratio of 2 or more, DT less than 160 milliseconds, IVRT 60 milliseconds or less, pulmonary venous systolic filling fraction 40% or less of the diastolic fraction, mitral A-flow duration shorter than the atrial reversal wave duration, and an average E/e′ ratio greater than 13 (or septal E/e′ greater than 15 or more and lateral E/e′ greater than 12 or more).

Left Atrial Pressure

The indices used to estimate LAP are discussed in detail in the earlier section that describes the evaluation of diastolic dysfunction. The current recommendation suggests different algorithms for the evaluation of LAP based on the EF.[99] These recommendations are summarized in Figs. 14.47 and 14.48. Mitral inflow patterns may be used with reasonable accuracy to estimate LAP in patients with depressed EFs. If the E/A ratio is less than 1 and the E wave is 50 cm/sec or less, then the LAP is probably normal; if E/A pressure is greater than 2 and the DT is less than 150 milliseconds, then the LAP is probably elevated. In the intermediate E/A ratios or a high E-wave velocity, other indices must be considered as well. Signs consistent with normal LAP include E/e′ less than 8, E/V_p less than 1.4, pulmonary venous systolic pressure greater than diastolic velocity, Ar-A duration less than 0 milliseconds, and systolic PA pressure less than 30 mm Hg. However, if E/e′ is more than 15, E/V_p is greater than or equal to 2.5, pulmonary venous systolic is less than diastolic velocity, Ar-A is greater than 30 milliseconds, and systolic PA pressure is greater than 35 mm Hg, then increased LAP should be suspected.

With a normal EF, the E/e′ ratio is the primary measurement to be considered (see Fig. 14.48). If the septal, lateral, or average E/e′ is less than or equal to 8, then the LAP is normal.[105] If the septal E/e′ is greater than or equal to 15, the lateral E/e′ is 12 or more, or the average E/e′ is greater than or equal to 13, then the LAP is considered elevated. For intermediate values of E/e′ ratio, other factors associated with diastolic function must be considered. LA volume greater than 34 mL/m^2, Ar-A duration longer than 30 milliseconds, PA systolic pressure greater than 35 mm Hg, or the ratio of the IVRT/$T_{E-e'}$ less than 2 (which is defined as the time difference between the QRS to E-wave interval and the QRS to e′) are supportive of increased LAP. If more than one of these conditions is present, then a conclusion of higher LAP may be made with greater confidence. LA volume less than 34 mL/m^2, Ar-A duration less

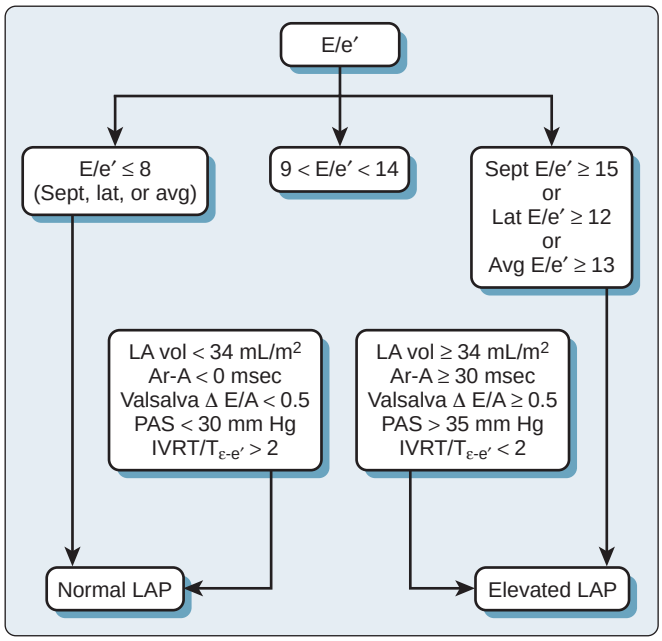

Fig. 14.48 Evaluation of left atrial pressure *(LAP)* in normal ejection fraction. *A*, Late diastolic transmitral velocity; *Ar-A*, difference between pulmonary venous atrial reversal duration and transmitral A-wave duration; *Avg*, average; *DT*, E-wave deceleration time; *E*, early diastolic transmitral velocity; *e′*, early diastolic tissue Doppler velocity; *IVRT*, isovolemic relaxation time; *LA*, left atrial; *Lat*, lateral; *PAS*, pulmonary artery systolic pressure; *Sept*, septal.

than 0 milliseconds, systolic PA pressure less than 30 mm Hg, or the ratio of the IVRT/TE $T_{E\text{-}e'}$ greater than 2 are supportive of normal LAP.

Right Ventricular Function

The right ventricle is a complex structure that pumps venous blood to the normally low pressure–low resistance pulmonary arterial circuit. Owing to the historical focus on the left side of the circulation, lack of geometric assumptions of RV shape, and the difficulty in imaging the right-sided heart, information regarding the right ventricle has been limited until relatively recently. When RV function and loading conditions are normal, the right ventricle is typically triangular when viewed in the ME four-chamber view, yet crescent-shaped when viewed in the TG mid-SAX view. The right ventricle consists of three portions: (1) the inflow portion near the TV, chordae tendineae, and papillary muscles; (2) the trabeculated apical myocardium; and (3) the RVOT near the ventricular septum and PV. These three portions of the right ventricle create a *wrap-around* appearance, which is apparent in an ME RV inflow-outflow view. Unlike the left ventricle, which has a pistonlike contraction, the right ventricle contracts in a peristaltic-like manner with contraction of the inflow, followed in sequence by the apical and outflow portion. Although the RV SV is the same as the left ventricle, the low resistance and high-compliance pulmonary circulation results in an RV stroke work that is normally 25% of the LV stroke work.[106] Because the RV afterload is low, the RV wall thickness is approximately one half that of the left ventricle, and the RV myocardial mass is one sixth of the LV mass. Finally, the left and right ventricles share the IVS because of their close anatomic relationship enclosed within the pericardial sac.[107,108] This ventricular interdependence plays a significant role in the RV pathophysiologic dysfunction because the septum contributes to nearly one third of the typical RV stroke work.[109]

RV dysfunction is often in response to increased pulmonary vascular afterload and pulmonary hypertension, which leads to increased RV wall tension and an imbalance of RV oxygen supply and demand. Myocardial ischemia is another source of RV dysfunction. When

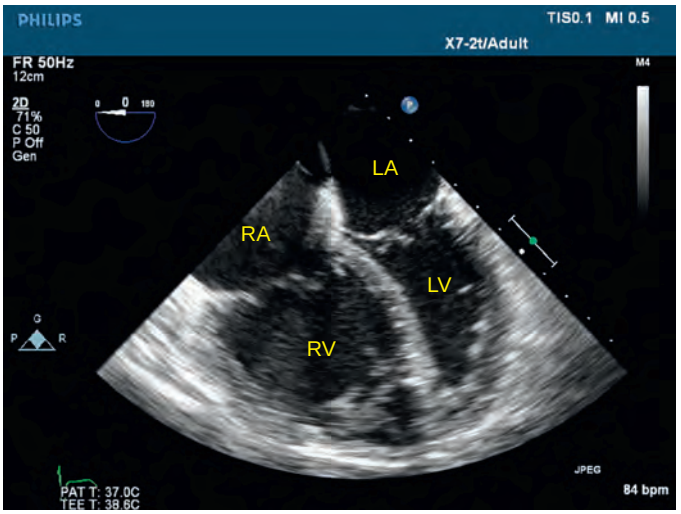

Fig. 14.49 Midesophageal four-chamber view with the probe turned to the patient's right side, bringing the right atrium *(RA)* and right ventricle *(RV)* into view. Note the RV appears larger in area than the LV, which indicates severe right ventricular enlargement. *LA*, Left atrium; *LV*, left ventricle. (Video clip available online.)

increased afterload and/or RV ischemia occur, these result in decreased systolic function with a rise in RV diastolic pressures and chamber dilatation. The chamber dilatation and septal shift toward the left ventricle from rising RV pressures worsens the RV CO. RV dilation leads to a dilated TV annulus, subsequent TR, RA enlargement, and further RV volume overload. Perioperatively, patients with co-existing RV dysfunction fare more poorly than patients without RV dysfunction.[110,111] Therefore appropriate perioperative echocardiographic evaluation of RV function is essential to a comprehensive TEE examination. The specific TEE views required to assess the right ventricle have been described earlier in this chapter.

Right Ventricular Anatomic Assessment

As previously described, the right ventricle is particularly sensitive to increases in afterload. The presentation of this response to chronic increases in afterload may be volume- or pressure-related changes such as RV dilation, hypertrophy, septal wall abnormalities, and RV failure. RV dilation is readily identified by echocardiography and may be assessed qualitatively or quantitatively. Qualitatively, the RV size is compared with the LV size in the ME four-chamber view in which its CSA normally occupies two-thirds of the *normal* LV CSA. Mild enlargement is an increase greater than two thirds; moderate enlargement is present when the chambers are equal in size, whereas severe enlargement is present when the RV area is larger than the LV area (Fig. 14.49; see Video 14.47). Quantitatively, the right ventricle is difficult to assess because of the complex RV shape and poor interobserver reproducibility of RV chamber size measurements. Current chamber quantification guidelines suggest upper reference values for a diameter of 4.1 cm at the base and 3.5 cm in the midlevel of the right ventricle on a transthoracic RV-focused apical four-chamber view.[79] Guidelines specific to TEE are unavailable.

RV hypertrophy in response to pulmonary hypertension is defined as an RV free-wall thickness greater than 5 mm at end-diastole. Chronic severe pulmonary hypertension often results in an RV free-wall thickness greater than 10 mm. ME four-chamber, RV inflow-outflow, or TG RV inflow views with M-mode echocardiography may be used to assess this wall thickness (Fig. 14.50).

RV pressure or volume overload may cause distortion or flattening of the IVS most easily identified in the TG mid-SAX view. The overload of the right ventricle, as well as the underfilled left ventricle from reduced RV CO, leads to a leftward deviation of the septum and a *D-shaped* LV chamber appearance. The timing of this septal flattening

allows the identification of RV pressure or volume overloading. RV pressure overload causes septal flattening at end-systole when the pressure is the highest in the right ventricle, whereas volume overload causes septal flattening at end-diastole when the RV volume is at its greatest[112] (Fig. 14.51; see Videos 14.48 and 14.49).

Right Ventricular Systolic Function

Similar to the difficultly with anatomic assessments, the asymmetric right ventricle creates challenges in the evaluation of RV systolic function. Several modalities, including 2D-, Doppler-, strain-, and 3D-based methods, exist to evaluate RV function. Most have been validated with reference values using transthoracic echocardiography (TTE), and this data have been extrapolated to TEE.[113]

Two Dimensional–Based Methods

Although the right ventricle contracts in a peristaltic-like manner from the base through the apex to the outflow portion, the largest contributor to its systolic function is the longitudinal basal contraction.

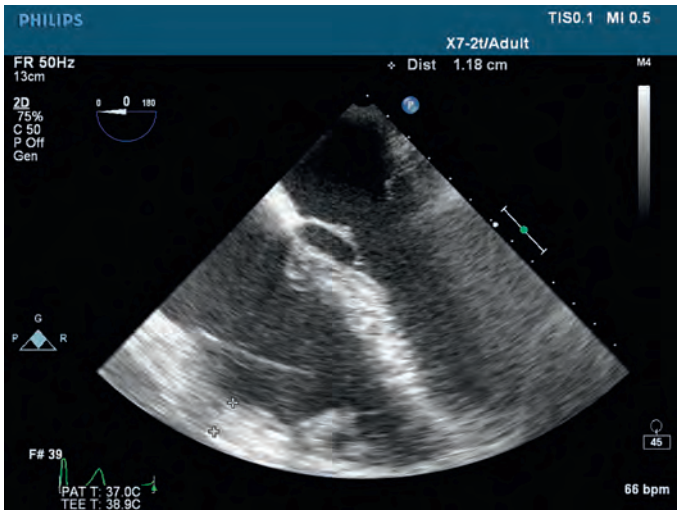

Fig. 14.50 Midesophageal four-chamber view of a patient with severe chronic thromboembolic pulmonary hypertension, demonstrating significant right ventricular hypertrophy (wall thickness measuring 11.8 mm).

Therefore one of the easily deployed and widely used measurement tools is tricuspid annular plane systolic excursion (TAPSE), which is a measurement of the longitudinal contraction of the lateral tricuspid annulus toward the apex during systole. Because the septal segment of the tricuspid annulus is fixed, the longitudinal contraction of the right ventricle causes a hingelike movement of the lateral annulus. This movement can be measured in the ME four-chamber view as the change in distance from annulus to apex in diastole and systole.[112] M-mode scan of this movement is often helpful in a transthoracic four-chamber view. However, the off-axis alignment of tricuspid motion in a transesophageal ME four-chamber view does not allow proper measurement; therefore a modified TG RV inflow-outflow aided by M-mode echocardiography allows for a more accurate measurement[95] (Figs. 14.52 and 14.53; see Video 14.50). Current chamber quantification guidelines suggest that a value less than 17 mm is suggestive of RV systolic dysfunction.[79]

Used in a similar manner as LV systolic evaluation, RV fractional area of change is another 2D-based method of systolic function evaluation. This measurement may be obtained in an ME four-chamber view, tracing the right ventricle from the lateral tricuspid annulus, down the RV free wall to the apex, and returning along the septum to the tricuspid annulus. The change in this area measurement between diastole and systole is calculated as a percent of change (Fig. 14.54). As with TTE, in which an RV-focused, four-chamber view is necessary, anteflexion or probe insertion is necessary to obtain an RV-focused ME four-chamber view to avoid RV foreshortening.[113] An RV fractional area of change less than 35% is indicative of RV dysfunction.[79]

Although the left ventricle allows typical geometric assumptions, yielding estimates of volume (ie, disk summation), the right ventricle's asymmetric nature precludes an accurate estimation of RV volumes. Attempts at RV volumes from 2D imaging typically results in an underestimation when compared with MRI techniques, whereas 3D echocardiography has the ability to overcome this shortcoming and is discussed in the following text.[113]

Doppler-Based Methods

The rate in rise of pressure (dP/dt) may be used to assess RV systolic function. Using a CWD signal of a TR jet and the simplified Bernoulli equation at 0.5 and 2 m/sec allow the determination of the change in pressure and the time required generating that pressure (Fig. 14.55). A dP/dt value less than 400 mm Hg divided by time in seconds likely reflects abnormal RV function; however, normative data are lacking.[113]

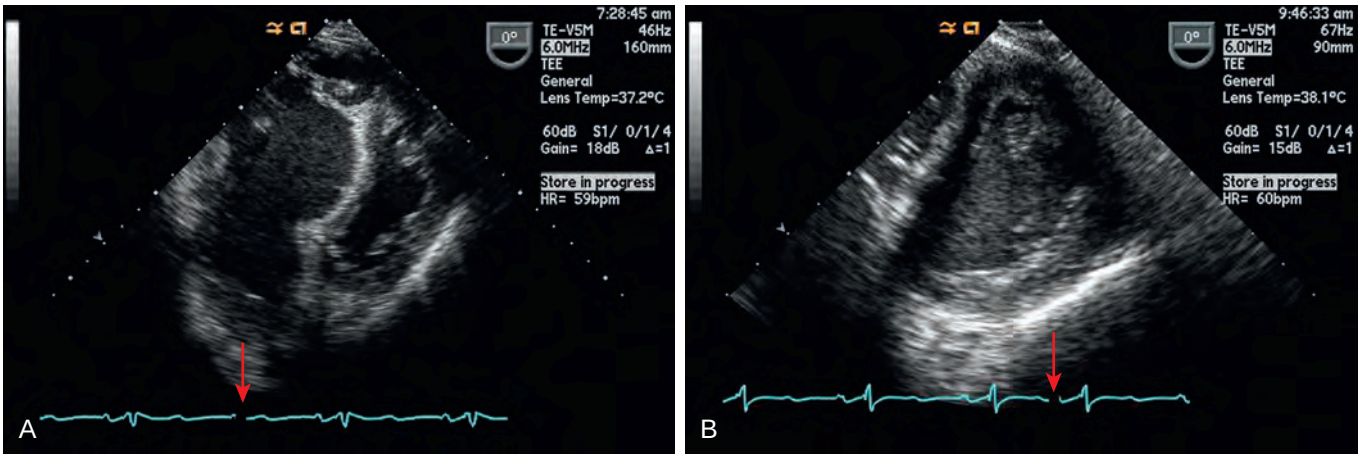

Fig. 14.51 Right ventricular overload (RV) is identified by the timing of septal flattening in the transgastric midpapillary short-axis view. (A) A D-shaped interventricular septum is identified at end-diastole, demonstrating RV volume overload. The *red arrow*, at the end of the P-wave on the electrocardiogram (ECG), marks end-diastole. (B) Septal bowing is noted at end-systole identifying RV pressure overload. The *red arrow*, at the end of the T-wave on the ECG, marks end-diastole. (Video clips available online.)

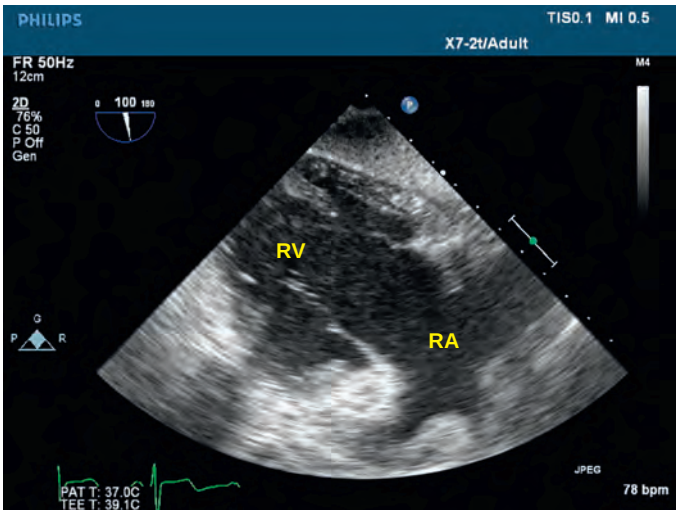

Fig. 14.52 Modified transgastric right ventricular inflow view obtained by deeper insertion and anteflexion of the transesophageal echocardiography probe from the conventional transgastric right ventricular inflow view, offers improved alignment with the tricuspid annulus for M-mode and tissue Doppler imaging interrogation. *RA*, Right atrium; *RV*, right ventricle. (Video clip available online.)

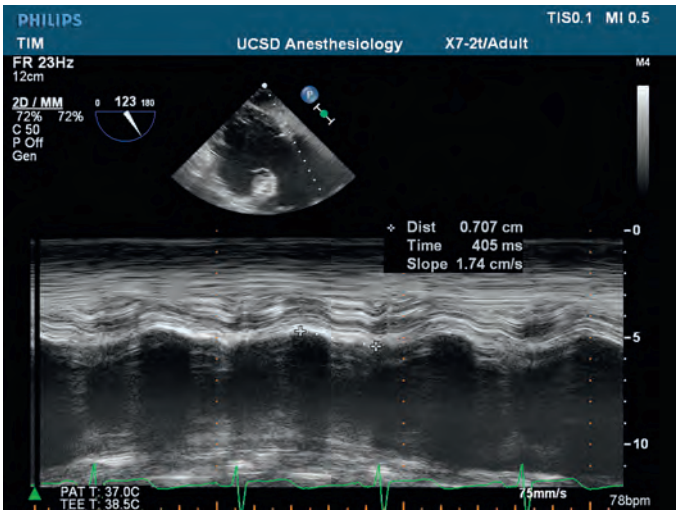

Fig. 14.53 M-mode interrogation of the tricuspid valve annulus is demonstrated in a modified transgastric right ventricular inflow view. The calipers note a reduced tricuspid annular plane systolic excursion (TAPSE) in a patient with pulmonary hypertension and decreased right ventricular function.

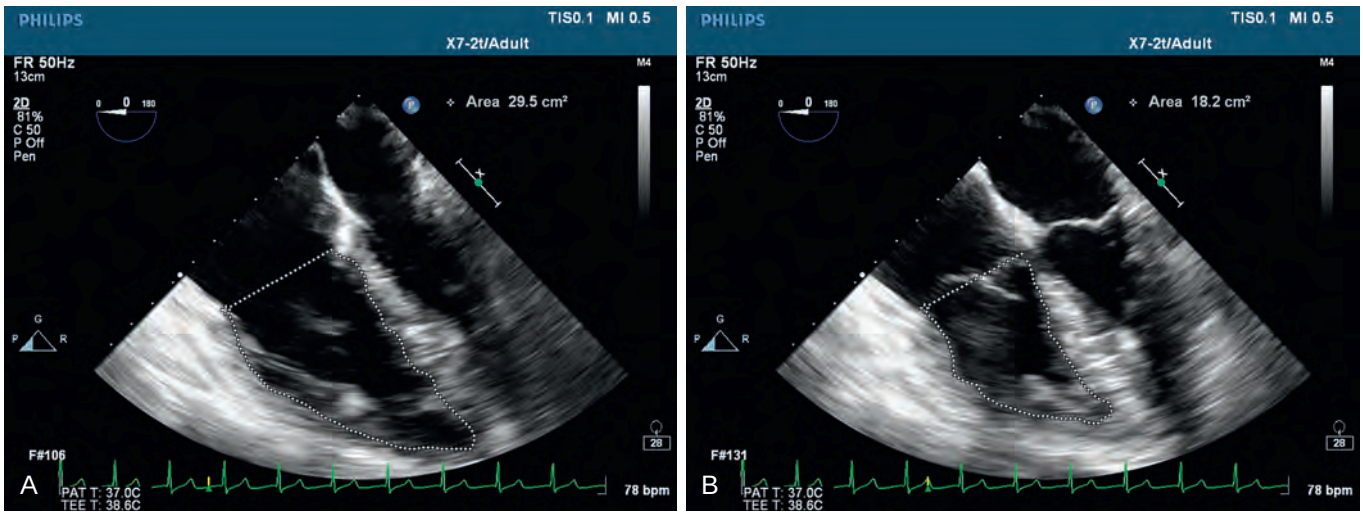

Fig. 14.54 Midesophageal four-chamber view in diastole (A) and systole (B) with the endocardial borders traced from lateral tricuspid valve annulus toward the apex and returning to the septal tricuspid valve annulus. This patient exhibits normal right ventricular systolic function with an FAC of 38.3%. FAC = (EDA – ESA)/EDA. *EDA*, End-diastolic area; *ESA*, end-systolic area. *FAC*, fractional area change.

Tissue Doppler imaging of the RV myocardial motion allows the assessment of both global and regional systolic function. A PWD tissue profile of the lateral basal RV segment near the tricuspid annulus allows measurement of peak systolic velocity (S′) and RV index of myocardial performance (RIMP).

As described earlier with respect to TAPSE, the longitudinal contraction of the lateral wall is a major contributor to RV systolic function. Measurement of the peak systolic velocity of the lateral tricuspid annulus is an easily obtained method of RV assessment (Fig. 14.56). Again, the angle of the Doppler beam is important, rendering the ME four-chamber view suboptimal, whereas a modified RV inflow view provides improved angle alignment.[95] This method correlates well with RV EF determined by MRI; however, assessment can be influenced by severe TR.[114,115] Similar to TAPSE, this method is an extrapolation from a regional measurement to global RV systolic function. Current guidelines suggest a value less than 9.5 cm/sec as indicative of dysfunction.[79]

Finally, the RIMP method of measurement is used to estimate global systolic and diastolic RV function. RIMP is defined as a ratio of the isovolumic time (isovolumetric relaxation time [IVRT] and isovolumetric contraction time [IVCT]) and the ejection time (ET):

$$\text{RIMP} = [(\text{IVRT} + \text{IVCT})/\text{ET}] \qquad \text{[Eq. 14.17]}$$

These time measurements may be measured by either the PWD method or tissue Doppler method. However, different normative values exist, based on the method used to determine RIMP. The PWD method uses two separate cardiac cycle measurements. ET is measured as the duration of flow in the RVOT from either a UE aortic arch SAX view or a TG RV inflow-outflow view. From a separate cardiac cycle, IVRT and IVCT can be measured as the tricuspid closure opening

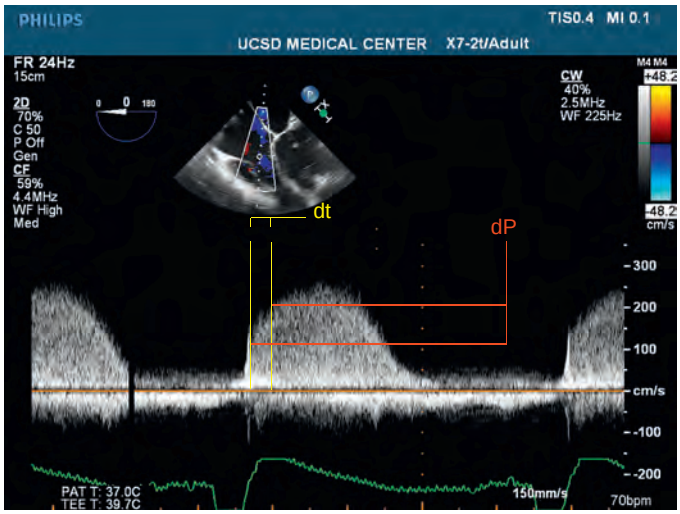

Fig. 14.55 Spectral Doppler analysis of the tricuspid regurgitation jet shows how to perform the calculation of derivative of pressure measured over time *(dP/dt).* Flow velocities of 1 and 2 m/sec are marked, and the time interval between them is measured, converting milliseconds to seconds. The change in pressure in this case is 16 – 4 = 12 mm Hg. dP/dt is calculated as 12 mm Hg/time (in seconds). Values less than 400 mm Hg/sec suggests right ventricular dysfunction.

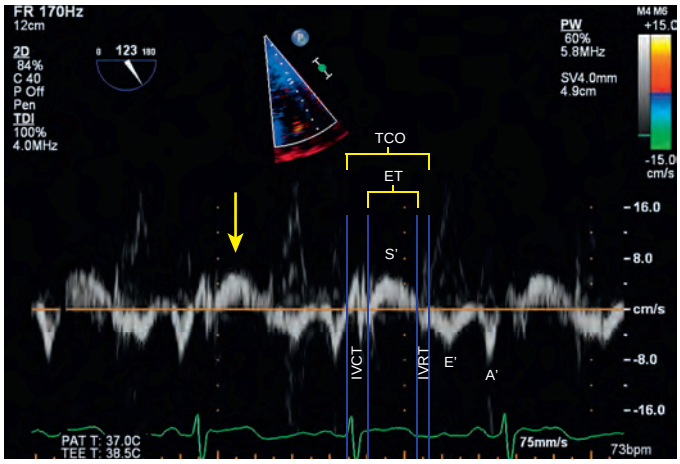

Fig. 14.56 Pulsed-wave tissue Doppler imaging of the lateral tricuspid valve annulus in a modified transgastric right ventricular inflow view. The *yellow arrow* marks the maximum (peak) tissue velocity *(S′).* A peak velocity less than 9.5 cm/sec indicates right ventricular dysfunction. This image also allows the determination of tissue Doppler method of right ventricular myocardial performance index (RIMP), calculated as (TCO–ET)/ET. *A′,* Atrial tricuspid velocity; *E′,* Early tricuspid diastolic velocity; *ET,* ejection time; *IVCT,* isovolumic contraction time; *IVRT,* isovolumic relaxation time; *S′,* peak tricuspid systolic velocity; *TCO,* tricuspid closure opening time.

time (TCO) minus the ET (TCO is the time between the end of a transtricuspid A wave to the beginning of an E wave that includes IVRT, IVCT, and ET). This measurement may be obtained from an ME four-chamber view or ME-modified bicaval view. RIMP may then be calculated using the following equation (Fig. 14.57):

$$\text{RIMP} = \text{TCO} - \text{ET}/\text{ET} \qquad \text{[Eq. 14.18]}$$

The tissue Doppler method, however, can determine RIMP with a single cardiac cycle, reducing heart rate variability from the PWD method. A tissue Doppler profile of the basal RV segment near the tricuspid annulus provides S′, E′, and A′ measurements. ET is the duration of S′, during which TCO is the duration of time between the

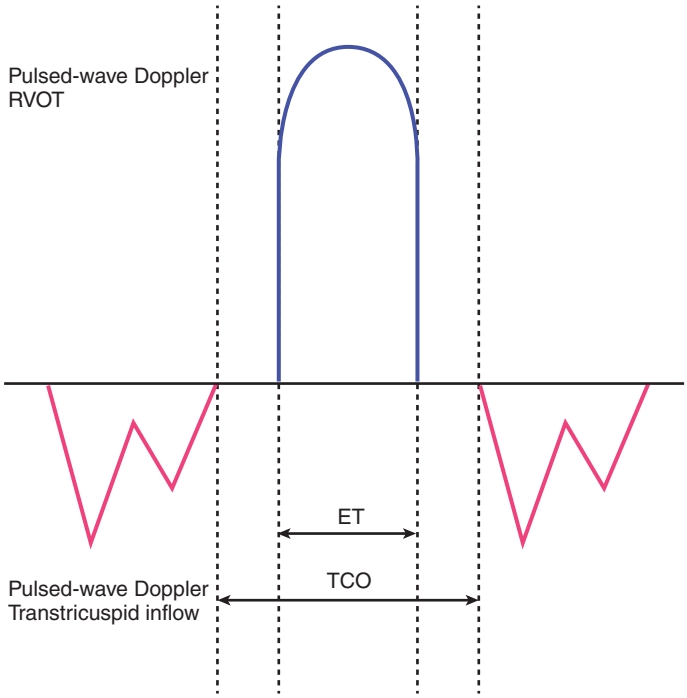

Fig. 14.57 Schematic diagram of time intervals from separate Doppler-derived interrogations of right ventricular outflow tract *(RVOT)* and transtricuspid flow. Above the baseline represents transesophageal echocardiography (TEE)-based Doppler of the RVOT (such as from the upper esophageal [UE] aortic arch short-axis view); below the baseline represents TEE-based Doppler measurement of transtricuspid inflow (such as from the midesophageal four-chamber view). Myocardial performance index is calculated as (TCO – ET). *ET,* Ejection time; *TCO,* tricuspid closure opening time.

end of A′ and the beginning of E′. The calculation of RIMP (TCO – ET/ET) remains the same (see Fig. 14.56). Elevated values of RIMP indicate greater global RV dysfunction with differing normal values between PWD and tissue Doppler methods. Current quantification guidelines note an upper limit of normal as RIMP is greater than 0.43 by PWD and greater than 0.54 by tissue Doppler.[79] Elevated RIMPs have been correlated to severely reduced RV EF by cardiac MRI and predicts hemodynamic instability and mortality after cardiac valvular surgery.[114,116]

Strain-Based Methods

As discussed in Chapter 15, strain represents the percentage of change in myocardial deformation, whereas strain rate represents the rate of the deformational change. When applied to the right ventricle, an ME four-chamber view can provide longitudinal strain measurement by evaluating the myocardial deformation of the base toward the apex (Fig. 14.58). RV global longitudinal strain (RV GLS), an average of strain measurements along the RV free wall, was found to be a sensitive marker of RV dysfunction, had the potential for detecting early RV dysfunction, and correlated well with mortality.[117–119] Both tissue Doppler-based and speckle tracking–based strain require off-line analysis and often use vendor-specific algorithms, which complicate the compilation of normative data. Current guidelines suggest that an RV GLS less than 20% in deformation is suggestive of abnormal RV function; however, further research is necessary to evaluate its perioperative role.[79]

Three-Dimensional Methods

Three-dimensional echocardiography (with off-line semiautomatic border detection) allows volumetric renderings of the right ventricle, as well as the determinations of right ventricular end-diastolic volume (RVEDV) and right ventricular end-systolic volume (RVESV),

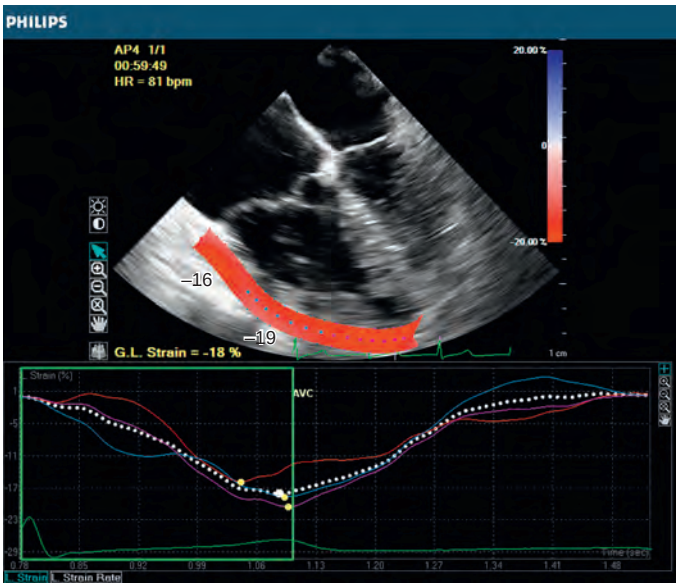

Fig. 14.58 Speckle-tracking–based strain evaluation of the right ventricle from a midesophageal four-chamber view in a patient with right ventricular (RV) enlargement and pulmonary hypertension. RV global longitudinal strain (RV GLS) is calculated as an average of strain measurements along the right ventricular free wall, including basal, midportion and apical RV segments.

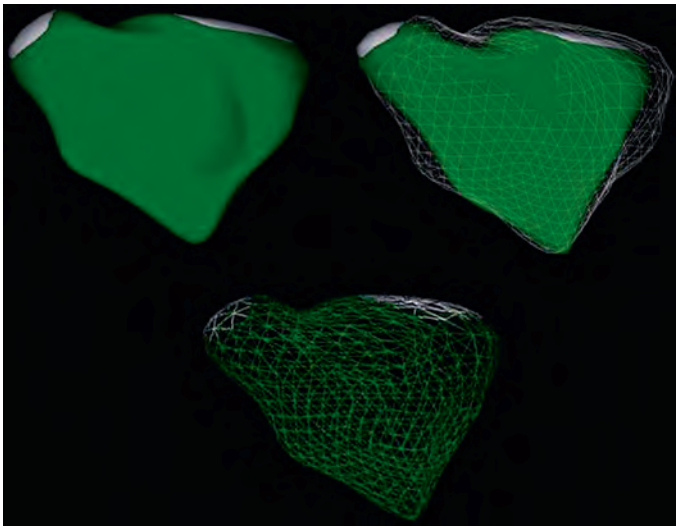

Fig. 14.59 Three-dimensional volumetric analysis using the off-line four-dimensional right ventricular-function software (TomTec Imaging Systems, Germany). *(Reproduced with permission from Jainandunsing JS, Matyal R, Shahul SS, et al. 3-dimensional right ventricular volume assessment.* J Cardiothorac Vasc Anesth. *2013;27:367–375.)*

SV, and EF, which are not dependent on geometric assumptions. One commercially available package, 4D RV-function (TomTec Imaging System, Munich, Germany), uses RV-focused 3D echocardiography data sets from either TTE or TEE origin and provides semiautomatic volume rendering with RV volumes and EF[120] (Fig. 14.59). This package may be used intraoperatively from TEE-derived data sets.[117,121] Three-dimensional echocardiography–based RV volumes correlated to cardiac MRI and radionuclide ventriculography, whereas intraoperative 3D echocardiography–based RV EF has been correlated to both TTE-based 3D echocardiography RV EF and 2D-based measurements of RV function, such as RV FAC and TAPSE.[121–123] Current guidelines suggest a 3D echocardiography RV EF less than 45% is indicative of RV dysfunction.[79]

Hemodynamic Assessment

Intravascular Pressures

Echocardiographic techniques may be used to estimate intracardiac and intravascular gradients. Newton's conservation of energy states that the energy within a closed system must remain the same. If blood passes through an area of stenosis, then the potential energy (as represented by high pressure) must be converted into kinetic energy as observed as high blood-flow velocities. In addition, if the system is pulsatile, then some energy will be expended for blood acceleration and deceleration. Finally, some energy will be lost as heat by the viscous forces generated by friction. These relationships have been described by Bernoulli as:

$$p_1 - p_2 = \tfrac{1}{2}\rho(v_2^2 - v_1^2) + \rho\int(dv/dt)ds + R(\mu) \qquad \text{[Eq. 14.19]}$$

where, p_1 is the pressure proximal to the obstruction; p_2 is the pressure proximal to the obstruction; $p_1 - p_2$ is the pressure difference over the obstruction; v_1 is the velocity proximal to the obstruction; v_2 is the velocity proximal to the obstruction; ρ is the density of blood, which is equal to approximately 1.06 gm/mL; $\int(dv/dt)ds$ is the integral of the blood-flow acceleration over a given distance; and $R(\mu)$ is the resistance (R) and a function of blood viscosity (μ).

The first term represents the kinetic energy expenditure that results in the acceleration of blood over the obstruction. The second term of the equation represents unsteady acceleration and deceleration of pumping blood. These are *inertial* terms. The final term represents kinetic energy loss attributable to viscous friction. The Bernoulli equation assumes reasonably that blood is incompressible. During clinical application, the energy expended attributable to the cyclic acceleration and deceleration, as well as the energy loss attributable to viscous forces, are both negligible and may be ignored, leaving just the first term. Because both velocities are squared and v_2 is significantly larger than v_1 ($v_2 \gg v_1$), v_1 may be ignored as well, the equation may be simplified to:

$$p_1 - p_2 = 0.5\,\rho(v_2^2) \qquad \text{[Eq. 14.20]}$$

For clinical echocardiography, the simplified Bernoulli equation may be modified further to convert SI units (pascals [Pa], kg/m^2) to mm Hg. Because 1 mm Hg is equal to 133.3 Pa:

$$p_1 - p_2 \times 133.3 = 0.5 \times 1060 \times v_2^2$$

Thus $p_1 - p_2 = 3.976v_2^2$

Therefore the clinically relevant simplified Bernoulli equation is:

$$p_1 - p_2 = 4v_2^2 \qquad \text{[Eq. 14.21]}$$

With this formula and canceling assumptions, the pressure gradient across a fixed orifice can be approximated. It may be applied to the measurement of intravascular pressures, as well as the gradient across a stenotic orifice.

Determination of Intravascular Pressures

The velocity of blood traveling through a regurgitant valve is a direct application of pressure gradient calculations and can be used to calculate intracardiac pressure. For example, TR velocity reflects systolic pressure differences between the right ventricle and the right atrium. RV systolic pressure can be obtained by adding estimated or measured RA pressure (RAP) to the systolic pressure gradient across TV during systole. This systolic gradient may be estimated as 4(TR velocity)^2. In the absence of RVOT obstruction, PA systolic pressure will be the same as RV end-systolic pressure (RVESP). For example,

If TR velocity = 3.8 m/sec and RAP = 10 mm Hg, then,

$$\text{RVESP} = (\text{TR velocity})^2 \times 4 + \text{RAP}$$

$$4(3.8)^2 = 58 \text{ mm Hg} + 10 \text{ mm Hg}$$

$$\text{RVESP} = \text{PA systolic} = 68 \text{ mm Hg}$$

Similarly, pulmonary regurgitation (PR) velocity represents the diastolic pressure difference between the PA and the right ventricle. Therefore PA end-diastolic pressure = right ventricular end-diastolic pressure (RVEDP) + 4(PR end-diastolic velocity)^2. Note that RVEDP is equal to RAP (estimated or measured). MR velocity represents the systolic pressure difference between the left ventricle and the left atrium. In patients *without LVOT obstruction or AS*, systolic blood pressure is essentially equal to LV systolic pressure; therefore LAP is equal to SBP – 4(MR)^2. Finally, aortic regurgitation (AR) velocity reflects the diastolic pressure gradient between the aorta and the left ventricle. In summary,

$$\text{PAP systolic} = \text{RVESP} = 4(\text{TR})^2 + \text{RAP}$$

$$\text{PAP diastolic} = 4(\text{PR})^2 + \text{RAP}$$

$$\text{LAP} = \text{SBP} - 4(\text{MR})^2$$

$$\text{LVEDP} = \text{DBP} - 4(\text{AR})^2$$

Stevenson[124] compared six different echocardiographic techniques to measure PAP. When compared with direct measurements, some of these techniques yielded highly accurate correlations (r = 0.97), but they were not always applicable in all patients.

Cardiac Output

Two-Dimensional Echocardiographic Measurement

SV is calculated as the difference between EDV and ESV. The ASE has recommended that the diastolic dimension coincide with the Q wave on the ECG. The end-systolic dimension is best measured at the time of the peak downward motion of the posterior endocardium. When TEE was used to obtain ventricular dimensions, correlations between echo and indicator dilution varied from r = 0.72 in patients undergoing cardiac surgery to r = 0.97 in critically ill patients.[125] In patients undergoing CABG, SV was derived from 2D SAX views using echocardiography.[126] Comparisons of echo-derived CI with simultaneous thermodilution-derived CI yielded a correlation coefficient of 0.80.

Doppler Measurements

In addition to measuring gradients, the measurements of blood-flow velocity may be used to estimate flow with a given structure. The derivative of a function is the slope of the curve at a given point, whereas an integral of a function is the area under the curve between two points along its X axis. Given an equation that would describe distance traversed, the time derivative or slope at any given point would represent its velocity; the time derivative of the velocity at any given point would be its acceleration (Fig. 14.60). Similarly, given a graph of acceleration versus time, the integral would yield a velocity measurement; the integral of a velocity-versus-time graph would yield a distance traversed (ignoring initial conditions). A CWD velocity profile is a display of velocity versus time. If this velocity profile is integrated between two time points, that is, calculates the area under the curve, then the distance traversed of a "region of blood" during this period may be estimated. Because flow velocity is not constant throughout a flow cycle, all of the flow velocities during the entire ejection period are integrated to measure "distance traversed" of this "region of blood." This integration of flow velocities in a given period is called the *velocity-time integral* (VTI) and has the units centimeters. When flows at a particular location along the LVOT or aorta are required (ie, spacial specificity is necessary), then PWD should be used, provided velocity does not exceed the phased-wave Nyquist limit. High PRF can be used. Multiple regions of interest points may be seen, indicating range ambiguity of the cursor. If the velocities are too high, then localizing the jet without assumptions is not possible.

VTI may be used to calculate flow. The cross-sectional area (CSA) for a circular orifice, such as the LVOT is:

$$\text{CSA} = \pi(\text{D}/2)^2 \qquad \text{[Eq. 14.22]}$$

where D represents the diameter obtained by 2D imaging. Flow across a given orifice or SV is equal to the product of the CSA of the orifice and distance traversed during a single cardiac cycle, as calculated by the VTI. SV and CO may thus be calculated as:

$$\text{SV} = \text{CSA} \times \text{VTI} \qquad \text{[Eq. 14.23]}$$

$$\text{CO} = \text{SV} \times \text{HR} \qquad \text{[Eq. 14.24]}$$

When using these equations, there are a number of assumptions, including (1) laminar blood flow in the area interrogated; (2) a flat or blunt flow velocity profile, such that the flow across the entire CSA interrogated is relatively uniform; and (3) Doppler angle of incidence between the Doppler beam and the main direction of blood flow is less than 20 degrees, so that the underestimation of the flow velocity is less than 6%.

An example of the use of PWD to measure SV is illustrated. In Fig. 14.61A, the ME LAX view is used to image the LVOT. The diameter of the LVOT is 2.2 cm, which corresponds to a radius of 1.1 cm. As described earlier,

$$\text{CSA} = \pi\, r^2 = 3.14\,(1.1)^2 = 3.80\ \text{cm}^2$$

In Fig. 14.61B, a PWD spectrum is measured through the LVOT as imaged in the deep TG view, and the VTI is calculated as 19 cm. The SV is:

$$\text{SV} = \text{CSA} * \text{VTI} = 3.8\ \text{cm}^2 * (19\ \text{cm}) = 72\ \text{cm}^3$$

A number of Doppler methods have been attempted to calculate SV. Probably the most popular and accepted method is the LVOT approach. Other methods using the mitral, tricuspid, and pulmonic orifices have been attempted with variable results. Their respective accuracy is dependent on the angle between the insonated Doppler signal and blood flow. It should be noted, however, that the major determinant of variability in estimating SV by the use of any technique is the accurate measurements of the CSA. As described in Equation 14.20, the measurement of the CSA is directly proportional to the

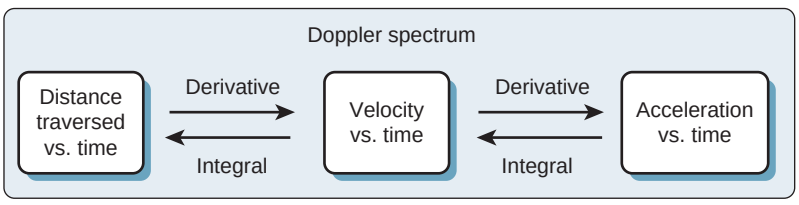

Fig. 14.60 Relationship among distance, velocity, and acceleration. The derivative of the function of position versus time results in its velocity; the derivative of the velocity at any given point would be its acceleration. Similarly, the integral of acceleration is velocity; the integral of velocity is the distance traversed. A Doppler spectrum is displayed a velocity versus time spectrum. If one integrates this spectrum between two time points, that is, calculates the area under the curve, the distance traversed during this period may be calculated.

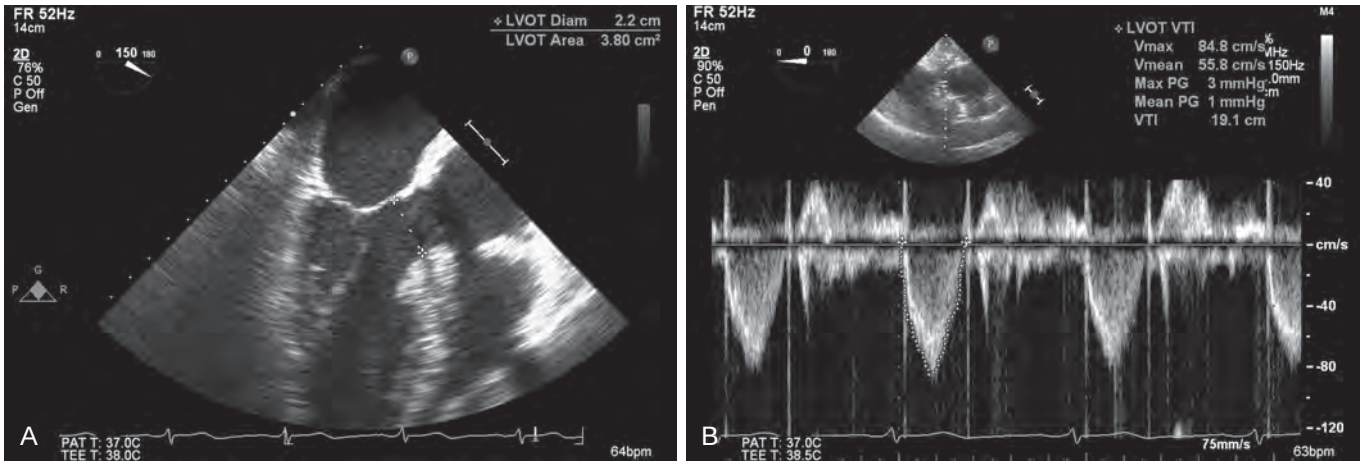

Fig. 14.61 Calculation of cardiac output. (A) Midesophageal long-axis view. The diameter of the left ventricular outflow tract is measured. (B) Velocity time integral through the left ventricular outflow tract. Since spatial specificity is necessary, a pulsed-wave Doppler spectrum is used.

square of the radius; therefore any error in diameter measurement would be squared in the final results.

A second source of variability in measuring flow involves the proper recording of reproducible Doppler signals. If the LVOT is chosen as the CSA, then the VTI should be obtained from the Doppler signal at this level. For this purpose, the systolic forward flow must be obtained from either a deep TG or TG LAX view. The sample volume of the PWD should be placed in the high portion of the LVOT *exactly* at the same level where the diameter was measured. Occasionally, the Doppler signal is difficult to obtain, and the morphologic structure of the spectrum may be similar to a triangle with a spike at the peak velocity rather than a round "bell-shape" flow signal. Under such circumstances, estimating the VTI is inappropriate, because underestimations or overestimations are likely to result. If attention is given to proper recording techniques, then the interobserver variability in measuring the aortic VTI in normal subjects should be less than 5%.

When the results of various studies are compared, it is important to know the method of calculating the VTI and the CSA, as well as where the Doppler sampling volume was located. Because PWD provides a spectral display of instantaneous velocities, mean velocities or velocity modes are used for the integration of flow velocity. The measurement of the mitral orifice diameter should probably be repeated at various angles. It has been well established that the size of the mitral orifice varies with varying flows. The importance of the sample volume location has been demonstrated in several studies.[127] The SV is underestimated when the sampling volume is placed at the mitral leaflet tips and overestimated when placed at the mitral annulus.

Using TEE, Roewer and colleagues[128] calculated SV in 27 surgical patients. A comparison of Doppler-determined CO values with those obtained by thermodilution yielded an excellent correlation (r = 0.95). LaMantia and associates,[129] who performed a similar study in 13 cardiac surgical patients, found only a modest correlation (r = 0.68). Other investigations have used pulmonary arterial Doppler-flow velocity integrals and estimations of the vessel area to perform off-line calculations of SV and CO.[130] Muhiudeen and colleagues[131] found that transmitral Doppler CO did not correlate with that obtained by thermodilution and pulmonary arterial Doppler CO correlated only weakly (r = 0.65) with that obtained by thermodilution. They concluded that transesophageal Doppler has significant limitations at the off-line monitor of CO. In contrast, Savino and associates[130] found good agreement and correlation (r = 0.93) between transesophageal pulmonary arterial Doppler and thermodilution CO. They were, however, unable to visualize the main PA in 24% of patients. In addition, the method was tedious and not suitable for online analysis with current equipment and software.

In 50 cardiac surgery patients, CO obtained by thermodilution was compared with deep TG PWD through the LVOT.[132] Of these patients, 7 patients were excluded from analysis because Doppler measurements could not be obtained. Good correlations were obtained with a bias of 0.015 L/min with 29% error. The authors estimated that these Doppler estimates of CO were 92% sensitive and 71% specific for detecting more than 10% change in CO.

The use of 3D echocardiography may increase the accuracy of CO measurements. Because geometric variability is more easily compensated in these measurements, ESV and EDV may be calculated and CO may be determined. Culp and associates[133] compared 3D echocardiographic determinations of CO with thermodilution during the period before bypass in 20 patients undergoing cardiac surgery. In their study, the mean bias was 0.27 L/min with a plus or minus 35% limit of agreement. They observed a good correlation between these two measurements; however, there were significant bias and wide limits of agreements among the measurements. Off-line analysis of 3D echocardiographic images may be used to estimate CO. In a study of 40 patients undergoing heart transplantation, 3D echocardiographic reconstruction of LVEDV and LVESV were estimated, allowing for the calculation of SV and CO.[127] These CO measurements were closely correlated with thermodilution-derived measures, with a mean bias of 0.06 L/min and a standard deviation of 0.4 L/min. It should be noted, however, that each measurement required approximately 3 minutes per case, and poor image quality precluded analysis in four patients. Three-dimensional TTE determination of SV was highly correlated to catheterization data.[134] These 3D data sets tended to underestimate the SV by 7.5 mL or 17%.

As described earlier, homogeneous laminar flow and a cylindrical outlet is assumed during Doppler measurements. This, unfortunately, may not be the case. Three-dimensional color-Doppler echocardiography may be used to more accurately define the CSA of either the LVOT or the MV, as well as more accurately describe the blood flow through these areas. In 3D color-Doppler determination of CO, multiple 2D echocardiographic slices with their associated Doppler data are obtained through a particular surface. Flow data may be computed using Gaussian control surface theory.[135] Gaussian theory states that for a curved surface, the flow passing through the surface is equal to the sum of all velocity components normal to the surface (Fig. 14.62).

In a group of 47 postcardiac transplantation patients, CO was determined by thermodilution, as well as 2D and 3D Doppler echocardiography through both the LVOT and the MV.[136] The 3D measurement provided a lower bias and narrower limits of agreement both in the LVOT measurements (−1.84 ± 16.8 vs −8.6 ± 36.2 mL) and in the MV inflow position (−0.2 ± 15.6 vs 10.0 ± 26 mL).

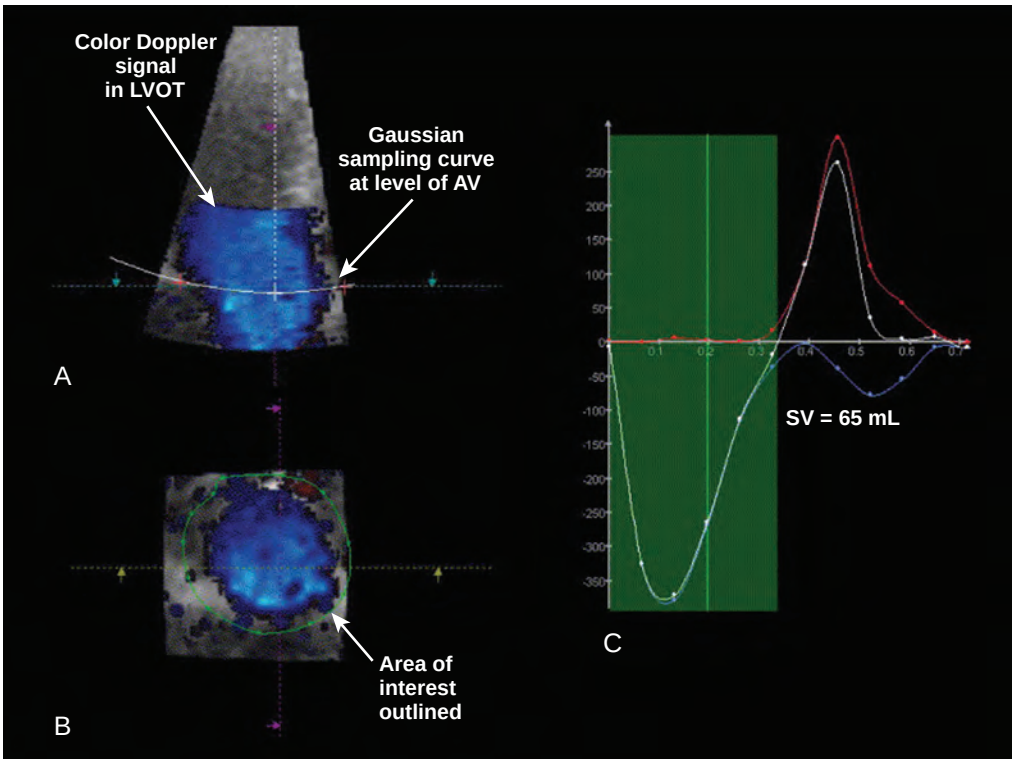

Fig. 14.62 Calculation of flow using Gaussian control surface theory. Contrast Applications

Diagnostic applications for contrast echocardiography include enhancement of endocardial borders from qualitative assessment of wall-motion abnormalities, measurement of LV function, assessment of congenital heart disease, quantification of valvular regurgitation, enhancement of CFD signals, and assessment of myocardial perfusion. During cardiac surgery, the special and unique applications of myocardial contrast echocardiography (MCE) include measurements of perfusion area after CABG surgery, assessment of the quality of coronary artery grafts and cardioplegia distribution, and correct assessment of the results of surgery for ventricular septal defect. Noncardiac intraoperative applications include assessment of perfusion in the kidney and in skeletal muscle. Work is ongoing to investigate the potential for analyzing cerebral blood flow with contrast-echocardiographic techniques.

Enhancement of Right-Sided Structures

Hand-agitated saline solutions are still useful to enhance right-sided structures. These saline solutions can be easily prepared by hand agitation of saline between two 10-mL Luer lock syringes connected by a three-way stopcock; small amounts of blood or air may be added to improve right-sided opacification. This technique is most commonly used to opacify the right atrium and right ventricle, assisting in the diagnosis of intraatrial and ventricular shunts and to enhance pulmonary arterial Doppler signals. The most common indication is the detection of a PFO. After obtaining a bicaval view, a Valsalva maneuver is induced, and hand-agitated saline is injected into a large vein. After the right atrium is opacified, the Valsalva is released, and the left atrium is examined for contrast (Fig. 14.63; see Video 14.51).

Left Ventricular Opacification

The commercially available contrast agents allow for left ventricular opacification (LVO) as well. Relatively low MI modes are usually used (less than 0.2) to allow for bubble detection without bubble destruction. The images are processed such that the linear scatters from tissue are completely eliminated, leaving only nonlinear scatters from the bubble contrast. The LVO allows enhancement of LV endocardial borders in patients whose normal studies are challenging.[137,138] Such challenging studies include patients who are obese, with pulmonary disease, are critically ill, or are on a ventilator.[21] The use of LVO substantially increases the accuracy of LV volume determination, compared with electron-beam computed tomography measurements. In addition, its use decreases interobserver variability associated with these measurements and increases the number of myocardial segments that may be accurately described during stress echocardiography.[139,140] Underestimation of LV volume measurements, which is common with standard echocardiography, may be virtually eliminated with the use of LVO.[141] Finally, LVO provides greater visualization of structural abnormalities such as apical hypertrophy, noncompaction, ventricular thrombus, endomyocardial fibrosis, LV apical ballooning (Takotsubo cardiomyopathy), LV aneurysms or pseudoaneurysms, and myocardial rupture.[21]

Aortic Dissections

Echocardiographic contrast may be used to diagnosis aortic dissections. Artifacts may be distinguished from true aortic dissection and artifact by the homogeneous distribution of contrast within the aortic lumen.[21] The intimal flap may be visualized, the entry and exit points may be identified, and the extension into major aortic branches may be

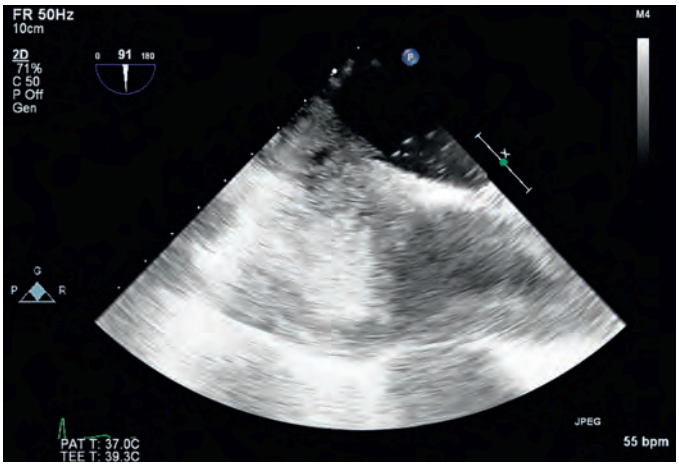

Fig. 14.63 Injection of hand-agitated saline. The right atrium is opacified by hand-agitated saline central venous injection. Several bubbles may be seen in the left atrium after traversing a patent foramen ovale in the atrial septum. (Video available online.)

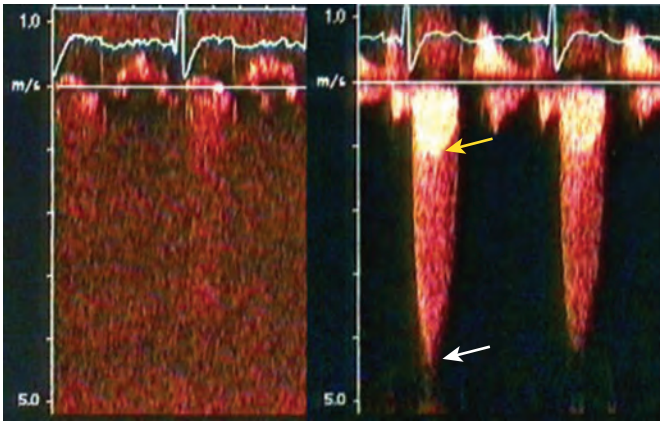

Fig. 14.64 Doppler enhancement of aortic stenosis. The image displays the Doppler spectrum through the left ventricular outflow tract in a patient with aortic stenosis. The image on the *left* is without contrast and the image on the *right* is after contrast enhancement. The contrast-enhanced image clearly demonstrates the high-velocity envelope consistent with aortic stenosis that could not be visualized without contrast. The *yellow arrow* indicates the velocity through the left ventricular outflow tract, and the *white arrow* denotes flow through the aortic valve. *(Reproduced with permission from Mulvagh SL, Rakowski H, Vannan MA, et al. American Society of Echocardiography Consensus Statement on the Clinical Applications of Ultrasonic Contrast Agents in Echocardiography.* J Am Soc Echocardiogr. *2008;21:1179–1201.)*

more easily defined. The use of contrast further increases the successful differentiation between the true and false lumen.

Doppler Enhancement

The administration of contrast will enhance the echocardiographic Doppler spectrum, in which the signal is weak or suboptimal.[142] The enhancement is particularly useful in the evaluation of AS but may also be used with transmitral evaluation, pulmonary venous flow determination, or regurgitant tricuspid valvular flow (Fig. 14.64). Whereas the threshold for detecting contrast is substantially less for Doppler, compared with 2D imaging, contrast agents are usually used initially for the latter application.

Myocardial Perfusion

The second-generation agents allow for perfusion of the myocardial microcirculation. This perfusion allows for the assessment of perfusion patterns, coronary artery stenosis, and myocardium at risk during acute coronary syndromes.[20] Currently, only Imagify has US Food and Drug Administration (FDA) approval for myocardial perfusion imaging.

TABLE 14.9 Diagnosis of Fixed Myocardial Deficits, Ischemia, Stunning, and Hibernation Based on Perfusion and Wall Motion Findings

	Rest Perfusion	*Stress Perfusion*	*Rest Wall Motion*	*Stress Wall Motion*
Fixed deficit	Deficit	Deficit	Akinetic	Akinetic
Ischemia	Normal	Deficit	Normal	RWMA
Stunning	Normal		RWMA	
Hibernation	Hypoperfusion		Hypokinetic	

RMWA, Regional wall motion abnormality.

Lindner and colleagues[143] described a method for the quantification of myocardial blood flow using contrast echocardiography. If a contrast agent is administered at a steady rate, then the blood concentration and myocardial concentration of the contrast agent will equilibrate. If a single high-amplitude (ie, high MI) ultrasound pulse is delivered to a myocardial region of interest, then the microbubbles will be destroyed; they will be replenished as the contrast-filled blood perfuses the myocardium. The rate of contrast replenishment in the myocardium is directly related to myocardial blood flow. Repeated ultrasound pulses are delivered at short frequencies until a maximum MCE signal is obtained. A time-myocardial contrast intensity curve is constructed. Myocardial-contrast echocardiographic-derived indications of myocardial perfusion rate have relatively good between-study and between-reading reproducibility.[144]

If contrast echocardiography is used in conjunction with traditional echocardiography, then different flow patterns can be described as outlined in Table 14.9. A fixed myocardial deficit may be diagnosed with a perfusion deficit during rest and stress with akinetic segments during both of these periods. An ischemic segment may be defined as a segment with normal perfusion and wall motion with rest and a perfusion deficit during stress that is accompanied by a RWMA. Myocardial stunning may be diagnosed if normal perfusion is observed during rest in the presence of a hypokinetic rest wall motion, and hibernation may be diagnosed with rest hypoperfusion and with hypokinetic rest wall motion. The addition of MCE may increase the sensitivity, but not the specificity, of dipyridamole-exercise echocardiography. Moir and colleagues[145] combined MCE with dipyridamole-exercise echocardiography in 85 patients. They detected significant coronary artery stenosis in 43 patients involving 69 coronary areas. The addition of MCE-improved sensitivity for the detection of CAD (91% vs 74%; $P = 0.02$) and accurate recognition of disease extent (87% vs 65% of territories; $P = 0.003$).

Valvular Evaluation

Aortic Valve Evaluation

Two-dimensional TEE provides information on valve area, leaflet structure, and mobility. The valve has three fibrous cusps, right, left, and noncoronary, that are attached to the root of the aorta. Each cusp has a nodule, the nodule of Arantius, in the center of the free edge at the point of contact of the three cusps. The spaces between the attachments of the cusps are called the *commissures*, and the circumferential connection of these commissures is the *sinotubular junction*. The aortic wall bulge behind each cusp is known as the *sinus of Valsalva*. The sinotubular junction, the sinuses of Valsalva, the valve cusps, the junction of the AV with the ventricular septum, and the anterior MV leaflet comprise the AV complex. The aortic ring is at the level of the ventricular septum and is the lowest and narrowest point of this complex. The three leaflets of the AV are easily visualized, and vegetations or calcifications can be identified on basal transverse imaging or longitudinal imaging.

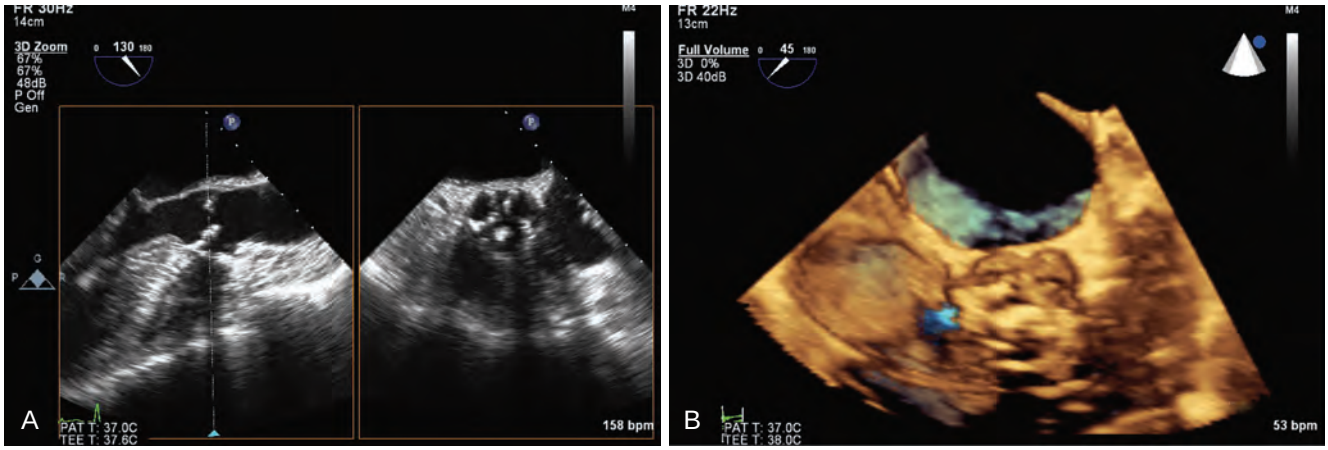

Fig. 14.65 Aortic stenosis. (A) Both midesophageal aortic valve (AV) short- and long-axis views are demonstrated. The AV is stenotic, thickened, and calcific with significant valvular restriction. (B) Three-dimensional reconstruction. The AV is viewed from the ascending aorta. (Video available online.)

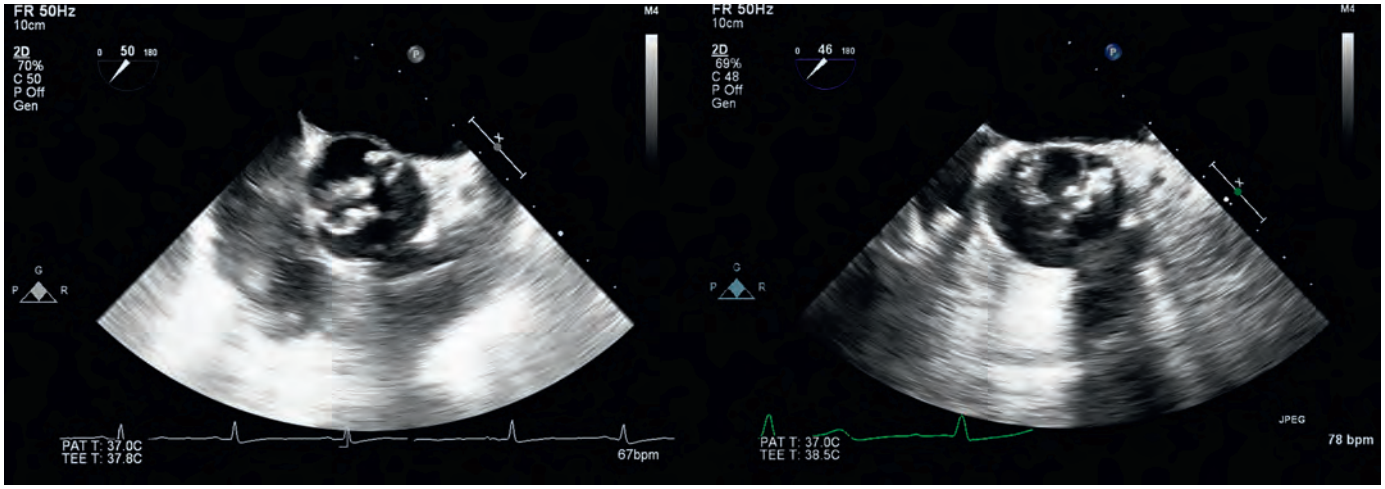

Fig. 14.66 Aortic stenosis. Bicuspid versus unicuspid aortic stenosis. Midesophageal aortic valve short-axis views. *(Left)* Bicuspid aortic valve. A fusion of the right and left coronary cusps is demonstrated, producing a bicuspid aortic valve. *(Right)* Unicuspid aortic valve is characterized by a single commissure opening and closing as a single unit. (Video available online.)

Aortic Stenosis

AS may be caused by congenital unicuspid, bicuspid, tricuspid, or quadricuspid valves; rheumatic fever; or degenerative calcification of the valve in older adults (Figs. 14.65 and 14.66; see Video 14.52).[146,147] Valvular AS is characterized by thickened, echogenic, calcified, immobile leaflets and is usually associated with concentric LV hypertrophy and a dilated aortic root. The valve leaflets may be domed during systole; this finding is sufficient for a diagnosis of AS.[148]

The quantification of AS is summarized in Table 14.10. Aortic valve area (AVA) may be measured by planimetry (Fig. 14.67).[149] A cross-sectional view of the AV orifice may be obtained by using the ME AV SAX view, which corresponds well to measurements of the AVA obtained by TTE and cardiac catheterization, assuming the degree of calcification is not severe. With severe calcification, echocardiographic shadowing is significant, which limits the accuracy of this measurement.

Alternatively, AS may be quantified using CWD echocardiography (Fig. 14.68).[150] The evaluation of severity, however, is contingent on the alignment of the ultrasonic beam with the direction of blood flow through the LVOT. This alignment may be obtained using either a deep TG or TG LAX view. Because severe stenosis limits AV opening, the imaging of the actual AV orifice may be challenging. Superimposition of a CFD spectrum over the calcific AV may guide accurate CWD curser placement (Fig. 14.69; see Video 14.53). Normal Doppler signals across the AV have a velocity of less than 1.5 m/sec and have peak signals during early systole. With worsening AS, the flow velocity increases and the peak signal is later in systole. Severe AS is characterized by a peak velocity of greater than 4 m/sec, which will usually correspond to a mean gradient greater than 40 mm Hg.[151] These high

TABLE 14.10 Summary of Aortic Stenosis

	Aortic Sclerosis	*Mild*	*Moderate*	*Severe*
Aortic jet velocity (m/sec)	≤2.5	2.6–2.9	3.0–4.0	>4.0
Mean gradient (mm Hg)		<20	20–40	>40
Aortic valve area (cm^2)		>1.5	1.0–1.5	<1.0
Indexed aortic valve area (cm^2/m^2)				≤0.6

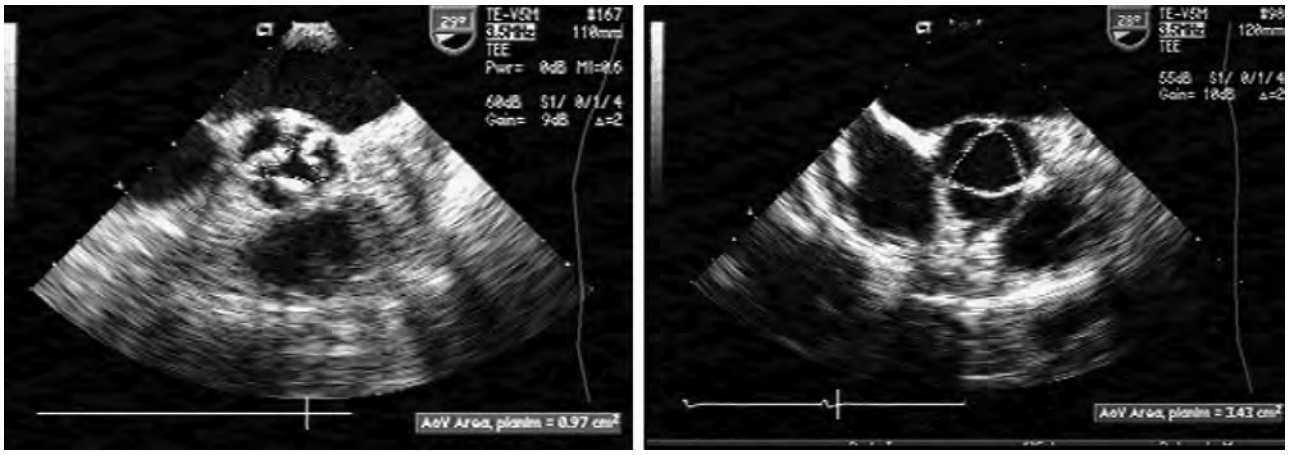

Fig. 14.67 Aortic valve stenosis by planimetry. The panel on the *left* illustrates a stenotic aortic valve, whereas the panel on the *right* illustrates a normal aortic valve. Because calcification is not significant, planimetry may be used to estimate aortic valve area.

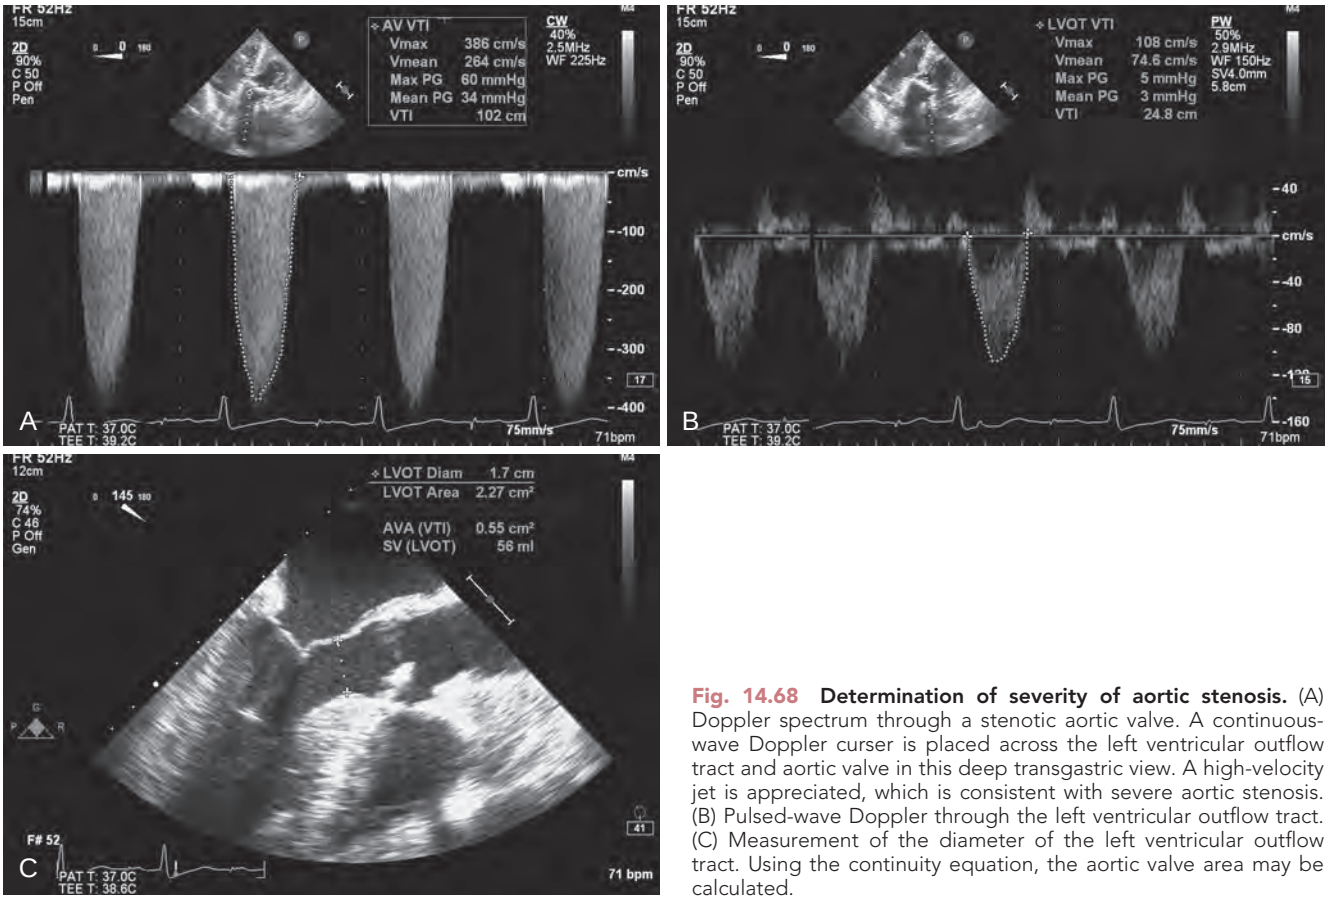

Fig. 14.68 Determination of severity of aortic stenosis. (A) Doppler spectrum through a stenotic aortic valve. A continuous-wave Doppler curser is placed across the left ventricular outflow tract and aortic valve in this deep transgastric view. A high-velocity jet is appreciated, which is consistent with severe aortic stenosis. (B) Pulsed-wave Doppler through the left ventricular outflow tract. (C) Measurement of the diameter of the left ventricular outflow tract. Using the continuity equation, the aortic valve area may be calculated.

velocities will limit the use of PWD and necessitate the use of either CWD or high PRF Doppler.

The higher velocity central jet is characterized by a high-pitched audio sound and a fine feathery appearance on the Doppler signal and is usually less dense than the thicker parajets that are distal to the valve. Peak and mean transvalvular gradients may be calculated using the peak and mean velocities of the signals, respectively. Peak gradients measured by Doppler ultrasonography tend to be higher than those measured in the cardiac catheterization laboratory because Doppler-determined peak gradients are instantaneous, whereas those reported by the cardiac catheterization laboratory are peak-to-peak systolic pressure differences. In addition, Doppler determinations of peak gradient may overestimate the gradient because of pressure recovery effects (Fig. 14.70). As blood flows past a stenotic AV, the potential energy of the high-pressure left ventricle is converted into kinetic energy; there is a decrease in pressure with an associated increase in velocity. Distal to the orifice, flow decelerates again with both conversion of this loss of kinetic energy into heat, as well as a reconversion of some kinetic energy into potential energy with a corresponding increase in pressure. This increase in pressure distal to the stenosis

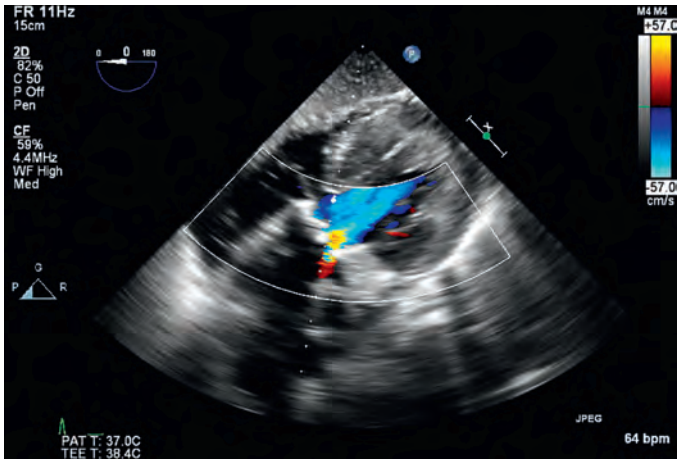

Fig. 14.69 Lining up the cursor: deep transgastric view. Superimposition of color-flow Doppler across the stenotic aortic valve allows for a more accurate identification of the limited aortic valve opening. With this information, the cursor may be more easily placed to obtain a continuous-wave Doppler spectrum.

is called the *pressure recovery effect*.[152] Although usually minor, these differences in the observed gradient become more significant with a small aorta and moderate-to-severe AS.[153]

Alternatively, AVA may be calculated using the continuity equation by comparing blood flow through the LVOT with blood through the AV (see Fig. 14.68). As previously discussed in greater detail, SV may be estimated by multiplying the CSA of a particular orifice by the VTI over one cardiac cycle through that orifice. The continuity equation describes the conservation of a physical quantity, that is, energy and mass. Blood flow in one portion of the heart must be equal to the blood flow in another portion of the heart. This application of the continuity equation is commonly used to calculate the AVA. In this case, it is assumed that the blood flow as measured at the level of the LVOT must be equal to the blood flow through the AV. Using either a deep TG or TG LAX view, the Doppler spectrum of the AV and LVOT is displayed. Whereas spatial specificity is necessary for the LVOT measurement, PWD is used. The high velocities that are detected over a stenotic AV usually preclude the use of PWD because of aliasing (ie, exceeding the Nyquist limit); therefore CWD is used. Although CWD allows the measurement of high velocities, spacial specificity is lost. This loss of spacial specificity is not important, since physiologically, these high-velocity flows must be over the stenotic AV if that is the smallest orifice. Once these Doppler spectra have been obtained, the VTI over one cardiac cycle through each of these structures is calculated. The diameter of the LVOT is measured in an ME LAX view. Remembering,

$$SV = CSA * VTI \qquad \text{[Eq. 14.25]}$$

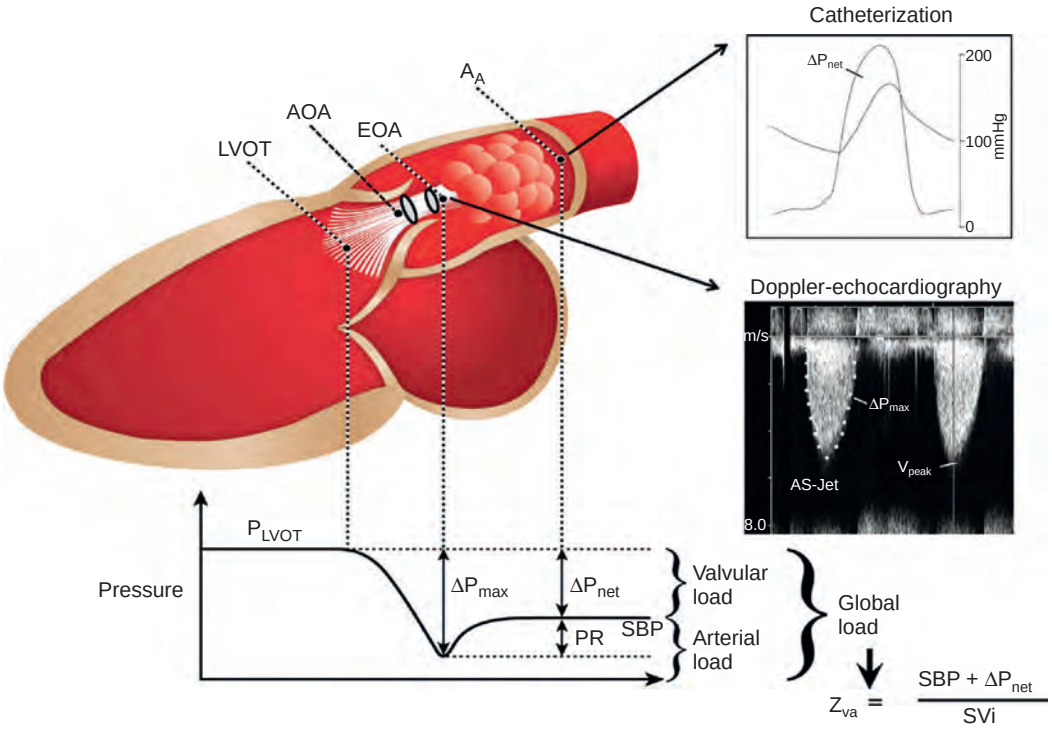

Fig. 14.70 Pressure recovery effect. When the blood flow contracts to pass through a stenotic orifice (anatomic orifice area *[AOA]*), a portion of the potential energy of the blood (namely, pressure) is converted into kinetic energy (namely, velocity), thus resulting in a pressure drop and acceleration of flow. Downstream of the vena contracta (effective orifice area *[EOA]*), a large part of the kinetic energy is irreversibly dissipated as heat because of flow turbulences. The remaining portion of the kinetic energy that is reconverted back to potential energy is called the *pressure recovery (PR)*. A_A, Cross-sectional area of the aorta at the level of the sinotubular junction; ΔP_{max}, maximum transvalvular pressure gradient recorded at the level of vena contracta (mean gradient measured by Doppler); ΔP_{net}, net transvalvular pressure gradient recorded after pressure recovery (mean gradient measured by catheterization); *LVOT*, left ventricular outflow tract; *PLVOT*, pressure in the LVOT; *SBP*, systolic blood pressure; *SVi*, stroke volume index; V_{peak}, peak aortic jet velocity; Z_{va}, valvuloarterial impedance. *(Reproduced with permission from Pibarot P, Dumesnil JG. Improving assessment of aortic stenosis.* J Am Coll Cardiol. *2012; 60:169–180.)*

where SV is stroke volume, CSA is cross-sectional area, and VTI represents velocity time integral. The continuity equation states that:

$$SV_{LVOT} = SV_{AV} \quad \text{[Eq. 14.26]}$$

where LVOT represents left ventricular outflow tract, and AV is aortic valve.

Substituting the SV equation into the continuity equation,

$$CSA_{LVOT} * VTI_{LVOT} = CSA_{AV} * VTI_{AV} \quad \text{[Eq. 14.27]}$$

Rearranging the terms,

$$CSA_{AV} = CSA_{LVOT} * VTI_{LVOT} / VTI_{AV} \quad \text{[Eq. 14.28]}$$

Because the LVOT is essentially cylindrical, the CSA_{LVOT} may be estimated by

$$CSA_{LVOT} = \pi (radius_{LVOT})^2 \quad \text{[Eq. 14.29]}$$

Because CSA_{LVOT}, VTI_{LVOT}, and VTI_{AV} are known, the CSA_{AV} or AVA may be calculated (see Fig. 14.68 for an example of the calculation of AVA).

Multiple sources of error may affect the calculation of the AVA using the continuity equation.[154] LVOT measurements may vary from 5% to 8%; therefore when the LVOT measurement is squared in the continuity equation, it may become a large source of error. Because the accuracy of the SV measurement through the LVOT assumes laminar flow, any of the sources of turbulence will affect results. In the presence of AI, the required high-systolic velocities may result in a skewed velocity profile. As discussed earlier, patients with a small aorta and moderate-to-severe AS may have significant pressure recovery effects that may overestimate the severity of the gradient and hence underestimate the AVA. Garcia and associates[155] proposed an index called the energy-loss coefficient (ELCo):

$$ELCo = (AVA \times A_a)/(A_a - AVA) \quad \text{[Eq. 14.30]}$$

where A_a is the cross section of the aorta measured 1 cm downstream from the sinotubular junction. This coefficient is closer to the AVA obtained at the time of catheterization and may be more representative of the energy loss caused by the stenosis and thus of the increased burden on the ventricle.[156]

AS severity should be described by maximum velocity, mean gradient, and AVA. Aortic velocity allows classification of stenosis as mild (2.6 to 2.9 m/sec), moderate (3 to 4 m/sec), or severe (greater than 4 m/sec).[154] Normal AVA is 3 to 4 cm^2. AVA consistent with mild AS is greater than 1.5 cm^2. An AVA of 1.0 to 1.5 cm^2 is consistent with moderate AS, and an area less than 1 cm^2 or 0.6 cm^2/m^2 is consistent with severe disease.[154,157]

Although multiplane TEE planimetric estimations of AVA may be flawed by heavy aortic valvular calcification, measurements using the continuity equation are accurate, compared with Gorlin-derived values.[158,159] In a study using TEE, Stoddard and colleagues[160] reported good correlation between AVA measurements using the continuity equation and planimetry; however, they reported a steep learning curve for the acquisition of a suitable TG LAX view that adequately aligns flow through the AV with the ultrasound beam.

Classical Low Flow–Low Gradient, Paradoxic Low Flow–Low Gradient, and Pseudosevere Aortic Stenosis

In addition to the normal flow, high-gradient AS observed in patients with normal EFs and normal COs, a subgroup of patients may have low flow–low gradient AS.[161] In particular, patients with a low SV, secondary to either severe systolic or diastolic dysfunction, may have severe AS as quantified by an AVA with low transaortic-valve gradients. In classical low flow–low gradient AS, the measured gradient underestimates the severity of the AS. If the resistance through the AV is constant, then the pressure gradient is directly related to the CO; a low CO is associated with a low-pressure gradient across the AV. Stated differently, a given severity of AS will result in a higher gradient across the AV with normal ventricular function, compared with a patient with decreased ventricular function. The presentation of patients with severe LV dysfunction and significant AV disease may be the classical low flow–low gradient AS, which is a low AVA with a mild-to-moderate gradient across the AV. These patients with low flow–low gradient severe AS may have AVA less than 1.0 cm^2 or 0.6 cm^2/m^2, a mean transvalvular gradient less than 40 mm Hg, and a low LV EF.[161]

One of the major diagnostic challenges in the evaluation of low flow–low gradient AS is its differentiation from pseudosevere AS. The evaluation of AV gradients must be considered in the context of LV function. Although the determination of AVA takes into account CO, AVA may, nonetheless, vary with flow rates.[162] Although this effect is not clinically significant with normal LV function, it becomes more pronounced with LV dysfunction, because a minimum blood flow is required to maximally open the AV. When LV systolic dysfunction is sufficiently severe, then there may be insufficient power to open the AV. The inability to open the AV attributable to myocardial dysfunction is known as pseudosevere AS. With increases in contractility, the AV may be opened to a near-normal area. In other words, severe AS is a valvular disease, whereas pseudosevere AS is a myocardial disease; patients with pseudosevere AS will not generally benefit from AV replacement.[161] Differentiation between severe AS with LV systolic dysfunction from mild-to-moderate AS with another cause of LV dysfunction may be made with dobutamine stress testing. With improved cardiac function, there is an increase in transvalvular gradient with no change in AVA in patients with classical low flow–low gradient AS. With pseudosevere AS, an improvement in cardiac function will not result in an increase in transvalvular gradient, but an improvement will result in an increase in AVA.

As opposed to patients with severe systolic dysfunction with classical low flow–low gradient AS, patients with small hypertrophied ventricles secondary to concentric remodeling may exhibit normal EF or paradoxic low flow–low gradient AS.[163,164] These patients have a preserved EF (greater than 50%) with an SV less than 35 mL/m^2 and significant diastolic dysfunction (ie, restrictive cardiomyopathy). Patients with this restrictive disease have decreased SV and flow; therefore the left ventricle may not be able to produce a large gradient across a stenotic AV, even with a normal EF. Typically, these patients have echocardiographic signs of diastolic dysfunction, including a high E/A ratio, decreased E-wave DT, decreased color M-mode propagation velocity, and a decreased tissue Doppler e′-wave velocity. Such patients may exhibit a normal EF and concentric hypertrophy or myocardial fibrosis, low-to-moderate AV gradient, and an AVA consistent with severe disease (see Chapter 21).

Aortic Regurgitation

AR may result from either diseases of the aortic leaflets or the aortic root.[165] Valvular lesions that may result in AR include leaflet vegetations and calcifications, perforation, or prolapse. AR may be caused by annular dilation secondary to a variety of causes, including annuloaortic ectasia, Marfan syndrome, aortic dissection, collagen vascular disease, and syphilis.

Cusp pathologic conditions (eg, redundancy, restriction, mobility, thickness, integrity), commissural variations (eg, fusion, splaying, alignment, attachment site), and root morphologic characteristics (eg, septal hypertrophy, root dimensions) should be ascertained.[165,166] Leaflet movement (excessive, restricted, or normal), origin of jet (central or peripheral), and direction of regurgitant jet (eccentric or central) should be determined to provide insight into the underlying pathologic conditions. Other signs that may be associated with AR include high-frequency diastolic fluttering of the MV (see Video 14.54), premature closing of the MV, or reverse doming of the MV.[167,168]

The mechanism of AR may be classified according to leaflet movement (Table 14.11).[165,169] Type I dysfunction is a result of dilation of the aortic annulus, sinuses of Valsalva, or sinotubular junction without any other causes of regurgitation (Figs. 14.71 and 14.72; see Video 14.55). This dilation results in the tethering of the AV cusps as a result of a mismatch between AV annular and the sinotubular junction

diameters.[170] This functional AR appears as an anatomically normal AV with a coaptation leaflet height (ie, maximum distance between point of cusp coaptation and the annular plane) greater than 8 to 10 mm and a sinotubular junction-annulus ratio greater than 1.6, resulting in a concentric jet of AR. Type II lesions result in eccentric jets. The cusp tissue quality and quantity is good. Cusp prolapse or flail is classified as Type IIa dysfunction (Fig. 14.73). The cusp prolapse may be further subdivided: cusp flail, partial cusp, and whole-cusp prolapse. Cusp flail is defined as the complete eversion of a cusp into the LVOT, which is usually seen best in the ME LAX view. Partial-cusp prolapse occurs when the distal part of a cusp prolapses into the LVOT. There is a clear bending of the cusp in the LAX view and the presence of a small circular or oval structure near the cusp free edge in the SAX view. Whole-cusp prolapse is the overriding of the free edge of the cusp of the plane of the AV with a billowing of the cusp into the LVOT. When the LVOT is viewed in the SAX view, the billowing of the cusp may be seen as a circular or elliptical figure (Fig. 14.74 and Video 14.56). Type IIb dysfunction is a free-edge fenestration. In these cases, there is an eccentric AR jet without definite evidence of a cusp prolapse. Finally Type III dysfunction is a result of a poor quality or quantity of leaflet tissue (Fig. 14.75 and Video 14.57). This may be a result of thickened, rigid, or destroyed valves attributable to endocarditis or calcification. If present, then the degree of calcification should be graded (Table 14.12).

Physiologic factors that may affect the estimated severity of AR include aortic diastolic pressure, LVEDP, heart rate, and LV compliance.[171] The severity of AR may be underestimated in the presence of eccentrically directed jets. In addition, several technical factors affect the perceived severity of regurgitation as well, including severe

TABLE 14.11 Classification of Aortic Regurgitation

Type	*Description*	*Echocardiographic Findings*
I	Enlarged aortic root with normal cusps	Aortic root dilation with retraction of aortic valve leaflets
IIa	Cusp prolapse	
	• Cusp flail	Complete eversion of a cusp into the LVOT in long-axis views
	• Partial cusp prolapse	Distal part of a cusp prolapsing into the LVOT (clear bending of the cusp body on long-axis views and the presence of a small circular structure near the cusp free edge on short-axis views)
	• Whole cusp prolapse	Free edge of a cusp overriding the plane of aortic annulus with billowing of the entire cusp body into the LVOT (presence of a large circular or oval structure immediately beneath the valve on short-axis views)
IIb	Cusp fenestration	Presence of an eccentric AR jet without definite evidence of cusp prolapse
III	Poor cusp tissue quality or quantity	Thickened and rigid valves with reduced motion Tissue destruction (endocarditis) Large calcification spots and extensive calcifications of all cusps interfering with cusp motion

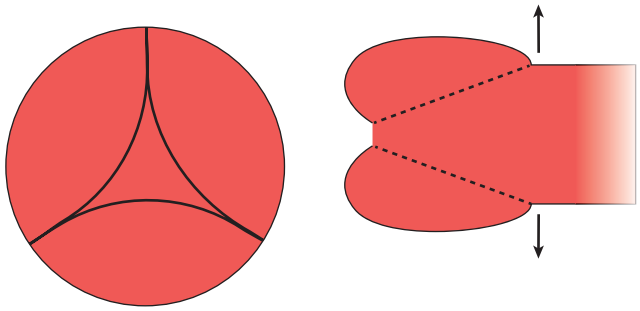

Fig. 14.71 Mechanism of aortic regurgitation type I. The *dotted lines* represent the attachment of the leaflet tips to the sinotubular junction. Normally the leaflet tips coapt fully in diastole (short-axis view) and that the diameter of the sinotubular junction is similar to that at the base of the annulus. This panel shows incomplete leaflet closure when the sinotubular junction dilates *(arrows)* relative to the aortic annulus, resulting in leaflet tethering and a persistent diastolic orifice. *(Reproduced with permission from Movsowitz HD, Levine RA, Hilgenberg AD, Isselbacher EM. Transesophageal echocardiographic description of the mechanisms of aortic regurgitation in acute type A aortic dissection: implications for aortic valve repair.* J Am Coll Cardiol. *2000;36:884–890.)*

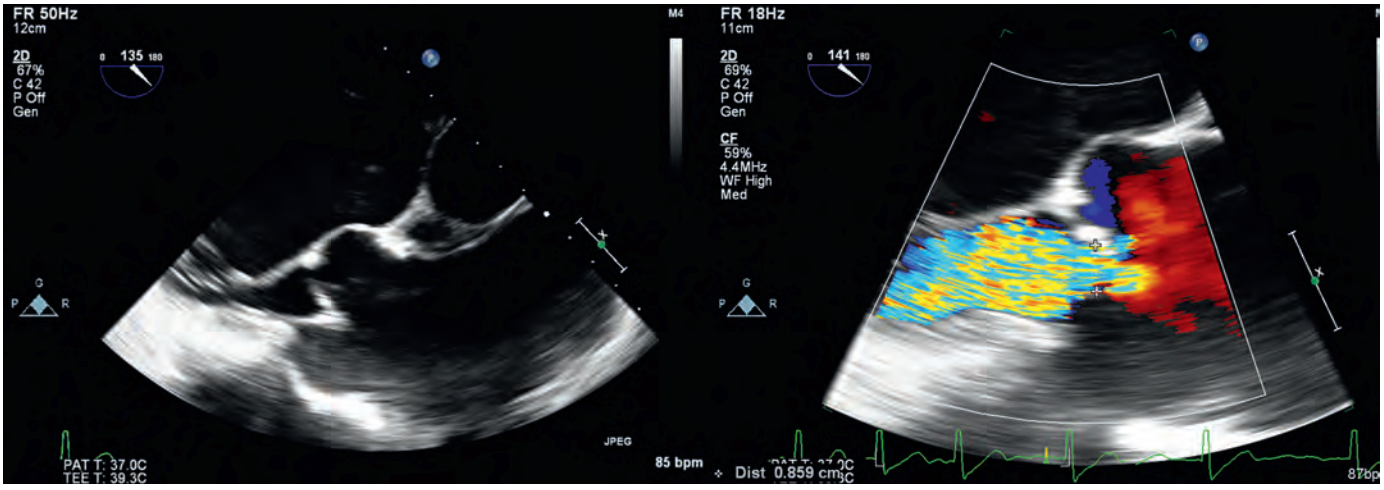

Fig. 14.72 Type I aortic regurgitation. Midesophageal aortic valve long-axis view demonstrates functional aortic regurgitation, secondary to an ascending aortic aneurysm. *(Left)* The sinus of Valsalva is very enlarged with respect to the aortic valve annulus. This enlargement results in the tethering of the aortic valve. The coaptation plane of the aortic leaflets are significantly distal to the plane of the aortic annulus. *(Right)* Addition of color-flow Doppler demonstrates severe aortic regurgitation. (Video available online.)

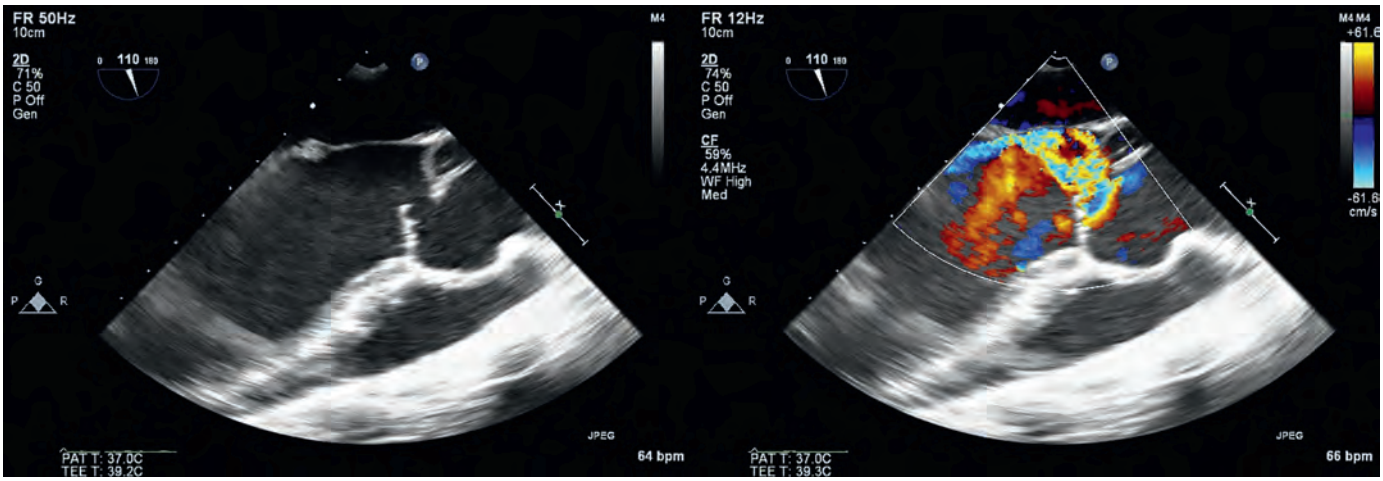

Fig. 14.73 Type II aortic regurgitation. Midesophageal aortic valve long-axis view demonstrates *(left)* the right coronary cusp *(most anterior)* prolapsing into the left ventricular outflow tract. *(Right)* Addition of color-flow Doppler reveals a large posteriorly directed regurgitant jet. An impressive proximal isovelocity surface area shell is seen on the aortic side of the aortic valve. (Video available online.)

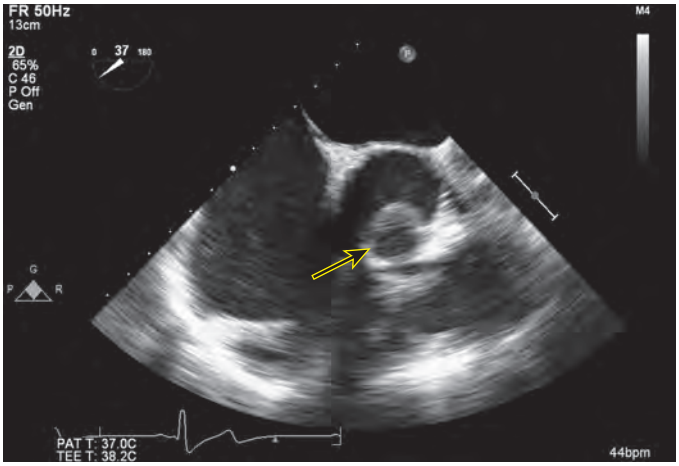

Fig. 14.74 Right coronary cusp in left ventricular outflow tract. After obtaining a midesophageal aortic valve short-axis view, the probe is advanced, allowing for the visualization of the left ventricular outflow tract. The right coronary cusp (see Fig. 14.73) may be visualized in the left ventricular outflow tract below the level of the aortic annulus as a circular structure *(yellow arrow)*. This image provides supportive evidence of a right coronary cusp prolapse. (Video available online.)

malalignment of ultrasonic planes with blood flow, the presence of a prosthetic MV interfering with ultrasound penetration, gain settings, and PRF.

The criteria for qualitative grading of AR are summarized in Table 14.13. CFD has traditionally been the major method of assessing the severity of valvular regurgitation. Nyquist limits should provide an aliasing velocity of approximately 50 to 60 cm/sec and a color gain that just eliminates the random color speckle from nonmoving regions.[172] Aortic regurgitant flow through the LVOT is characteristically a high-velocity, turbulent jet extending through the LVOT and left ventricle during diastole. In addition to providing the regurgitant jet area, the origin and width of the jet and the spatial orientation should be carefully defined. The severity of AR may be assessed by examining the width of the jet by CFD measurements. Unfortunately, the determination of the severity of AI by measurements of regurgitant jet areas alone has been questioned and is probably useful only for distinguishing mild from severe regurgitation.[173] Furthermore, the jet length and area measurements are very dependent on the LV diastolic pressure

TABLE 14.12 Grading of Aortic Valve Calcification

Grade	*Description*
1	No calcification
2	Isolated small calcification spots
3	Bigger calcification spots interfering with cusp motion
4	Extensive calcification of all cusps with restricted cusp motion

Adapted from Lancellotti P, Tribouilloy C, Hagendorff A, et al. Recommendations for the echocardiographic assessment of native valvular regurgitation: an executive summary from the European Association of Cardiovascular Imaging. *Eur Heart J Cardiovasc Imaging*. 2013;14(7):611–644.

gradient and ventricular compliance and therefore are not recommended to quantitate AR severity.[165] The severity of the regurgitant jet may be overestimated if the gain is too high or the Nyquist limits are too low. Furthermore, excessive degradation of frame rate may be encountered if the CFD field is too large.

The vena contracta is the narrowest portion of a regurgitant jet that usually occurs at or immediately upstream from the valve (Fig. 14.76). This jet width is directly proportional to the severity of the AR, and is usually characterized by high-velocity and laminar flow, and is slightly smaller than the regurgitant orifice.[172] A vena contracta diameter less than 0.3 cm is consistent with mild AR, and a diameter greater than 0.6 cm is consistent with severe AR. It should be noted, however, that jet shape might influence the estimation of the severity of regurgitation. An eccentric jet may be confined to a wall of the LVOT and thus appear very narrow, underestimating the severity of regurgitation. Similarly, central jets may expand fully in the LVOT and may overestimate the severity of regurgitation. The accuracy of the measurement may be improved by normalizing the jet width to the LVOT diameter by an examination of the ratio of the proximal jet width within the LVOT to the LVOT width (w_J/w_{LVOT}).[174,175] This ratio may be more accurately determined using color M-mode echocardiography (Fig. 14.77). Either an ME LAX or AV LAX view is obtained. CFD is superimposed on the image. The cursor is placed on the ventricular side of the AV to include both the LVOT and the regurgitant jet. M-mode imaging is initiated, and the LVOT diameter (w_{LVOT}) and AR jet width (w_J) is measured. A w_J/w_{LVOT} value of 0.25 discriminates mild from moderate regurgitation, and a valve of 0.65 discriminates moderate from severe regurgitation.[151,172]

CWD characteristics of the regurgitant flow may be used to estimate the degree of AR (Fig. 14.78). A very faint signal density is associated

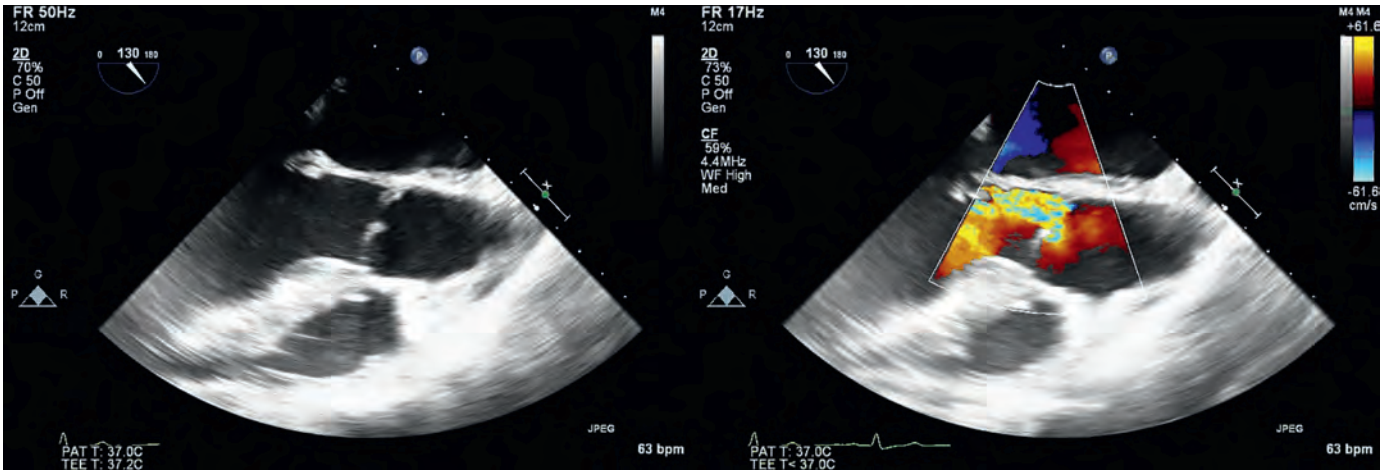

Fig. 14.75 Type III aortic regurgitation. *(Left)* Although the midesophageal aortic valve long-axis view reveals a normal anterior right coronary cusp, the more posterior cusps (left and noncoronary) are small and retracted. This retraction results in a large defect in the aortic valve. *(Right)* Addition of color-flow Doppler reveals a large regurgitant jet beginning at the posterior aspect of the aortic valve, which continues along the posterior wall of the left ventricular outflow tract. (Video available online.)

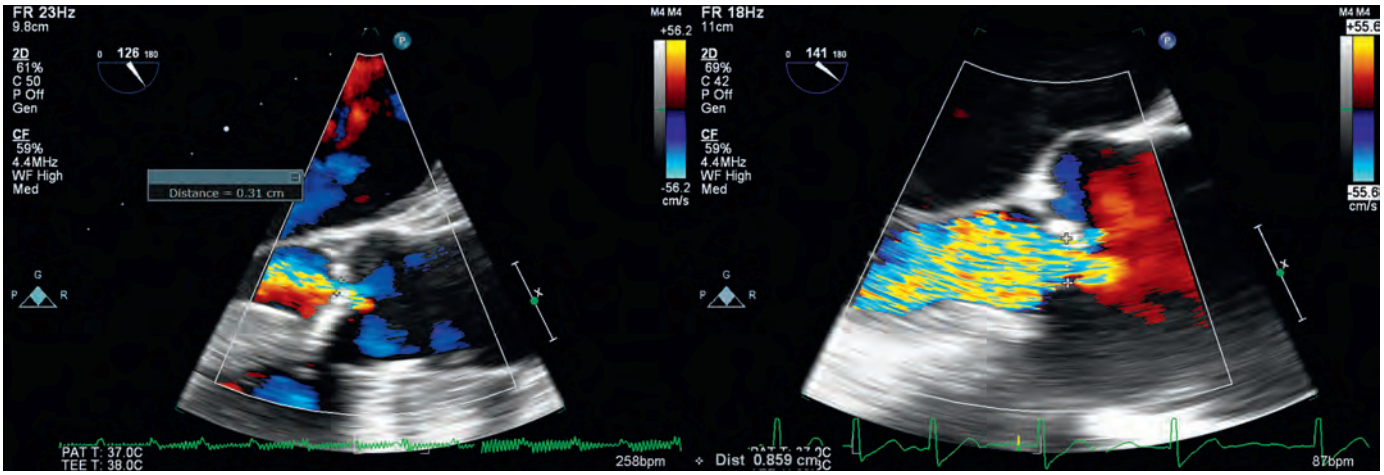

Fig. 14.76 Color-flow Doppler spectrum of a regurgitant aortic valve. Midesophageal aortic valve long-axis view visualizes an aortic regurgitant jet in the left ventricular outflow tract. *(Left)* The vena contracta is approximately 3 mm, which is consistent with mild regurgitation. *(Right)* The vena contracta is greater than 8 mm, which is consistent with severe aortic regurgitation.

TABLE 14.13 Quantification of Aortic Regurgitation

		Moderate		
	Mild	*Mild-to-Moderate*	*Moderate-to-Severe*	*Severe*
Left atrial size	Normal	Normal or dilated		Usually dilated
Aortic cusps	Normal or abnormal	Normal or abnormal		Abnormal and flail or wide coaption defect
Jet width in LVOT[a]	Small in central jets	Intermediate		Large in central jets; variable in eccentric jets
Continuous wave jet density	Incomplete or faint	Dense		Dense
Jet deceleration rate (pressure half time, ms)	Slow >500	Medium 200–500		Steep <200
Vena contracta width (cm)[a]	<0.3	0.3–0.6		≥0.6
Jet width/LVOT width (%)[a]	<25	25–45	46–64	≥65
Jet CSA/LVOT CSA (%)[a]	<5	5–20	21–59	≥60
Regurgitant orifice area (cm^2)	<0.1	0.10–0.19	0.20–0.29	≥0.3
Regurgitant volume (mL/beat)	<30	30–44	45–59	≥60
Regurgitant fraction (%)	<30	30–39	40–49	≥50

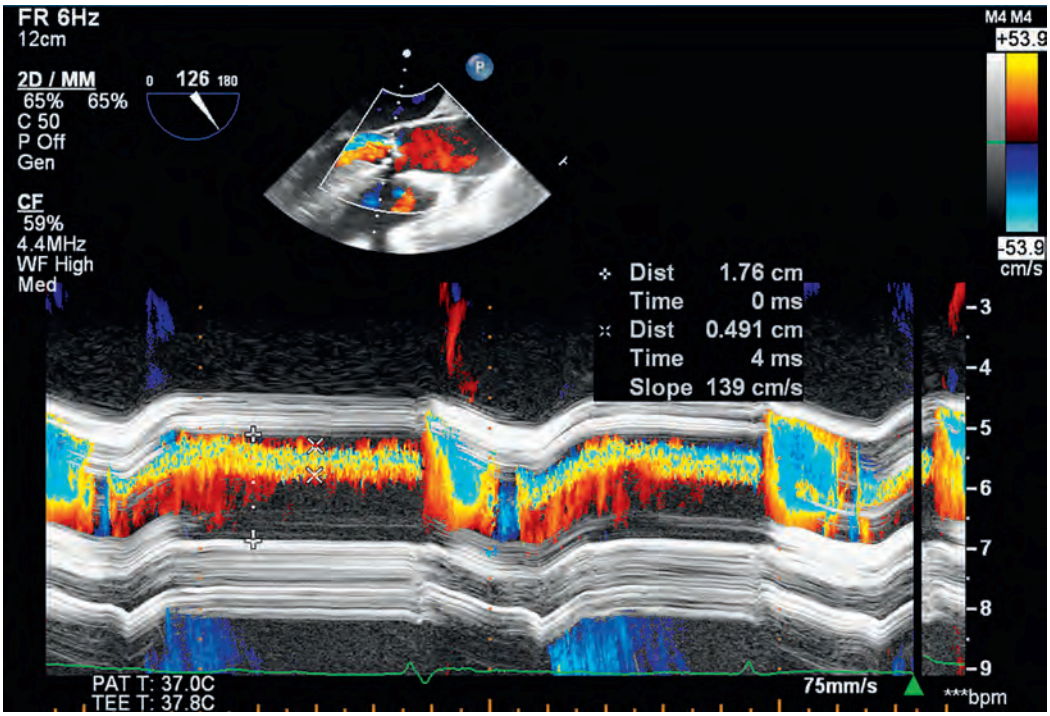

Fig. 14.77 Color M-mode image of the vena contracta. Color-flow Doppler is superimposed on the left ventricular outflow tract (LVOT), and the cursor is positioned at the downstream origin of the regurgitant aortic flow. This results in a high temporal resolution spectrum, allowing the accurate measurement of both the vena contracta and the width of the LVOT. In this case, the vena contracta is 0.49 cm and the LVOT 1.76 cm. These measurements yield a vena contracta to LVOT width ratio of 0.28, which is consistent with moderate aortic insufficiency.

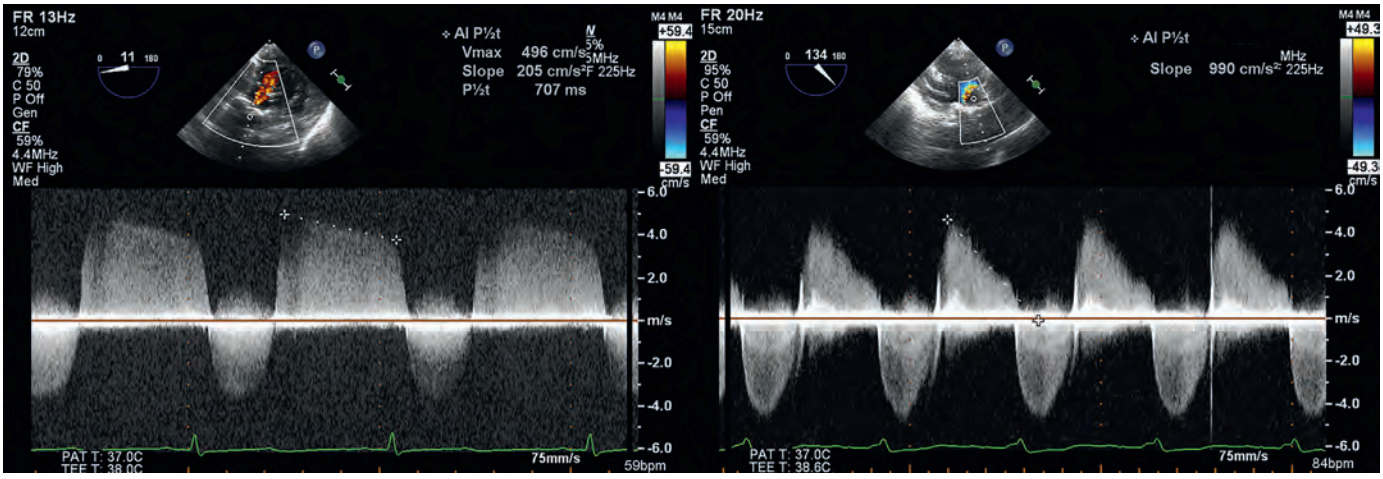

Fig. 14.78 Continuous-wave Doppler determination of aortic regurgitation severity. Continuous retrograde flow from the aorta into the left ventricle through a regurgitant aortic valve may be demonstrated with continuous-wave Doppler. *(Left)* In this example, the flow velocity mildly degrades during diastole, yielding a shallow slope. This low slope value is consistent with mild aortic insufficiency. *(Right)* Severe aortic insufficiency results in a greater slope of the regurgitant Doppler spectrum, which is consistent with severe aortic insufficiency.

with mild AR, whereas a dense signal may represent more retrograde flow. In addition, the pressure half-time or slope of the AR jet may be determined. A normally functioning AV will maintain a large gradient during diastole between the aorta and the left ventricle. With a small degree of AR, there will be a small volume of blood entering the left ventricle through the AV, resulting in a slow increase in LV pressure during diastole. Doppler measurements will show a regurgitant flow of high velocity, which is maintained during most of diastole (corresponding to a long pressure half-time). As aortic regurgitant flow becomes more severe, there is a more rapid equilibration between aortic and LV diastolic pressure, with the nadir of the gradient at end-diastole. As pressures equilibrate, the driving pressure across the AV decreases and Doppler-derived AR velocities decrease over the diastole. This pattern of AI flow is characterized by short pressure half-time.

Pressure half-time measurements have been validated as a measure of the severity of AR.[176] A pressure half-time of less than 200

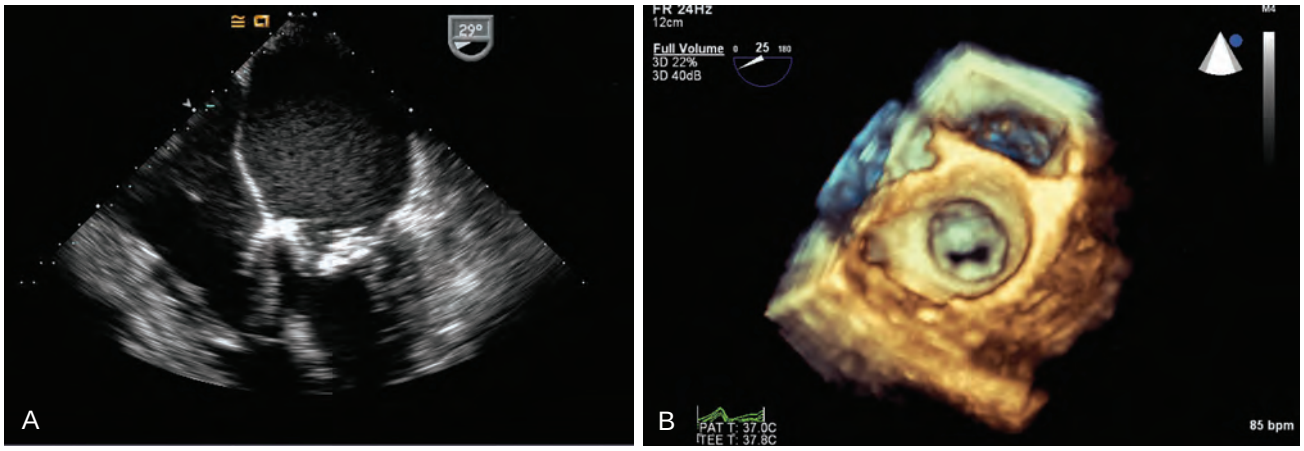

Fig. 14.79 Mitral stenosis. (A) Midesophageal four-chamber view demonstrates a severely stenotic mitral valve with severe calcification of the annulus and leaflets, which is associated with severe left atrial dilation. (B) A significant commissural fusion with severe leaflet restriction is reveals in a three-dimensional reconstruction in another patient with rheumatic heart disease. (Video available online.)

milliseconds is consistent with severe AR, whereas a pressure half-time greater than 500 milliseconds is consistent with mild AR.[172] The accuracy of this technique may be influenced by physiologic variables.[177] A higher systemic vascular resistance increases the rate of decline, whereas a reduced ventricular compliance will increase the rate of intraventricular pressure rise, which will also affect the diastolic slope without affecting valvular competence. In a given patient, however, pharmacologic manipulation of afterload or inotropy may result in changes in aortic regurgitant slopes and pressure half-times that are contradictory to other measures of regurgitation. The density of the pressure half-time spectrum does not provide useful information concerning the severity of AR.[165]

Proximal isovelocity surface area (PISA) measurements and flow convergence are secondary techniques for the evaluation of the severity of AI; their calculation is discussed in greater detail in the MR section of this chapter. A PISA measurement provides accurate quantification of the severity of AR.[178] Furthermore, aortic diastolic flow reversal may provide an indication of the severity of regurgitation. With increasing AR, both the duration and velocity of the flow velocity increase; holodiastolic reversal is consistent with at least moderate AR.[179] Finally, the SV calculation through the LVOT may be compared with either the MV or pulmonary valve, assuming there is no more than minimal regurgitation of these latter valves. The difference in SV will be equal to the regurgitant volume.

Mitral Valve Evaluation

The MV consists of two leaflets, chordae tendineae, two papillary muscles, and a valve annulus. The anterior leaflet is larger than the posterior and is semicircular; however, the posterior MV leaflet has a longer circumferential attachment to the MV annulus.[180] The posterior valve leaflet may be divided into three scallops: lateral (P1), middle (P2), and medial (P3). The leaflets are connected to each other at junctures of continuous leaflet tissue called the *anterolateral* and *posteromedial commissures*. Primary, secondary, and tertiary chordal structures arise from the papillary muscle, subdividing as they extend and attach to the free edge and several millimeters from the margin on the ventricular surface of both the anterior and posterior valve leaflets.[181] The annulus of the MV primarily supports the posterior MV leaflet, whereas the anterior MV leaflet is continuous with the membranous ventricular septum, AV, and aorta.

Mitral Stenosis

The most common cause of MS is rheumatic heart disease; other causes are congenital valvular stenosis, vegetations and calcifications of the leaflets, parachute MV, and annular calcification. In addition to

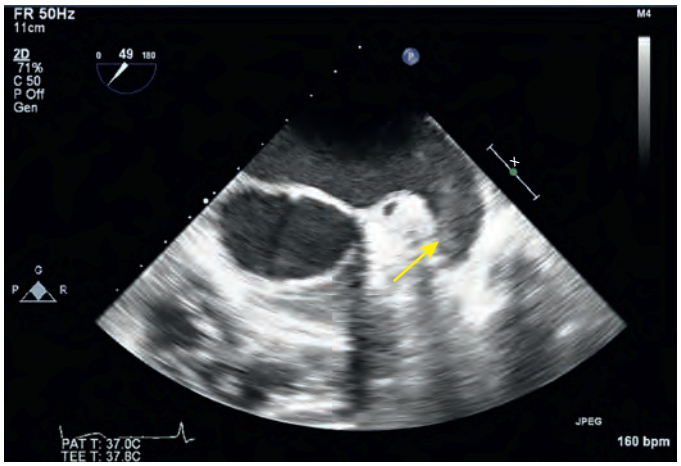

Fig. 14.80 Spontaneous echocardiographic contrast. Because of the low flow in the left atrium, there is low-velocity blood flow with subsequent rouleaux formation by red blood cells *(yellow arrow)*. (Video available online.)

structural valvular abnormalities, MS may be caused by nonvalvular causative factors such as intraatrial masses (myxomas or thrombus) or extrinsic constrictive lesions.[182,183] Generally, MS is characterized by restricted leaflet movement, a reduced orifice, and diastolic doming (Fig. 14.79 and Video 14.58).[184] The diastolic doming occurs when the MV is unable to accommodate all the blood flowing from the left atrium into the left ventricle; consequently, the body of the leaflets separates more than the edges. In rheumatic disease, calcification of the valvular and subvalvular apparatus, as well as thickening, deformation, and fusion of the valvular leaflets at the anterolateral and posteromedial commissures, produce a characteristic fish mouth–shaped orifice.[185] Other characteristics that may be associated with chronic obstruction to LA outflow include an enlarged left atrium, spontaneous echocardiographic contrast or smoke (which is related to low-velocity blood flow with subsequent rouleaux formation by red blood cells[186]) (Fig. 14.80 and Video 14.59), thrombus formation, and RV dilation.

The leaflets, annulus, chordae, and papillary muscles may be assessed in the ME four-chamber, commissural, two-chamber, and LAX views. If annular calcification is significant, then the TG views may be necessary to assess the subvalvular apparatus. Because of the propensity for thrombus formation, the entire left atrium and the LAA should be carefully interrogated for thrombus.

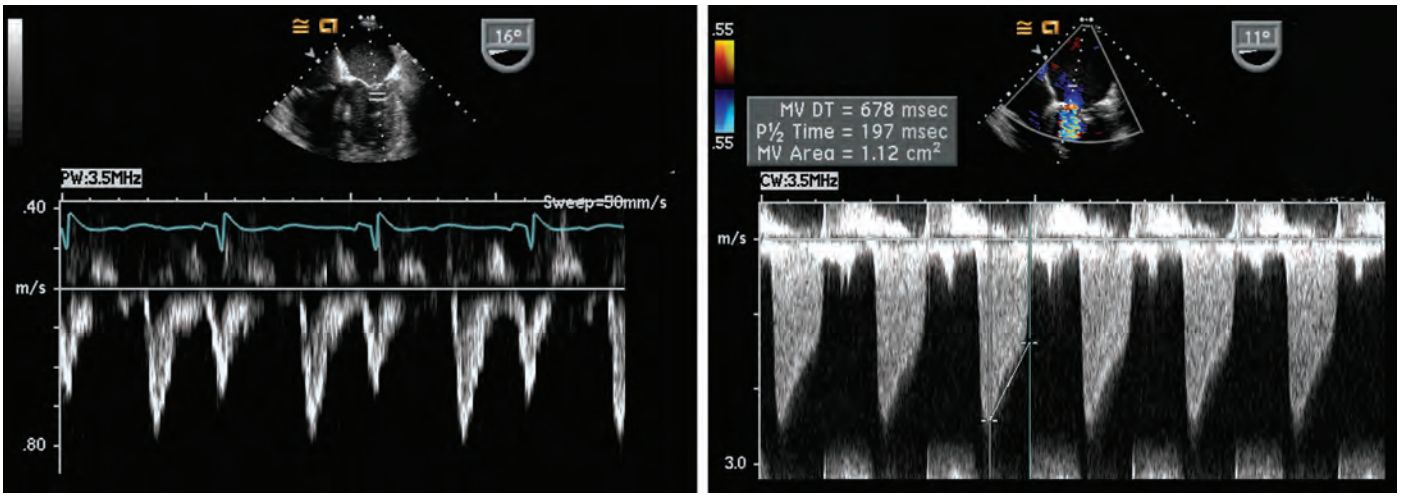

Fig. 14.81 Transmitral Doppler spectrum. The panel on the *left* is the normal transmitral Doppler flow measured using pulsed-wave Doppler. A clean envelope is visualized with E-wave velocity greater than the A-wave velocity. Both waves have velocities less than 1 m/sec with a normal deceleration time. The panel on the *right* visualizes the transmitral flow in the presence of mitral stenosis. Because of the high gradient, continuous-wave Doppler was used. High-velocity gradients may be appreciated, and a longer pressure half-time is consistent with significant mitral stenosis.

Because planimetry of the MV orifice is not influenced by assumptions of flow conditions, ventricular compliance, or associated valvular lesions, its use is the reference standard for the evaluation of mitral valve area (MVA) in MS.[154] This orifice opening is best visualized in the TG basal SAX view and is best measured in mid-diastole. Although technically difficult at times, care should be taken to image the orifice at the leaflet tips. Severe calcification of the MV may interfere with MVA determination, and, in patients with significant subvalvular stenosis, the underestimation of the degree of hemodynamic compromise may occur when determining MVA by planimetry.[148]

Doppler Assessment of Mitral Valvular Stenosis

A transmitral Doppler spectrum is measured along the axis of transmitral blood flow, which usually may be obtained in an ME four- or two-chamber view (Fig. 14.81). Transmitral valve flow is characterized by two peaked waves of flow away from the transducer. The first wave (E) represents early diastolic filling, whereas the second wave (A) represents atrial systole. Transvalvular gradient may be estimated using the modified Bernoulli equation: pressure gradient = 4 × velocity^2.[187] Because peak gradient is heavily influenced by LA compliance and ventricular diastolic function, the mean gradient is the relevant clinical measurement.[154] The values obtained through this method have high correlation with those obtained using a transeptal puncture during cardiac catheterization.[188] The high velocities that may occur with MS limit the use of PWD echocardiography; CWD echocardiography should be used.

Normally, with MV opening during early diastole, a torrential increase in transmitral flow occurs, which rapidly decreases to zero during diastasis when the LA and LV pressures equilibrate. With MS, a gradient between the left atrium and the left ventricle may be maintained for a longer period. This sustained pressure differential maintains flow between the atrium and the ventricle, decreasing the slope of this early transmitral flow. The rate of decline of the E-wave velocity may be described by its pressure half-time, which is the time interval from the peak E-wave velocity to the time when the E-wave velocity has declined to one half of its corresponding peak pressure value. The pressure half-time is inversely proportional to the MVA[189]:

$$\text{MVA} = 220/\text{pressure half-time} \qquad \text{[Eq. 14.31]}$$

The E-wave may have a bimodal characteristic, with an initial rapid decline in transmitral velocity in early diastole, compared with the latter aspect of diastole. In these cases, this latter gentler slope should be measured. The advantage of this technique is that it is independent of valvular geometry. This formula assumes that the MV is at least mildly stenotic. The presence of either MR or AR will decrease the accuracy of pressure half-time measurements for the determination of MS.[190] If there is associated AR, then care should be taken that the aortic regurgitant jet is not included in the transmitral flow measurement.[191] Inadvertent inclusion of this aortic regurgitant flow may result in a false elevation of transmitral velocity, as well as a false decrease in pressure half-time.[192] Alternatively, AR may result in a rapid increase in diastolic LV pressures, thus decreasing transmitral flow velocity. The continuity equation, using either the LVOT or the PA and PISA method, may be used as secondary methods for the evaluation of the severity of MS.

TABLE 14.14 Quantification of Mitral Stenosis

	Mild	*Moderate*	*Severe*
Valve area (cm^2)	>1.5	1.0–1.5	>1.5
Mean gradient (mm Hg)	<5	5–10	>10

The assessment of the severity of MS is summarized in Table 14.14. The mean transmitral gradient and the MVA, as determined by the pressure half-time, are the major measurements to be considered; however, planimetry may be used if discrepancy between these two measures occurs.[154] Determination of the severity of MS by PISA measurement or by the continuity equation should not be considered as primary indices for evaluation.

Mitral Regurgitation

MR may be classified as primary or secondary. Primary causes of regurgitation are structural or organic, whereas secondary causes are functional without evidence of structural abnormalities on the MV. The most common causes of primary MR are degenerative (Barlow disease, fibroelastic degeneration, Marfan syndrome, Ehlers-Danlos syndrome, annular calcification), rheumatic disease, toxic valvulopathies, and endocarditis.[165] MR may be caused by disorders of any component of the MV apparatus, specifically, the annulus, the leaflets

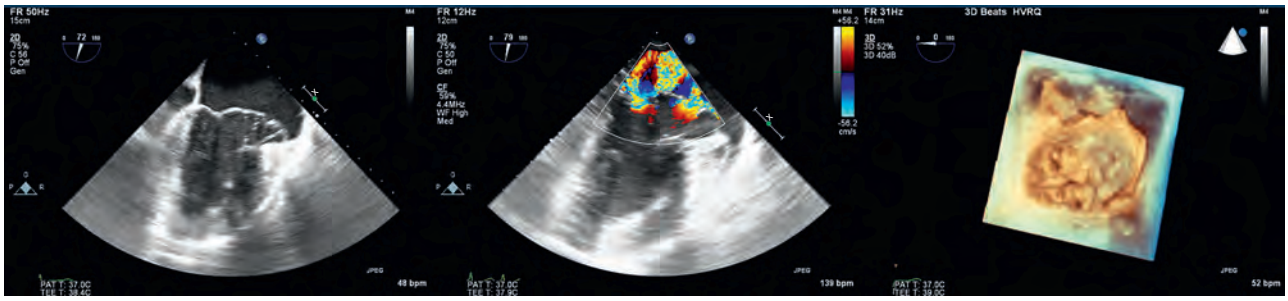

Fig. 14.82 Barlow disease. *(Left and center)* Midesophageal commissural view demonstrates Barlow disease, which is usually characterized by gross redundancy of multiple segments of the anterior or posterior leaflets and chordal apparatus. The leaflets are bulking and billowing with multiple areas of prolapse. The chordae are more often elongated rather than ruptured. Atrialization of the leaflets (ie, displacement of the leaflet attachment toward the atrium) occurs, especially at the origin of P1 at the right side of the image. There is significant annular dilation. *(Center)* Addition of color-flow Doppler reveals complex and multiple areas of regurgitation. *(Left)* Three-dimensional reconstruction of the mitral valve illustrates the redundancy of the leaflets and the prolapse of multiple sections of the leaflet. (Video available online.)

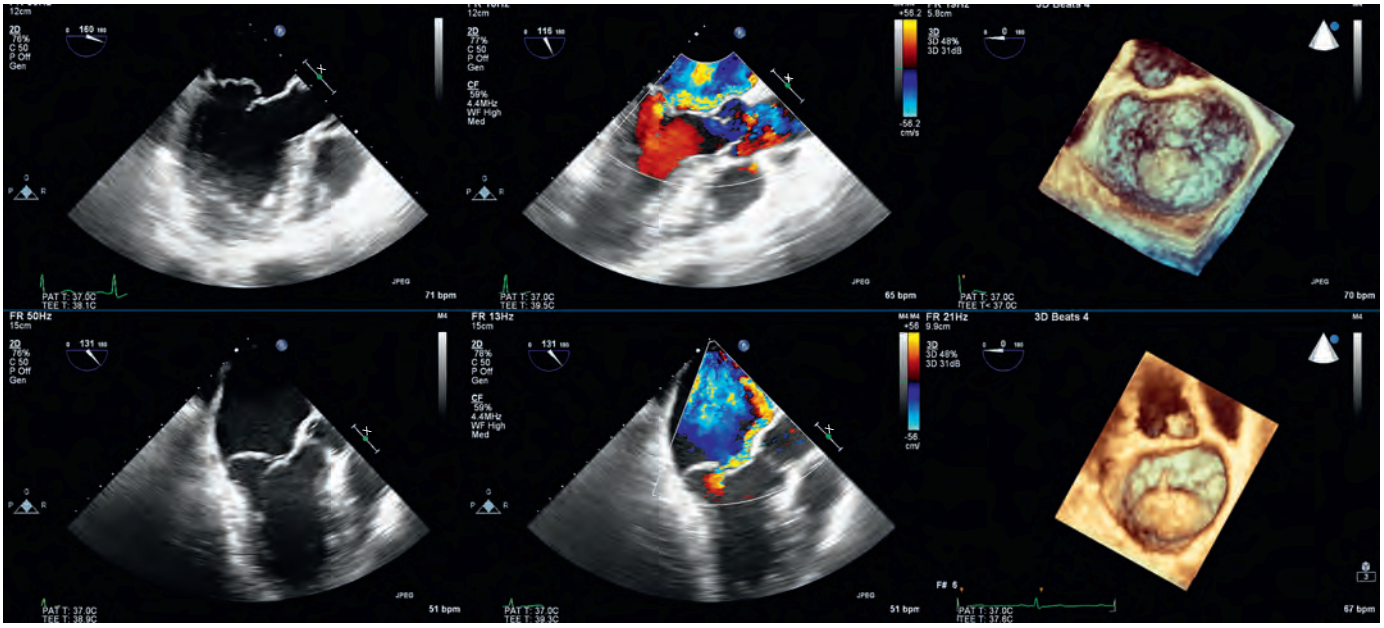

Fig. 14.83 Fibroelastic deficiency. Prolapse versus flail. *Left and center* images are the midesophageal long-axis view. The *top row* of images illustrates prolapse of the center scallop of the posterior leaflet (P2). The leaflet is seen above the level of the annular plane, but the leaflet tip is pointing toward the ventricular side. With the application of color-flow Doppler *(center image)*, a large anteriorly direct jet may be appreciated. *(Right image)* Three-dimensional reconstruction as seen from the atrium. The posterior leaflet is visualized in the lower aspect of the image. The prolapsed segment is clearly seen above the level of the other mitral valve segments. *(Lower row, left image)* In contrast to the prolapse, the P2 segment is flailed. A chordae is attached to P2, which rides above the anterior leaflet during systole. The tip of P2 is directed toward the atrium. Color-flow Doppler reveals a large eccentric jet similar to the case of leaflet prolapse. *(Right)* The three-dimensional reconstruction clearly reveals the ruptured chordae associated with P2. (Video available online.)

and chordae, or the papillary muscles. With chronic regurgitation, the annulus and atrium dilate and the annulus loses its normal elliptical shape, becoming more circular.[193] Annular dilation, in turn, leads to poor leaflet coaptation and worsening of valve incompetence. Although increased LA and LV dimensions may suggest severe MR, smaller dimensions do not exclude the diagnosis.[194]

The most common cause of chronic primary MR in developed countries is MV prolapse.[151] Younger individuals exhibit Barlow syndrome, whereas older populations have fibroelastic deficiency disease. A Barlow valve is usually characterized by gross redundancy of multiple segments of the anterior or posterior leaflets and chordal apparatus (Fig. 14.82 and Video 14.60). The leaflets are bulky and billowing with multiple areas of prolapse.[195] The chordae are more often elongated rather than ruptured. The leaflets are thickened with severe myxomatous degeneration. Atrialization of the leaflets (ie, displacement of the leaflet attachment toward the atrium) may occur. The annulus is usually severely dilated and may be calcified.

In contrast, fibroelastic deficiency usually affects only a single segment (Fig. 14.83 and Video 14.61). The nonaffected leaflets tend to be thin, with a thickening of the affected segment. Elongated chords may produce prolapse of one or both attached leaflets; if only one leaflet is affected, then leaflet malalignment may occur during systole.

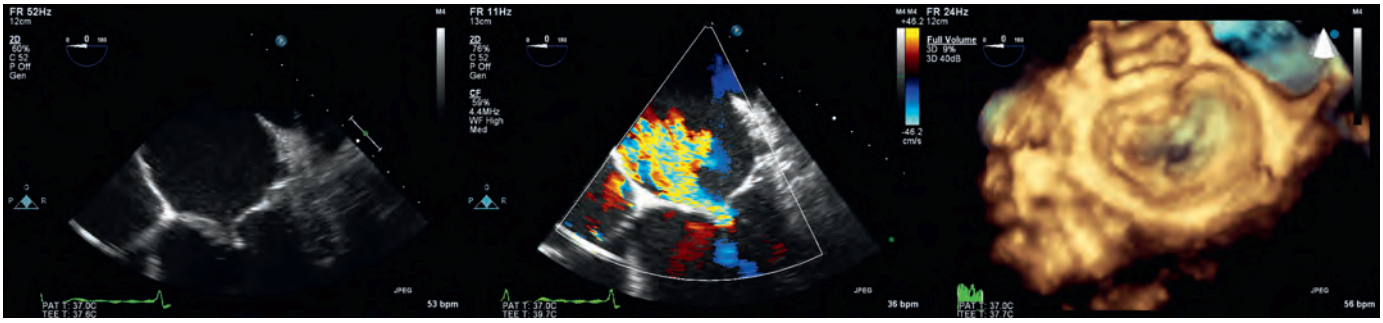

Fig. 14.84 Mitral regurgitation Type IIIa. *(Left and center)* Midesophageal four-chamber view reveals the thickened mitral valve leaflets that are seen coapting below the level of the annular plane. Although not apparent on the still images, leaflet movement both during systole and diastole is restricted, which is characteristic of type IIIa mechanism. In this particular case, the posterior leaflet is thicker with a more restricted movement. *(Center)* Color-flow Doppler demonstrates a large jet directed toward the restricted posterior leaflet. *(Right)* The three-dimensional reconstruction reveals the restriction of the mitral valve leaflets. (Video available online.)

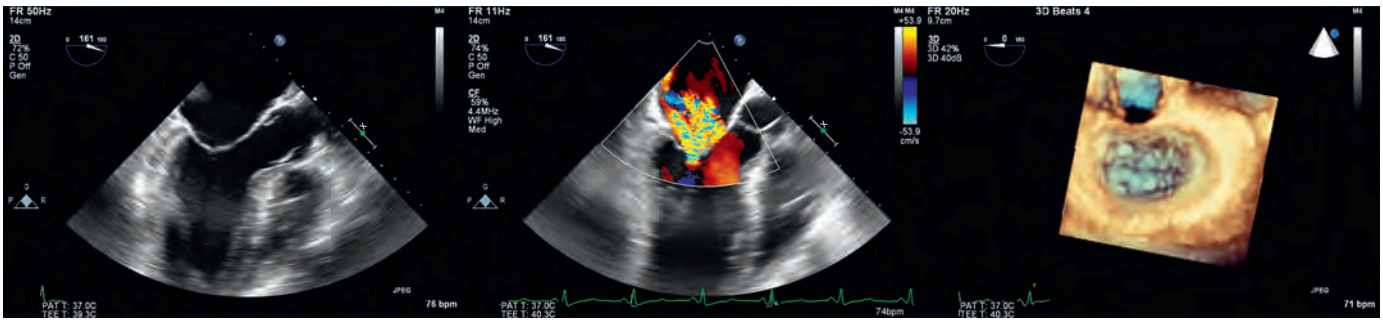

Fig. 14.85 Mitral regurgitation Type IIIb. *(Left and center)* Midesophageal long-axis view demonstrates the thin and anatomically normal anterior and posterior leaflets. Both leaflets are visualized coapting below the level of the mitral valve annulus. Although not apparent on the static images, they move well during diastole but are restricted during systole. *(Center)* Application of color-flow Doppler reveals a severe mitral regurgitant jet. Because the cause of the regurgitation is functional, a regurgitant orifice area greater than 0.2 cm^2 is considered severe. *(Right)* Three-dimensional reconstruction reveals the posterior and anterior leaflets; both leaflets are seen coapting below the level of the mitral valve annulus with resultant compromised coaptation. (Video available online.)

Excessively mobile structures near the leaflet tips during diastole may represent elongated chords or ruptured minor chords. These structures do not prolapse into the atrium during systole. In contrast, ruptured major chords are identified as thin structures with a fluttering appearance in the atrium during systole and are associated with evident prolapse of the affected leaflet; in this instance, the valve segment is termed as *flail*. A flail leaflet segment generally points in the direction of the left atrium, and this directionality of leaflet pointing is the principal criterion for distinguishing a flailed leaflet from severe valvular prolapse.[196,197] Flail leaflets are most commonly caused by ruptured chordae and less commonly caused by papillary muscle rupture.

Regurgitation may also be caused by papillary muscle infarction in association with infarction of the adjacent LV myocardium, attributable to a lack of the normal tethering function performed by these structures. When the adjacent segment is aneurysmal, the dyskinetic wall motion may prevent proper coaptation of the valve by restricting the normal movement of the mitral leaflets during systole.[198] Prior infarctions may be indicated by thinning of the myocardium, atresia of the papillary muscles, and dyskinetic wall segments. Atretic papillary muscles are identified by their diminutive size and increased echocardiographic density on SAX imaging. This shrinkage in papillary muscle size may result in retraction of chordae and subsequent MR. Papillary muscle rupture typically appears as a mass (papillary muscle head) that prolapses into the left atrium during systole and is connected to the leaflet only by its attached chords. In addition to these structural abnormalities, MR is suggested by LV volume overload, a dilated hypercontractile left ventricle, a high EF, and systolic expansion of the left atrium.[199]

In patients with recent endocarditis, vegetations may be attached to the leaflets or chords. With rheumatic valve disease, thickening and/or calcification of the leaflets, restriction of leaflets, and a variable degree of shortening and thickening of the subvalvular apparatus may be identified. Myxomatous degeneration produces ballooning and scalloping of the valve leaflets, as well as localized areas of thinning and thickening, which can be seen echocardiographically. This intrinsic disease progression associated with the leaflets may interfere with MV function with resultant regurgitation (Fig. 14.84; see Video 14.62).

With secondary or functional MR, the MV is structurally normal (Fig. 14.85; see Video 14.63).[151,165] LV dilation, secondary to another process such as myocardial infarction or idiopathic-dilated cardiomyopathies, result in papillary muscle displacement and annular dilation with resultant tethering of the MV leaflets with incomplete leaflet coaption. Since the valvular regurgitation is only one component of the disease process, its progress is worse than primary MR and its treatment is less clear.

Summarizing, the mechanism of MR is frequency described using the Carpentier classification, which is reviewed in Table 14.15 and Fig. 14.86.[200] The classification is based on leaflet movement. Type I is associated with normal leaflet movement (Fig. 14.87; see Videos 14.64

and 14.65). The cause of the MR may be secondary to annular dilation with poor leaflet coapation or may be caused by a leaflet cleft or perforation. Type II is associated with excessive leaflet movement or prolapse (see Fig. 14.83 and Video 14.61). Most commonly, this type of regurgitation is caused by chordal rupture. Type III is subdivided into Types IIIa and IIIb. Type IIIa is restricted leaflet motion during both systole and diastole (see Fig. 14.84 and Video 14.62). This type of MR is usually caused by processes of the leaflets, themselves, that interfere with normal leaflet function, such as rheumatic MV disease. Type IIIb, also known as functional MR, is restricted leaflet motion during systole (see Fig. 14.85 and Video 14.63). This is the most common mechanism for functional MR secondary to LV enlargement. The leaflets, themselves, are usually anatomically normal; however, substantial chordal tethering may interfere with complete valvular closure during diastole. This type of MR commonly occurs with LV dilation, which commonly results in restriction of P2 and P3.

TABLE 14.15 Carpentier Classification of Mitral Regurgitation[200]

	Leaflet Motion	*Etiology*
Type I	Normal	Annular dilation Leaflet perforation
Type II	Excessive (prolapsed)	Chordal elongation or rupture Papillary muscle elongation or rupture
Type IIIa	Restricted leaflet motion during systole and diastole	Leaflet and chordal thickening (eg, rheumatic heart disease)
Type IIIb	Restricted leaflet motion during systole	Left ventricular enlargement

Qualitative Grading Using Color-Flow Doppler

The diagnosis of MR is made primarily by the use of color-flow mapping. Because flow is best detected when it is parallel to the ultrasonic beam and because some MR jets may be thin and eccentric, multiple views of the left atrium should be interrogated for evidence of MR. It is important to remember that the regurgitant flow disturbances are 3D-velocity fields with complex geometry, which must be sampled from multiple imaging planes to provide an accurate estimate of the maximal spatial extent of the CFD signal. It is common to detect trivial degrees of MR that extend just superior and posterior to the MV leaflet. MR is detected more frequently by TEE, compared with TTE, and the degree of regurgitation is often graded as being more severe using TEE.[201,202]

Eccentric jet direction provides corroborative evidence of structural leaflet abnormalities, which may include leaflet prolapse, chordal elongation, chordal rupture, or papillary muscle rupture (Fig. 14.88). For example, a jet that is directed laterally along the posterior wall of the left atrium is associated with anterior leaflet prolapse. Similarly, a jet that is directed medially behind the anterior mitral leaflet is associated with prolapse of the posterior leaflet.

Atrioventricular valve regurgitation is graded semiquantitatively as mild, moderate, or severe and is summarized in Table 14.16. Regurgitation less than mild may be classified as either trivial or trace. Some authors have suggested subdividing moderate regurgitation into mild-moderate and moderate-severe grades.[165,172] The most common method of grading the severity of MR is CFD mapping of the left atrium. With the Nyquist limit set at 50 to 60 cm/sec, jet areas less than 4 cm^2 or 20% of the LA size are usually classified as mild, whereas jets greater than 10 cm^2 or 40% of the atrial volume are classified as severe.[172] The area of the Doppler jet may be influenced by technical factors such as gain setting, carrier frequency of the transducer, imaging of low-velocity flows, differentiation of regurgitant from

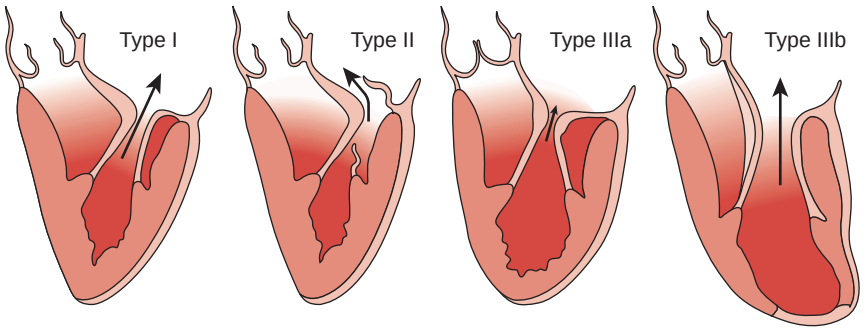

Fig. 14.86 Schematic representation of Carpentier classification of mitral regurgitation. *(Adapted from Adams D. Understanding degenerative disease (the pathophysiologic triad). Available at:* http://www.mitralvalverepair.org/content/view/58/.)

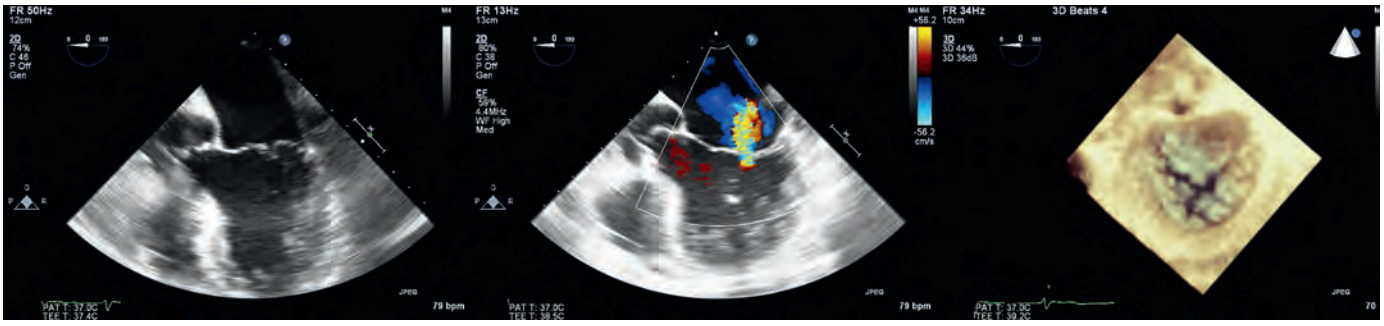

Fig. 14.87 **Mitral regurgitation Type I.** *(Left and center)* Midesophageal five-chamber view reveals the anterior and posterior leaflets coapt at the level of the mitral valve annulus, but the space between the two leaflets is significant. *(Center)* Application of color-flow Doppler reveals a central jet. *(Right)* In addition to the poor coaption of the anterior and posterior leaflet, this three-dimensional reconstruction visualizes a large cleft in the posterior leaflet, which contributes to the regurgitation. (Video available online.)

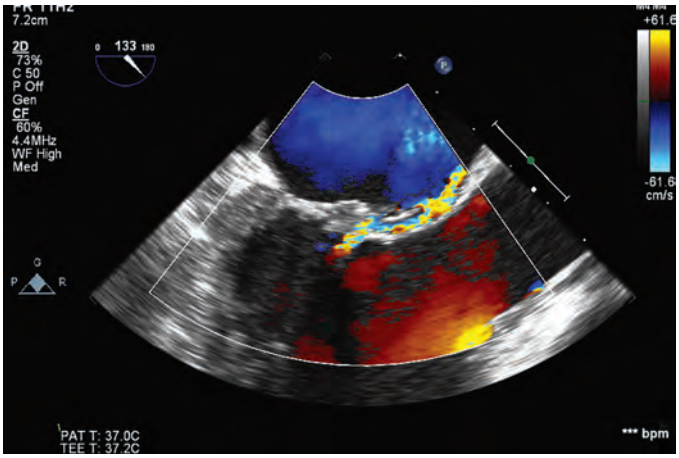

Fig. 14.88 Eccentric mitral valve regurgitant jet. An eccentric mitral regurgitant jet is being directed anteriorly. If the area of the jet, alone, is used to estimate the degree of regurgitation, then the severity of regurgitation will be underestimated.

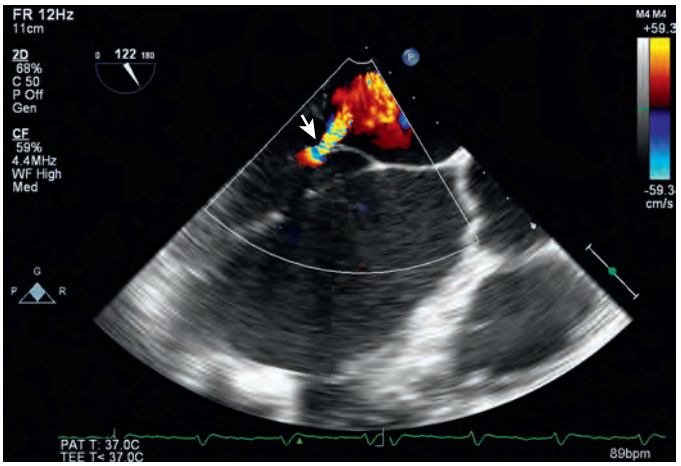

Fig.14.89 Mitral valve vena contracta is demonstration in the mid-esophageal long-axis view. The *arrow* points to the vena contracta of the mitral regurgitant jet.

TABLE 14.16 Summary of Mitral Regurgitation

		Moderate		
	Mild	*Mild-Moderate*	*Moderate-Severe*	*Severe*
Left atrial size	Normal	Normal or dilated		Usually dilated
Color-flow jet area[a]	Small central jet (<4 cm^2 or <20% left atrial area)			Large central jet (>10 cm^2 or >40% left atrium) or variable-sized wall impinging jet
Pulmonary venous flow	Systolic dominance	Systolic blunting		Systolic flow reversal
Continuous-wave jet contour	Parabolic	Usually parabolic		Early peaking triangular
Continuous-wave jet density	Incomplete or faint	Dense		Dense
Vena contracta width (cm)	<0.3	0.3–0.69		≥0.7
Regurgitant orifice area (cm^2)	<0.20	0.20–0.29	0.30–0.39	≥0.40

Adapted from Lancellotti P, Tribouilloy C, Hagendorff A, et al. Recommendations for the echocardiographic assessment of native valvular regurgitation: an executive summary from the European Association of Cardiovascular Imaging. *Eur Heart J Cardiovasc Imaging.* 2013;14(7):611–644; and Zoghbi WA, Enriquez-Sarano M, Foster E, et al. Recommendations for evaluation of the severity of native valvular regurgitation with two-dimensional and Doppler echocardiography. *J Am Soc Echocardiogr.* 2003;16:777–802.

displacement flow, complexities in jet geometry such as multiple jets and vortex flow, temporal variation of jet size during systole, and differences between machines in color-Doppler display.[203] In addition, jet direction should be considered when grading regurgitation, because eccentric jets that cling to the atrial wall (Coanda effect) have a smaller area than central (free) jets with similar regurgitant volumes and regurgitant fractions.[204–206] Because of these mitigating factors, the 2013 European guidelines do not recommend the use of regurgitant jet area to quantitate the severity of MR.[165] An alternative method of grading MR is based on the vena contracta width (Fig. 14.89).[207] Although the vena contracta is commonly circular, it may be elliptical in shape with secondary causes or functional regurgitation.[165] In these cases, multiple views of the vena contracta along different axes should be obtained and averaged. A vena contracta width of less than 0.3 cm is associated with mild MR, whereas a width greater than 0.7 cm is associated with severe MR.[172]

CWD integration may also be used in the assessment of the severity of MR (Fig. 14.90).[208] A peak velocity that occurs during early systole and is directed toward the left atrium can be appreciated with MR, and the intensity of this recording may be proportional to the severity of regurgitation.[209] A dense full signal is associated with severe MR, whereas an incomplete and faint signal is associated with less severe regurgitation.

Pulmonary Vein Flow Pattern

Pulmonary vein flow imaged by TEE provides useful information regarding regurgitant severity.[210] Normally, pulmonary venous flow consists of a phase of retrograde flow during atrial systole and two phases of antegrade flow during ventricular systole and diastole. Because systolic pulmonary venous flow is augmented by active atrial relaxation, systolic antegrade pulmonary venous flow is usually greater than diastolic antegrade pulmonary venous flow. With MR, LAP is increased during ventricular systole, which may either reduce antegrade systolic pulmonary venous flow or cause reversal of systolic flow in cases of severe regurgitation (Fig. 14.91). Systolic pulmonary venous flow reversal is a specific sign of severe MR.[165]

Interrogating both right and left pulmonary veins is important. With eccentric jets, flow reversal may be more prominent in the pulmonary veins toward which the jet is directed; however, central MR may also result in discordant pulmonary venous flow patterns.[211] Although discordant flow primarily occurred with eccentric mitral regurgitant jets with systolic reversal primarily in the RUPV, some patients with central regurgitation may also have discordant pulmonary venous flows.

Proximal Isovelocity Surface Area

In addition to these previously discussed indices of MR, regurgitant flow convergence and flow volume also may be used to assess the degree of MR (Fig. 14.92).[212] Quantification of MR by the PISA assumes that as blood flows toward a regurgitant lesion, flow converges radially. This convergence occurs along increasing isovelocity hemispheres converging on the regurgitant lesion. CWD may be used to identify these hemispheres of increasing velocity proximal to the lesion (identified by aliasing), and flow may be determined. Before performing the PISA calculations, a well-defined hemisphere must be imaged. This may be performed either by reducing the Nyquist limits or by shifting the CFD

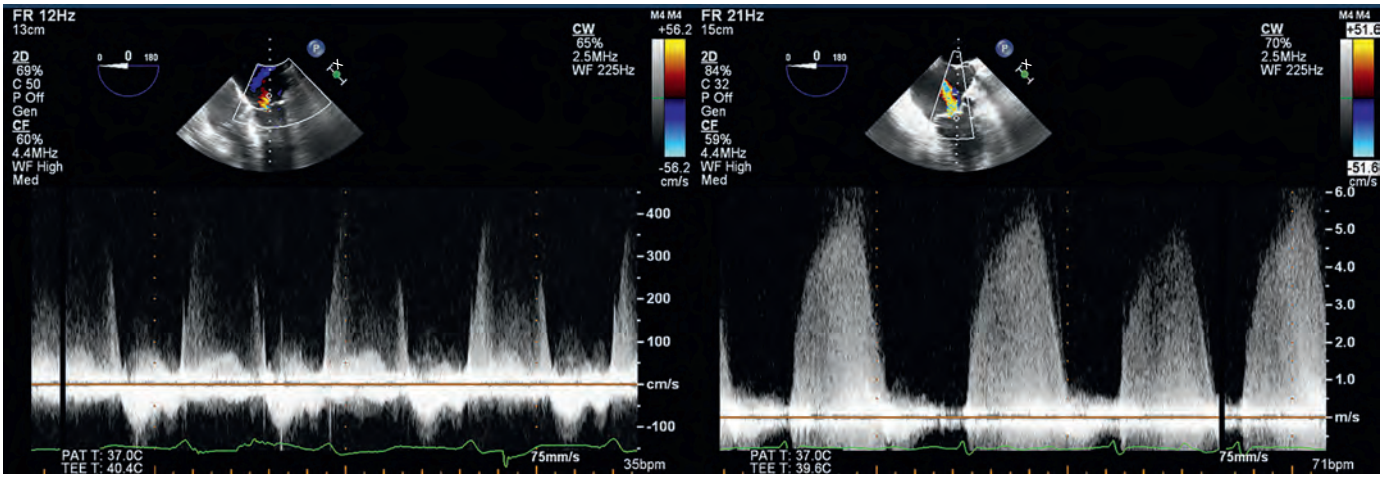

Fig. 14.90 Doppler spectrum with mitral regurgitation. *(Left)* Mild degree of mitral regurgitation results in a lighter incomplete Doppler spectrum when the regurgitant flow is visualized. *(Right)* With severe regurgitation, the Doppler spectrum becomes more solid and more intense in character.

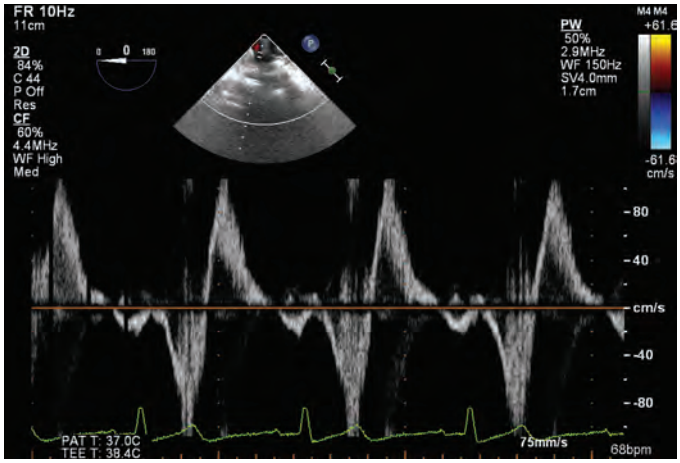

Fig. 14.91 Pulmonary venous flow with severe mitral regurgitation. The systolic component of the pulmonary venous tracing, which occurs immediately after the QRS wave, indicates flow away from the left atrium (away from the transducer). This pulmonary systolic venous reversal is consistent with severe mitral regurgitation.

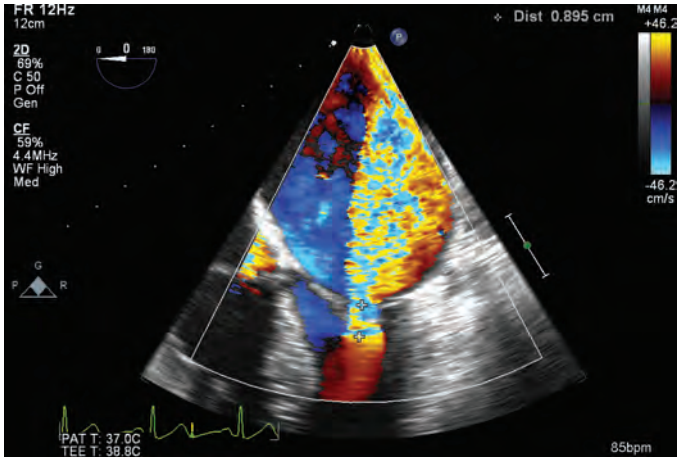

Fig. 14.92 Determination of mitral regurgitation by proximal isovelocity surface area (PISA). Assuming normal hemodynamics, the regurgitant orifice area (ROA) of the mitral regurgitant volume may be estimated. The Nyquist limit should be set for approximately 40 cm/sec, and the radius of the PISA shell in centimeters *(r)* is measured. The ROA in square millimeters (mm^2) is approximately equal to $r^2/2$. In this case, the PISA radius is approximately 0.9 cm, which would yield an ROA of approximate 0.4 mm^2.

mapping baseline toward the direction of flow. The flow through this well-defined hemisphere is:

$$\text{Flow} = (\text{surface area of the hemisphere}) \times (\text{velocity at the hemisphere}) \quad \text{[Eq. 14.32]}$$

$$\text{If surface area hemisphere} = 2\pi r^2 \quad \text{[Eq. 14.33]}$$

where r is the radius of the hemispheric spheres,

$$\text{then flow hemisphere is} = 2\pi r^2 v_n \quad \text{[Eq. 14.34]}$$

where v_n is the Nyquist limit.
Because flow through these isovelocity spheres equals flow through the regurgitant lesion,

$$2\pi r^2 v_n = \text{ROA } V_o \quad \text{[Eq. 14.35]}$$

where ROA is the area of the regurgitant orifice area (ROA), and V_o is the maximal regurgitant velocity. Solving for ROA, yields:

$$\text{ROA} = 2\pi r^2 v_n / V_o \quad \text{[Eq. 14.36]}$$

Because the regurgitant volume is equal to the area of the regurgitant lesion, multiplied by the velocity-time integral of the regurgitant velocity (VTI_{regurg}),

$$\text{Regurgitant volume} = \text{VTIregurg (ROA)} = \text{VTIregurg } (2\pi r^2 v_n / V_o) \quad \text{[Eq. 14.37]}$$

If the base of the hemisphere is not flat (ie, 180 degrees), then a correction for wall constraint should be performed by multiplying the ratio of the adjacent angle formed by the wall and 180 degrees.[172]

The PISA method of determining MR is time consuming; however, it has been validated as a method of identifying patients with severe MR.[213] Generally, it is most accurate for central jet compared with an eccentric one. Because the hemispheric radius is squared, care must be taken to ensure and measure a well-defined shell. If the Nyquist limits are set for 40 cm/sec and assuming that the patient has "normal" systolic blood pressures (the difference between the systolic LV pressure and LAP is approximately 100 mm Hg), then the calculation of ROA may be estimated to be[214]:

$$\text{ROA} = r^2/2 \quad \text{[Eq. 14.38]}$$

where r is the radius of the PISA shell in centimeters (see Fig. 14.92).

The quantification of the severity of chronic function MR (ie, Type IIIb) is more complex. Because the primary mechanism is severe LV

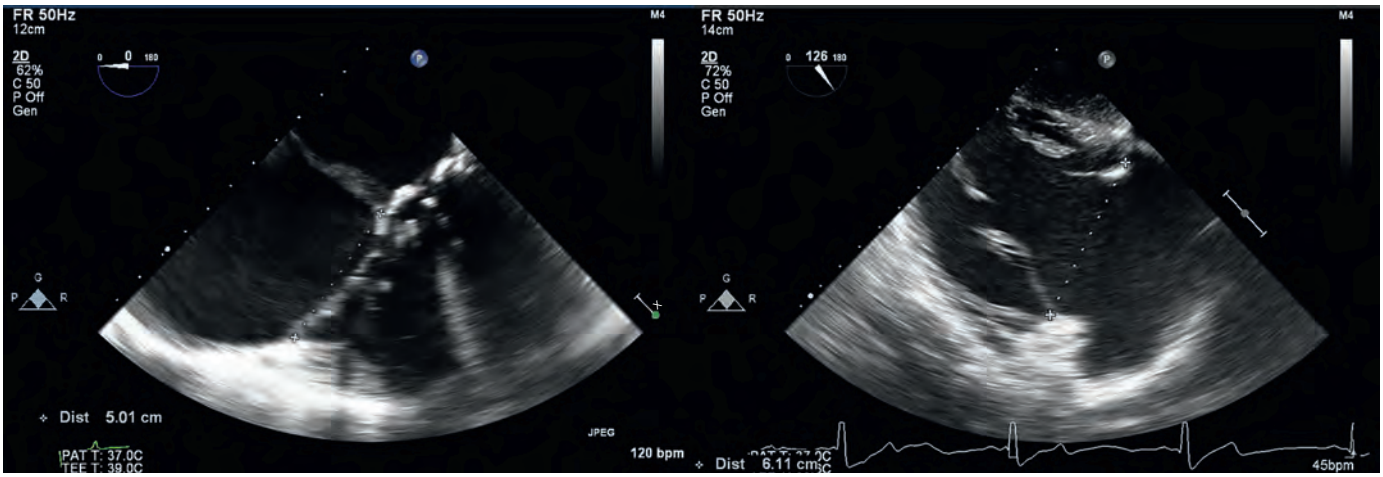

Fig. 14.93 Measurements of tricuspid annular diameters. The common views for the determination of tricuspid annular diameter are illustrated. (*Left*) Midesophageal four-chamber view. (*Right*) Transgastric right ventricular inflow.

dysfunction and ventricular dilation, secondary to either ischemic or nonischemic cardiomyopathy, adverse outcomes are associated with a smaller calculated effective regurgitant orifice, compared with MR of other causes.[151] Because of the crescent shape of the regurgitant orifice, 2D-based measurements underestimate the severity of the regurgitation. The 2014 AHA/ACC guidelines for the treatment of valvular disease suggest that an ROA greater than 0.2 cm^2, regurgitant volumes greater than 30 mL, and regurgitant percentages greater than 50% should be considered severe.

Tricuspid Valve

The TV consists of three leaflets, an annular ring, chordae tendineae, and multiple papillary muscles.[215] The anterior leaflet is usually the largest, followed by the posterior and septal leaflets. The septal leaflet of the TV is usually farther apical than the septal attachments of the MV. Chordae arise from a large single papillary muscle, double or multiple septal papillary muscles, and several small posterior papillary muscles, attached to the corresponding walls of the right ventricle.

Intrinsic structural abnormalities of the TV that can be well characterized by TEE include rheumatic tricuspid stenosis, carcinoid involvement of the TV, TV prolapse, flail TV, Ebstein anomaly, and tricuspid endocarditis. Rheumatic involvement of the TV, which is typically seen with concomitant MV involvement, is characterized by thickening of the leaflets (particularly at their coaptation surfaces), fusion of the commissures, and shortening of the chordal structures resulting in restricted leaflet motion.[216] Carcinoid syndrome results in a diffuse thickening of the TV and PV and endocardial thickening of right-sided heart structures, which may result in restricted TV motion (mixed stenosis and regurgitation).[217]

Supravalvular, valvular, or subvalvular restriction may cause tricuspid stenosis. The most common cause of tricuspid stenosis is rheumatic heart disease, whereas less common causes include carcinoid syndrome and endomyocardial fibrosis. Tricuspid stenosis is characterized by a domed thickened valve with restricted movement. TR may be secondary to annular or RV dilation, pathologic conditions of the leaflets, or subvalvular apparatus. CWD measurements of the inflow velocities across the TV can be used to estimate the mean diastolic TV gradient with the modified Bernoulli equation.[218] Optimal alignment of the Doppler cursor parallel to tricuspid inflow can be difficult to achieve from transesophageal imaging windows. Often alignment can be achieved, however, by positioning the probe deep within the stomach such that the RV apex is imaged at the top of the sector scan. Alternatively, probe positioning at more rostral levels can display the TV adjacent to a basal SAX view of the AV (multiplane crystal orientation 25 to 30 degrees), which may be suitable for CWD interrogation.

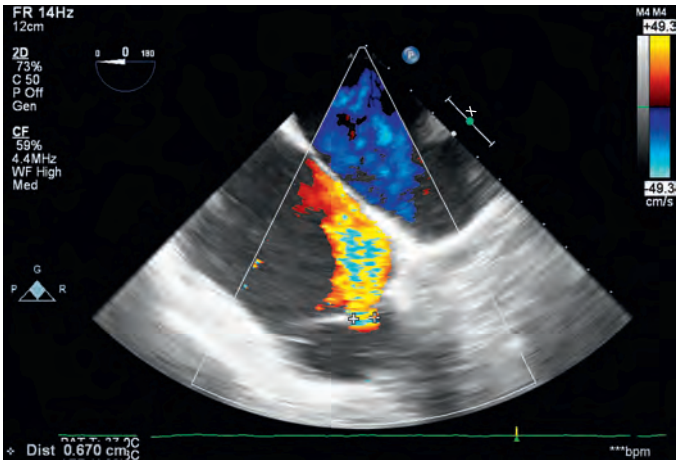

Fig. 14.94 Vena contracta of tricuspid regurgitant jet. Midesophageal four-chamber view visualizes a large tricuspid regurgitant jet. Measurement of the vena contracta of this jet is greater than 0.6 cm, which is consistent with severe tricuspid regurgitation. (Video available online.)

Although TR may have primary causative factors, most causes are secondary or functional as a result of either tricuspid annular dilation (>40 mm) or RV dilation (Figs. 14.93 and 14.94; see Video 14.66).[165] RV enlargement result in annular dilation and papillary muscle displacement with tethering of the TV leaflets. This tethering may result in poor leaflet coaption. This TR results in additional RV enlargement and further leaflet tethering with worsening TR.

Primary disorders of the tricuspid apparatus include rheumatic disease, prolapse, congenital disease, radiation, infective, carcinoid, blunt chest wall trauma, RV endomyocardial biopsy–related trauma, and intraannular RV pacemaker or implantable cardioverter-defibrillator leads.[151] The bulky and redundant tricuspid leaflet tissue observed in TV prolapse is associated with billowing of leaflet tissue superior to the tricuspid annular plane into the RA. In patients with an overtly flail TV, the disrupted leaflet tissue wildly prolapses into the RA, exhibiting high-frequency systolic vibrations. Destructive processes such as infective endocarditis, valve trauma induced by inadvertent endomyocardial biopsy of the tricuspid apparatus, and spontaneous rupture of chordae may all result in a partially flail TV apparatus.

Similar to MR, the mechanisms of TR may be classified using the Carpentier classification. Type I: leaflet perforation or pure annular

dilation; Type II: increased leaflet motion (eg, prolapse or flail); or Type III: restricted process, which may be either intrinsic or functional.[165] The normal tricuspid annular diameter in the ME four-chamber view is 28 ± 5 mm; a diameter greater than 35 mm is considered significant (see Fig. 14.93).[165] Evaluation of the severity of TR is frequently required in patients with severe MV disease, severe LV systolic dysfunction and secondary right-sided heart failure, or RV dysfunction attributable to long standing pulmonary hypertension.

The quantification of TR is summarized in Table 14.17. The apparent severity of TR is exquisitely sensitive to right-sided heart loading conditions. Thus during the intraoperative evaluation of TR, PA, and right atrial pressures should be kept near levels observed in the awake resting state. Some authors suggest that the severity of TR can be estimated by the apparent size (area in a given imaging plane, volume reconstructed in three dimensions) of the color-flow disturbance of TR relative to right atrial size.[219] A central jet area of less than 5 cm^2 is consistent with mild regurgitation, whereas a jet area greater than 10 cm^2 is consistent with severe regurgitation.[172] However, recent guidelines suggest that color-flow area of the regurgitant jet should not be used to quantitate the severity of TR.[165] A vena contracta width less than 0.3 mm is consistent with mild regurgitation, whereas a VC greater than 0.7 cm is consistent with severe regurgitation (see Fig. 14.94).[220] Although its application is limited, the severity of TR may also be quantified using flow convergence (PISA).[221] At a Nyquist limit of 28 cm/sec, a PISA radius less than 5 mm suggests mild TR, whereas a radius greater than 9 mm suggests severe TR; an ROA greater than 40 mm^2 or a regurgitant volume greater than 45 mL is also consistent with severe TR. To further assist in the evaluation of the hemodynamic significance of TR, the hepatic veins can be interrogated from deep gastric positioning of the transesophageal probe (Fig. 14.95). The presence of blunted systolic hepatic vein flow is associated with moderate TR, and retrograde systolic flow is associated with hemodynamically severe TR.

TABLE 14.17 Quantification of Tricuspid Regurgitation

	Mild	*Moderate*	*Severe*
Right atrial size	Normal	Normal or dilated	Usually dilated
Tricuspid valve leaflets	Usually normal	Normal or abnormal	Abnormal/flail or wide coaption defect
Jet area—central jets (cm^2)[a]	<5	5–10	>10
Continuous-wave jet density	Soft and parabolic	Dense, variable contour	Dense, triangular with early peaking
Vena contracta width (cm)[a]	Not defined	<0.7	>0.7
PISA radius (cm)[b]	≤0.5	0.6–0.9	>0.9
ROA mm^2	Not defined	Not defined	>40
Regurgitant volume	Not defined	Not defined	>45 mL
Hepatic vein flow	Systolic dominance	Systolic blunting	Systolic reversal

[a]At Nyquist limits of 50 to 60 cm/sec.
[b]At Nyquist limits of 28 cm/sec.

Myocardial Ischemia Monitoring

Regional Wall Motion and Systolic Wall Thickness

Echocardiography has been used for decades in assessing RWMAs associated with myocardial ischemia.[222] The ability to reliably detect RWMAs is clinically relevant because of its diagnostic and therapeutic implications. Consequently, it is important to note that RWMAs detected by TEE must always be interpreted within the clinical context, because not every RWMA is diagnostic for myocardial ischemia. Myocarditis, ventricular pacing, and bundle branch blocks can easily lead to wall motion abnormalities that can potentially lead to mismanagement of the patient.

When describing RWMAs, common classifications should be used to describe the anatomic localization and degree of dysfunction to ensure that communication is possible between the echocardiographer and nonechocardiographer, as well as documentation of ongoing disease course. Both the 16- and 17-segment models of the left ventricle have been published by the ASE (see Fig. 14.13A).[79,223] This model subdivides the left ventricle into three zones (basal, mid, and apical). The basal (segments 1 to 6) and midventricular zones (segments 7–12) are further subdivided into six segments each, whereas the apical zone consists of only four (segments 13–16). Another model published by the American Heart Association Writing Group on Myocardial Segmentation and Registration for Cardiac Imaging has added a 17th segment to the model. The 17th segment represents the apical cap of the previously described 16-segment model.

By understanding coronary anatomy, the echocardiographer can make assumptions regarding localization of a potential coronary artery

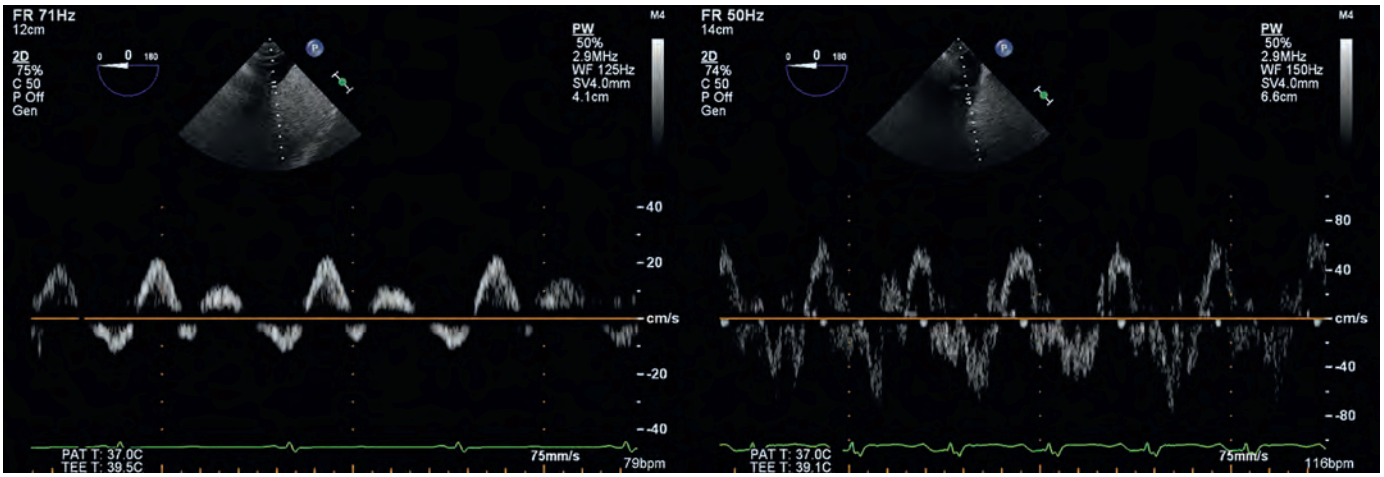

Fig. 14.95 Hepatic venous flow. *(Left)* The normal hepatic venous Doppler spectrum reveals flow toward the right atrium during both systole and diastole. *(Right)* With severe tricuspid regurgitation, flow is away from the right atrium during systole.

lesion based on the region of abnormal wall motion. Using the ASE model, the segments 1, 2, 7, 13, 14, and 17 are in the distribution territory of the LAD artery. Segments 5, 6, 11, 12, and 16 are associated with the circumflex artery and segments 3, 4, 9, 10, and 15 belong to the right coronary artery (see Fig. 14.13B). This segmental distribution can be variable among patients because of the variability of the coronary arteries. In addition to describing a system that defines the anatomic segments of the left ventricle, grading segment thickening and excursion is important.

Wall Motion

The simplest assessment of wall motion is performed by eyeballing the motion of the individual segments of the left ventricle as described earlier in the ASE model. This qualitative assessment is classified as being normal, hypokinetic, akinetic, dyskinetic, or aneurismal. Subsequently, a numeric score of 1 to 5 can then be assigned. A wall motion index can then be derived by dividing the total score by the number of segments observed. A score of 1 would represent a normal ventricle. The higher the score, the more abnormal the ventricle. This score can be used to predict outcome after cardiac surgery and risk stratifying patients for adverse cardiac events.[224–226]

In addition to movement, the normal myocardium thickens during systole. Wall thickening can be assessed qualitatively, or it can be quantitatively evaluated by calculating systolic wall thickening from the following equation:

$$\text{PSWT} = \text{SWT} - \text{DWT}/\text{SWT} \times 100 \qquad \text{[Eq. 14.39]}$$

where PSWT is the percentage of systolic wall thickening, SWT represents end-systolic wall thickening, and DWT is end-diastolic wall thickening.

The degree of thickening can also be used to assess overall function of the observed segment. A thickening greater than 30% is normal, 10% to 30% represents mild hypokinesia, 0% to 10% is severe hypokinesia, no thickening is akinesia; if the segment bulges during systole, then dyskinesia is present.

Diagnosis of Ischemia

The precise sequence of functional changes that occur in the myocardium after interruption of flow has been studied in models of acute ischemia, including percutaneous transluminal coronary angioplasty (PTCA).[227–229] Abnormalities in diastolic function usually precede abnormal changes in systolic function. Normal function is critical for LV filling and is dependent on ventricular relaxation, compliance, and atrial contraction. Diastolic ventricular function can be assessed by monitoring the rate of filling associated with changes in the chamber dimensions (see earlier discussion). Regional systolic function can be estimated by echocardiographic determination of wall thickening and wall motion during systole in both LAX and SAX views of the ventricle. The SAX view of the left ventricle at the papillary muscle level displays myocardium perfused by the three main coronary arteries and is therefore very useful. However, because the SAX view does not image the ventricular apex, which is a very common location of ischemia, the LAX and longitudinal ventricle views are also clinically important.[230]

Although wall thickening is probably a more specific marker of ischemia than wall motion, its measurement requires visualization of the epicardium, which is not always possible. Alternatively, by observing the movement of the endocardium toward the center of the cavity during systole, systolic wall motion can almost always be assessed. As the myocardial oxygen supply-demand balance worsens, graded systolic wall motion abnormalities progress from mild hypokinesia to severe hypokinesia, akinesia, and finally dyskinesia.[231] Normal contraction is defined as greater than 30% shortening of the radius from the center to the endocardial border. Mild hypokinesia refers to inward contraction that is slower and less vigorous than normal during systole, with radial shortening of 10% to 30%. Severe hypokinesia is defined as less than 10% radial shortening. The precise distinction between varying degrees of hypokinesia can be difficult. Akinesia refers to the absence of wall motion or no inward movement of the endocardium during systole. Dyskinesia refers to paradoxic wall motion or movement outward during ventricular systole (see Chapter 20). These measurements of regional wall motion are obviously based on the determination of the center of the ventricular cavity. Unfortunately, because of cardiac translation, this center may move during the cardiac cycle. Two reference systems have been used: fixed reference and floating reference. Because of its relative simplicity and the fact that in most situations the impact of translation is minimal, the fixed-reference system is generally used. In conditions of significant translation, such as after CPB, the more cumbersome floating-reference system may be more appropriate.[232]

Relation to Other Monitors

Clinical studies have indicated that RWMAs occur earlier and are a more sensitive indicator of myocardial ischemia than the abnormal changes detected with an ECG or PAC.[233–239] In one study, 30 patients undergoing PTCA were simultaneously monitored with 12-lead ECGs and echocardiography.[236] All the patients had isolated obstructive lesions in their LAD coronary arteries, stable angina, normal baseline ECGs, normal baseline myocardial function with no history of infarction, and no angiographic evidence of collateralization. In the study, all patients developed RWMAs approximately 10 seconds after coronary artery occlusion. Electrocardiographic changes occurred in 27 of 30 patients approximately 22 seconds after coronary occlusion.

Smith and colleagues[235] evaluated 50 patients at high risk for myocardial ischemia during peripheral vascular or cardiac surgery with TEE and a multilead ECG. In their study, 6 patients had repolarization changes diagnostic of ischemia and 24 had new evidence of RWMAs. ECG repolarization changes were always accompanied by a corresponding RWMA. In 50% of the patients who experienced ST-segment changes, the RWMAs had occurred minutes before. Three patients with evidence of new RWMAs developed perioperative myocardial infarctions; however, only one patient of the three had evidence of ST-segment changes.

The value of PCWP monitoring for ischemia has also been compared with changes in regional LV function assessed with TEE. In one study, PCWP, 12-lead ECG, and LV wall motion were evaluated in 98 patients before CABG at predetermined intervals.[237] Myocardial ischemia was diagnosed by TEE in 14 patients. In 10 of the 14 patients, ischemia was associated with repolarization changes on the ECG. An increase of at least 3 mm Hg in PCWP was tested as an indicator for ischemia and was sensitive only 33% of the time, with a positive predictive value of only 16%. Overall, most studies indicate that the sensitivity of wall motion analysis for the detection of myocardial ischemia is generally superior to that of the ECG or PCWP.

Limitations

Although TEE appears to have many advantages over traditional intraoperative monitors of myocardial ischemia, potential limitations remain as well. The most obvious limitation of TEE monitoring is the fact that ischemia cannot be detected during critical periods, such as induction, laryngoscopy, intubation, emergence, and extubation. In addition, the adequacy of RWMA analysis may be influenced by artifact.[240] The ultrasound system, itself, or the particular tangential section being imaged can produce artifacts.

The septum, in particular, must be given special consideration with respect to wall motion and wall thickness assessment.[240,241] The septum comprises two parts: the lower muscular portion and the basal membranous portion. The basal septum does not exhibit the same degree of contraction as the lower muscular part. At the most superior basal portion, the septum is attached to the aortic outflow track. Its movement at this level is normally paradoxic during ventricular systole. The septum is also a unique region of the left ventricle because it is a region of the right ventricle as well and is therefore influenced by forces from both ventricles. In addition, sternotomy, pericardiotomy, and CPB have been found to alter the translational and rotational motion of the heart within the chest, which may cause changes in ventricular septal motion.[241]

For these reasons, use of a floating reference system in the intraoperative period is recommended. Consequently, the exact imaging plane for wall motion assessment is critical. The SAX view of the left ventricle at the level of the midpapillary muscles is used to ensure constant internal landmarks as reference (anterior and posterior papillary muscles) and to ensure monitoring of the muscular septal region. It must be recognized that, although myocardial blood flow from the coronary arteries is best represented at the SAX midpapillary muscle level, there may be other myocardial regions that are underperfused and not adequately represented in one echocardiographic imaging plane.[242] One solution to this problem is to frequently reposition the probe to view other cross sections of the heart.

Another potential problem of RWMA assessment is the evaluation of the discoordinated contraction that occurs as a result of a bundle-branch block or ventricular pacing. In these situations, the system used to assess RWMAs must compensate for global motion of the heart (usually accomplished with a floating frame of reference) and evaluate not only regional endocardial wall motion but also myocardial thickening.

Not all RWMAs are indicative of myocardial ischemia or infarction. Clearly, under normal conditions, all hearts do not contract in a homogeneous and consistent manner.[243] It is reasonable to assume, however, that most of the time an acute change in the regional contraction pattern of the heart during surgery is likely attributable to myocardial ischemia. An important exception to this rule may apply in models of acute coronary artery occlusion. In these models, it has been established that myocardial function becomes abnormal in the center of an ischemic zone, but it is also true that the myocardial regions adjacent to the ischemic zones become dysfunctional as well. Several studies have reported that the total area of dysfunctional myocardium commonly exceeds the area of ischemic or infarcted myocardium.[244,245] The impairment of function in nonischemic tissue has been thought to be caused by a *tethering effect* (Fig. 14.96). Tethering, or the attachment of noncontracting tissue that is normally perfused, probably accounts for the consistent overestimation of infarction size by echocardiography when compared with postmortem studies.[246]

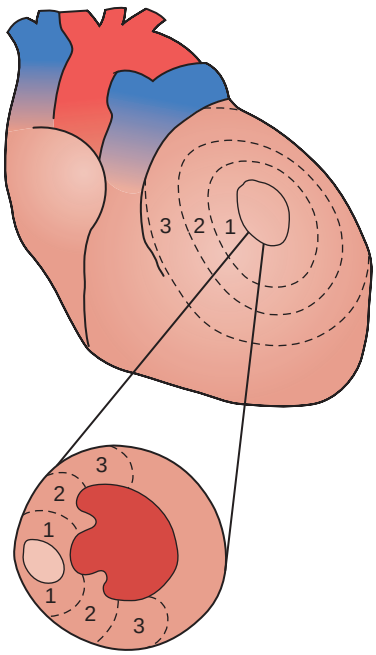

Fig. 14.96 Tethering effect. Myocardial function becomes abnormal in the center of an ischemic zone, as well as in regions adjacent to the ischemic zone. Attachment of noncontracting tissue *(central zone)* mechanically impairs contraction in normally perfused adjacent tissue (zones 1 through 3).

Another limitation of RWMA analysis during surgery is that it does not differentiate stunned or hibernating myocardium from acute ischemia, nor does it differentiate the cause of ischemia between increased oxygen demand and decreased oxygen supply.[247] Finally, it should be noted that areas of previous ischemia or scarring may become unmasked by changes in afterload and appear as new RWMAs.[248] This is particularly important in vascular surgery, during which major abrupt changes in afterload occur.

Outcome Significance

Data regarding the significance of intraoperative detection of RWMAs suggest that transient abnormalities unaccompanied by hemodynamic or ECG evidence of ischemia may not represent significant myocardial ischemia and are usually not associated with postoperative morbidity.[249] Hypokinetic myocardial segments appear to be associated with minimal perfusion defects compared with the significant perfusion defects that accompany akinetic or dyskinetic segments. Therefore hypokinesia may be a less predictive marker for postoperative morbidity.[235,250,251]

Intraoperative detection of new or worsened and persistent RWMAs during peripheral vascular surgery has been reported to be associated with postoperative cardiac morbidity by several investigators. The occurrence of new RWMAs during vascular surgery appears to be common; however, most of the time they are transient and clinically insignificant.[249–251] New RWMAs that are recognized to persist until the conclusion of surgery, in contrast, imply acute perioperative myocardial infarction. Intraoperative RWMAs therefore may be spurious, reversible with or without treatment, or irreversible. The former may be associated with clinically insignificant short periods of ischemia, whereas the latter are associated with significant ischemia or infarction.[235,250,251]

Intraoperative TEE has helped predict the results of CABG surgery. After CABG to previously dysfunctional segments, immediate improvement of regional myocardial function (which is sustained) has been demonstrated.[252,253] In addition, prebypass compensatory hypercontracting segments have been reported to revert toward normal immediately after successful CABG.[254] Persistent RWMAs after CABG appear to be related to adverse clinical outcomes, and lack of evidence of RWMAs after CABG has been shown to be associated with a postoperative course without cardiac morbidity.[247]

Stress Echocardiography

Dynamic imaging with stress echocardiography was first introduced in the late 1970s and may better distinguish viable from nonviable myocardium. Stress echocardiography uses mechanical, pharmacologic, or other stresses to the heart to achieve predetermined peak stress levels. Stress echocardiography has emerged as a safe and sensitive method for the detection of CAD and a cost-efficient alternative to scintigraphy. Reversible RWMAs attributable to transient myocardial ischemia are the hallmark of atherosclerotic CAD. Among the means for initiating the stress response are exercise, atrial pacing, intravenous dipyridamole, adenosine, and dobutamine. Exercise and dobutamine cause myocardial ischemia through significant increases in heart rate, systolic blood pressure, and contractility. Dipyridamole-induced ischemia, in contrast, is primarily due to blood flow maldistribution, with a reduction in subendocardial flow in the regions of myocardium supplied by a stenotic coronary artery. Because dipyridamole predominantly affects the supply part of the supply-demand ratio, flow maldistribution may not be severe enough to always induce endocardial ischemia. It is not surprising that sensitivity is greater for detecting ischemic heart disease with exercise followed by dobutamine, whereas specificity is greater with dipyridamole echocardiography. The application of stress echocardiography for the assessment of perioperative cardiac risk in patients undergoing major vascular surgery has been investigated and shown to be a safe and cost-efficient method for identifying patients at high and low risk of perioperative cardiac events. A metaanalysis by Mantha and associates[255] determined that its positive predictive

value compares favorably with dipyridamole-thallium, Holter ECG, and radionuclide ventriculography for perioperative risk stratification (see Chapters 1, 2, and 43).

A transient imbalance between oxygen supply and demand leads to ischemia. Signs of diastolic dysfunction, followed by RWMAs, occur before ECG changes and the clinical symptom of pain. Consequently, echocardiography is a useful tool because both diastolic dysfunction and RWMAs can readily be diagnosed. Since metabolic balance of the myocardium is a dynamic phenomenon, stress testing is frequently used to increase oxygen consumption. Although historically, bicycle or treadmill testing has been used to provoke RWMAs, these modes of stress can only be performed in patients able to exercise and require very rapid acquisition of sonographic images. Consequently, pharmacologic-induced stress is often preferred. Dobutamine is the preferred agent, since the effects observed on RWMAs are more pronounced when compared with adenosine or dipyridamole.

The test is performed by infusion of dobutamine, increasing the dose every 3 minutes based on a preset protocol (5, 10, 20, 30, 40 μg/kg/min). The goal is to increase the heart rate and metabolic demand, thus provoking RWMAs that can be visualized echocardiographically. The test is stopped if the target heart rate is achieved ([220 – age] × 0.85), ST depression greater than 2 mm, significant tachyarrhythmia, symptomatic severe hypotension, blood pressure greater than 240 mm Hg systolic or 140 mm Hg diastolic. Serious side effects are rare (1:1000 patients).[256] The accuracy of dobutamine stress echocardiography is consistently reported to be good with sensitivity and specificity averaging 82% and 81%, respectively.[257] These results are comparable to perfusion imaging and superior to exercise ECG. As with other forms of stress testing, the higher the degree of vascular disease (one- vs three-vessel disease) the more accurate the test.[258]

Ischemia-Related Diagnoses

Echocardiography is widely used in patients with ischemic heart disease for characterization of cardiac anatomy, as well as for analysis of intracardiac flow velocities by Doppler echocardiographic modalities. TEE has been shown to greatly enhance the diagnostic potential for detecting life-threatening sequelae of myocardial infarction, such as a ruptured ventricular septum or ruptured papillary muscles.[259,260] It has also been recognized that TEE may enable the identification of subtle, but potentially significant, problems that complicate the management of ischemic heart disease, such as anomalous coronary artery origins[261] and atrial infarction. In addition, it is important to note that the assessment of right- and left-sided heart function can be accomplished with intraoperative echocardiography. The assessment of right- and left-sided heart damage during intraoperative ischemia monitoring is essential because the presence of RV dysfunction may be a limiting factor and thus influence perioperative treatment.

Transesophageal Echocardiography: Advanced Echocardiography Concepts

SASHA K. SHILLCUTT, MD, FASE | FEROZE MAHMOOD, MD, FASE | NIKOLAOS J. SKUBAS, MD, FACC, FASE, DSc | NICHOLAS W. MARKIN, MD, FASE | CANDICE R. MONTZINGO, MD, FASE | GREGORY W. FISCHER, MD | ANDREW MASLOW, MD | RONALD A. KAHN, MD | TIMOTHY MAUS, MD, FASE

KEY POINTS

1. Intraoperative transesophageal echocardiography (TEE) plays a valuable role in interventional cardiac procedures, when used to guide transseptal puncture, evaluation of left atrial thrombus, closure of paravalvular leaks, transcatheter valve deployment, and during removal of transvenous lead extractions. Real-time three-dimensional (3D) TEE can be displayed to both the interventionalist and the echocardiographer for guidance and intraprocedural monitoring.
2. Precise evaluation of left ventricular function and synchrony may be characterized by measurements of tissue velocity and deformation in one or two dimensions. Myocardial strain is the systolic deformation of a myocardial fiber normalized to its original length, while strain rate expresses the speed of deformation. Doppler tissue imaging uses the Doppler signal while speckle-tracking imaging uses the two-dimensional speckled pattern of myocardium to calculate strain, strain rate, velocity, and displacement.
3. Intracardiac tumors are rare; when a cardiac mass is identified, it is frequently a thrombus or vegetation.
4. Hypertrophic cardiomyopathy is the most commonly inherited cardiomyopathy and often manifests with asymmetric thickening of the septum and dynamic outflow tract obstruction (>30 mm Hg gradient considered significant). Myocarditis can manifest clinically as a fulminant (hyperacute) course that demonstrates thickened, edematous myocardium with severely reduced left ventricular or biventricular ejection fraction. The patient is often critically ill with a good chance for recovery if supported through the initial process.
5. Dimensions of the aortic annulus should be measured in systole from leading edge to leading edge, whereas measurements of the aortic root and ascending aorta should be taken at end-diastole. Measuring from leading edge to leading edge produces dimensions similar to inner edge computed tomography and magnetic resonance imaging measurements.
6. The diagnosis of cardiac tamponade is pathophysiologic and requires both the presence of a pericardial effusion and an increase in pericardial pressure that limits ventricular filling. Echocardiographic findings that confirm the diagnosis of cardiac tamponade are early systolic right atrial collapse and diastolic right ventricular collapse when the pericardial pressure exceeds chamber pressure.
7. The use of both transthoracic echocardiography and TEE across the perioperative spectrum, such as in presurgical testing clinics, postanesthesia care units, and the critical care arena, can be accomplished by the development of a clinical perioperative echocardiography consult service. Quality assurance, ongoing education, and the implementation of appropriate use criteria are critical pieces in forming such a service.
8. Real-time, 3D TEE offers improved insight for diagnosing valve defects and predicting the success of surgical mitral valve repair.
9. A thorough echocardiography evaluation of valve positioning and description, evaluation of leaflet mobility, spectral Doppler flow profile, and color-flow Doppler assessment should be performed with all prosthetic valves. Abnormal leaflet mobility, color flow, or Doppler profile should alert the echocardiographer to prosthetic valve dysfunction.

The Development of a Perioperative Echocardiography Service

The practice of cardiac anesthesia has evolved over the past several years to require advanced skills in echocardiography. Many cardiac anesthesiologists perform consultative services in varies modalities such as transthoracic echocardiography (TTE), transesophageal echocardiography (TEE), and advanced three-dimensional (3D) imaging. The use of echocardiography across the perioperative spectrum, including presurgical testing clinics, postanesthesia care units, and critical care units, has led many specialists to provide echocardiography evaluation both inside and outside of the operating suite. Rescue echocardiography, both TTE and TEE, has been shown to change medical and surgical decision making, and many programs are expanding their resources to include cardiac ultrasound assessment by rapid response teams and during noncardiac surgical procedures.[1] Anesthesiology departments have begun to implement on-site TTE examinations into their preoperative clinics, where physicians who see patients can consult with a colleague who has expertise in TTE and obtain immediate results. The need for clinical echocardiography services beyond the clinical duties of cardiac cases has led some centers to develop perioperative echocardiography clinical services.[2] This section touches briefly on the development of a perioperative echocardiography clinical service.

Training Physicians in Perioperative Echocardiography

The ability for anesthesiologists to obtain both basic and advanced certification in perioperative TEE, as well as increasing trainee exposure to perioperative ultrasound, has led to various levels of training and expertise in echocardiography within institutions. Perhaps the most difficult task in developing a clinical service is the education and training of a critical mass of experts in perioperative echocardiography. Defining the team, establishing training and certification requirements, and credentialing physicians to lead the service is time consuming, costly, and yet crucial to success. Although the team may consist of mostly cardiac anesthesiologists with advanced training, echocardiography is expanding in the perioperative arena as its own subspecialty, and an echocardiography consult service may have a mixture of both advanced and basic perioperative echocardiography providers. Institutional support to train physicians and provide competency assessment and quality assurance programs must be solidified before the clinical service is developed.

Training in both TTE and TEE is becoming more and more prevalent. Although certification in perioperative TTE does not yet exist for anesthesiologists as it does for TEE, many critical care and cardiac anesthesiologists are learning the skill and implementing it in their clinical practice (see Chapter 17).

Echocardiography Equipment

Before a commitment to provide a clinical service can be made, echocardiography equipment and space must be solidified (see Chapter 14). With the creation of portable echocardiography or laptop machines, fast echocardiography assessment of an unstable or critically ill patient is more rapidly available. Handheld ultrasound devices, although simple to use and store, do not currently provide Doppler assessment that is needed in rescue echocardiography for hemodynamic evaluation or valve assessment. Access to portable machines that can be moved rapidly, similar to those in the emergency department, improves utilization.

Image Storage and Reporting

The importance of image acquisition and proper storage of reporting cannot be stressed enough. Perioperative patients that require either TTE or TEE examinations are often unstable or undergoing surgical evaluation, and different physician providers from various specialties need access to the reports and images for clinical decision making. The ability to store and transfer images must be implemented early on. Digital transfer of images into a hospital echocardiography database is important, as well as standard reporting of examinations performed. As the performance of ultrasound crosses specialty lines, so should the information. Reporting should follow recommendations from the American Society of Echocardiography and the Intersocietal Accreditation Commission.[3,4] Institutional expenditures and clinical revenue generated by the development of a perioperative echocardiography consult service were recently described in a paper by Shillcutt and colleagues.[2]

Clinical Areas of Implementation

Perioperative echocardiography can be implemented in several different anesthesia care areas from decision making to discharge. Perioperative echocardiography consult services include preoperative assessments of patients undergoing moderate- to high-risk noncardiac surgical procedures or patients with significant cardiac disease, rescue echocardiography (evaluation of unstable surgical patients in the operating rooms, recovery areas, or critical care units), and assessment of patients with unknown cardiac status who are undergoing urgent intervention. One report on the use of echocardiography in noncardiac surgical interventions at a single academic medical center found that the general surgery service, followed by vascular surgery, and the critical care service used the perioperative echocardiography consult service more often compared with other areas.[2] The most common indications for the use of both TTE and TEE in noncardiac operations were hypotension (49% of cases), a history of coronary artery disease (16% of cases), and a history of heart failure (12% of cases).[2]

Multiple studies suggest that perioperative echocardiography influences medical and surgical decision making.[5–8] Future studies need to determine the effect of perioperative echocardiography on operating room efficiency and improved patient outcomes.

Three-Dimensional Transesophageal Echocardiography

Three-Dimensional Reconstruction

Echocardiography has become a vital tool in the practice of contemporary cardiac anesthesiology. As with any technology, a considerable evolution has occurred since echocardiography was first introduced into the operating room in the early 1980s. Among the most important advances has been the progression from one-dimensional (eg, M-mode) imaging to two-dimensional (2D) imaging, as well as spectral Doppler and real-time color-flow mapping superimposed over a 2D image. The heart, however, remains a 3D organ. Although multiplane 2D images can be acquired easily with modern TEE probes by simply rotating the image plane electronically from 0 to 180 degrees, the final process occurs when the echocardiographer stitches the different 2D planes together to create a mental 3D image. Transmitting this mental image to other members of the surgical team can be challenging. By directly displaying a 3D image onto the monitor, cardiac anatomic and functional features can be assessed more rapidly and communication between the echocardiographer and the cardiac surgeon facilitated before, during, and immediately after surgery.[9]

Historic Overview

Concepts of 3D echocardiography (3DE) originated in the 1970s.[10] Because of the limitations of hardware and software capabilities in that era, the acquisition times required to create a 3D image prohibited widespread clinical acceptance, limiting its use for research purposes only. Technologic advances in the 1990s enabled 3D reconstruction from multiple 2D images obtained from different imaging planes. By capturing an image every 2 to 3 degrees as the probe rotated 180 degrees around a specific region of interest (ROI), high-powered computers were able to produce a 3D image, which could be refined further with postprocessing software. These multigated image planes were acquired under electrocardiographic (ECG) and respiratory gating to overcome motion artifact. The limitations of this technology were the time required to process and optimize the 3D image and the inability to obtain instantaneous, real-time imaging of the heart.

In 2007, a real-time 3D TEE probe with a matrix array of piezoelectric crystals within the transducer head was released on the market. This 3D imaging matrix array, compared to conventional 2D imaging transducers, not only has columns in a single one-dimensional plane but also rows of elements. That is, instead of having a single column of 128 elements, the matrix array comprises more than 50 rows and 50 columns of elements (Fig. 15.1). Although this matrix technology was available for TTE (precordial) scanning, a breakthrough in engineering design was required before the technology could be transitioned into the limited space of the head of a TEE probe.

Limitations of Three-Dimensional Imaging

Notably, 3DE is subject to the same laws of acoustic physics as 2DE. Artifacts such as ringing, reverberations, shadowing, and attenuation occur in 3D, as well as 2D, and M-mode. In addition, it is important to realize that the product of frame rate, sector or volume size, and imaging resolution equal a constant. That is, by increasing the requirements of one of these variables, a decrease in either one or both of the others will occur. For example, increasing sector size would result in a loss in either frame rate or image resolution, or both. Modern

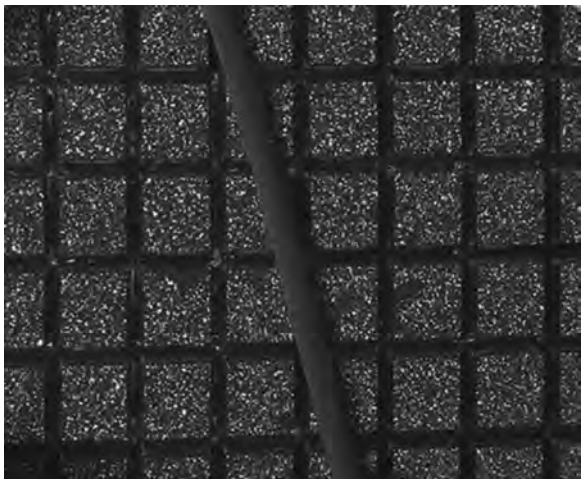

Fig. 15.1 Matrix array transducer consisting of 50 rows and 50 columns of piezoelectric elements. A human hair demonstrates the size of each individual element.

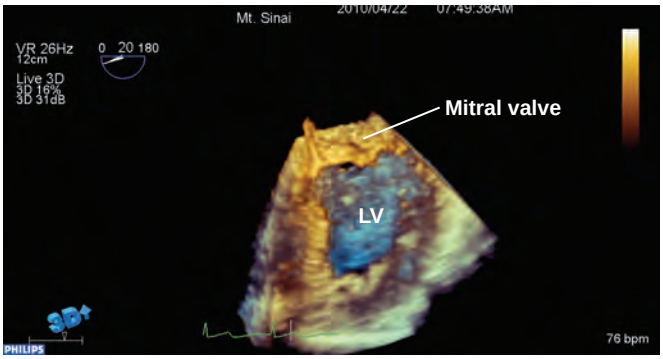

Fig. 15.2 Live three-dimensional image of mitral valve and left ventricle *(LV)*. Because of the matrix structure of the ultrasound transducer, this image represents a true live image. Change in transesophageal echocardiographic probe positioning by the echocardiographer results in instantaneous changes in the volumetric data set.

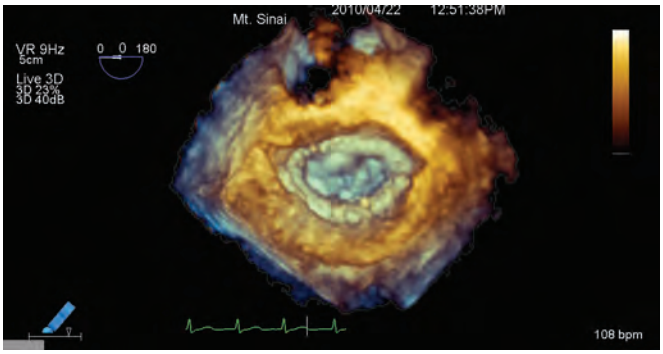

Fig. 15.3 Three-dimensional (3D) zoom mode acquisition of a mitral valve repair from the left atrial perspective. Annuloplasty ring is easily visualized. In analogy to the live 3D mode, the 3D zoom mode acquires instantaneous images.

ultrasound devices are equipped with incredible computing power, enabling them to display large 2D sectors while still maintaining excellent image resolution and high frame rates. Unfortunately, this does not apply to real-time instantaneous 3D imaging. The large number of data that must be acquired and processed requires the echocardiographer to reduce sector size to maintain adequate resolution and frame rate. The rate-limiting factor in 3D imaging is no longer processing power but rather the speed of ultrasound in tissue.

Display of Three-Dimensional Images

The classic 20 views of 2D TEE are not required in 3DE because entire volumetric data sets are acquired that can be spatially oriented and cropped at the discretion of the echocardiographer. Recently, the American Society of Echocardiography published guidelines detailing the acquisition and display of cardiac anatomy by 3D TEE. These views, given by experts, explain the surgical views for display intraoperatively.[11] In the operating room, every attempt should be made to place the views of the valve in the surgical orientation for communication of findings with the surgeon.

The limiting factor in 3DE is no longer processer performance but the speed of sound traveling through tissue (1540 m/s). Although the matrix configuration of the elements allows live and instantaneous scanning, the size of this sector is limited to guarantee adequate image resolution and frame rate. If larger sectors are to be scanned, the constraint of transmit time of ultrasound is sidestepped by stitching 4 to 8 gated beats together, which enables wider volumes to be generated while maintaining frame rate and resolution. Several modes of 3DE are described in the following subsections.

Narrow Sector (Live Three-Dimensional)–Real Time

In this mode, a 3D volume pyramid is obtained. The image shown in this mode is real time. The 3D image changes as the transducer is moved just as in live 2D imaging. Manipulations of the TEE probe (eg, rotation, change in position) lead to instantaneous changes in the image seen on the monitor (Fig. 15.2).

Wide Sector Focused (Three-Dimensional Zoom)–Real Time

If only a specific ROI requires imaging, the zoom mode can be used in a similar fashion as in 2DE. A typical example for this mode would be the mitral valve (MV) apparatus. The 3D zoom mode displays a small magnified pyramidal volume that may vary from 20 × 20 degrees up to 90 × 90 degrees, depending on the density setting. This small data set can be spatially oriented at the discretion of the echocardiographer. A key advantage to this mode is the fact that the real-time 3D images are devoid of rotational artifacts, as are commonly encountered with ECG-gated 3D acquisitions (Fig. 15.3).

Large Sector (Full Volume)–Gated

Because of insufficient time for sound to travel back and forth in large volumes while maintaining a frame rate greater than 20 Hz and reasonable resolution in live scanning modes, one maneuver to overcome this limitation entails stitching four to eight gates together to create a full-volume mode. These gated slabs or subvolumes represent a pyramidal 3D data set as would be acquired in the live 3D mode. This technique can generate more than 90-degree scanning volumes at frame rates greater than 30 Hz. Increasing the number of gates from four to eight creates smaller 3D slabs; this can be used to maintain frame rates, resolution, or both, as the volumes (pyramids) become larger (Fig. 15.4).

Unfortunately, as with any conventional gating technique, patients with arrhythmias are prone to motion artifacts when the individual data sets are combined; however, as long as the RR intervals fall within a reasonable range, a full-volume data set still can be reconstructed (eg, atrial fibrillation, electrocautery artifact). The acquired real-time 3D data set subsequently can be cropped, analyzed, and quantified using integrated software in the 3D operating system (QLAB; Philips Healthcare, Andover, Mass; Fig. 15.5).

Three-Dimensional Color Doppler–Gated

Because numerous data must be acquired with 3D color Doppler mode, a gating method similar to that of the full-volume mode must be used. However, because of the large number of data required, 8 to 11 beats must be combined to create an image. Jet direction, extent, and

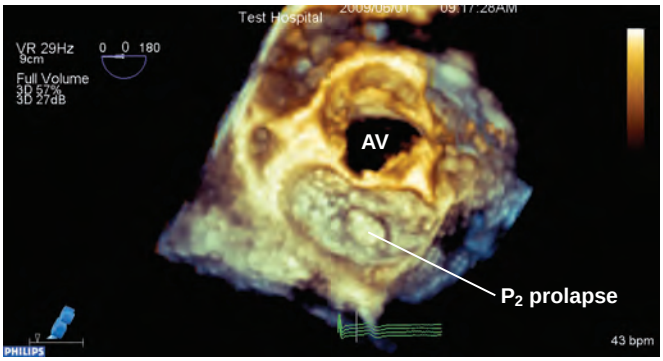

Fig. 15.4 Full-volume mode acquisition of the mitral valve from the left atrial perspective. Although the sector size is similar to that in Fig. 12-8, the improvement in temporal resolution is a consequence of the four-beat acquisition (9 vs 29 Hz). This mode does not permit instantaneous live imaging. *AV,* Aortic valve.

geometric features can be recognized easily with the use of this technique. Reports emerging in the late 1990s showed that the strength of this methodology lies in its ability to quantitate regurgitant lesions; 3D quantification of mitral regurgitation (MR) correlates better than 2D imaging, when using angiography as the gold standard.[12] In an experimental setting, 3D quantification was more accurate (2.6% underestimation) than 2D or M-mode methods, which had the tendency to underestimate regurgitant volumes (44.2% and 32.1%, respectively; Fig. 15.6).[13]

Clinical Applications

Right Ventricle

The right ventricle is a complex, crescent-shaped structure that does not lend itself easily to geometric assumptions as its left ventricle counterpart and has been the Achilles heel of 2D imaging. Because of the numerous reports that have linked right ventricular (RV) function to prognostic outcome in cardiopulmonary diseases, it is of great interest to quantify its function echocardiographically.[14]

A preliminary report showed that 3DE marginally underestimated RV volumes when compared with cardiac magnetic resonance imaging (MRI), and that correlation to cardiac MRI-measured volumes was

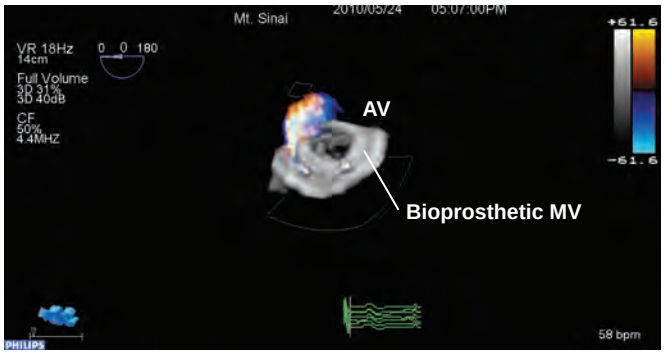

Fig. 15.6 Color three-dimensional acquisition of a mitral valve *(MV)* bioprosthesis. The aortic valve *(AV)* is labeled for orientation. Three paravalvular leaks can be identified.

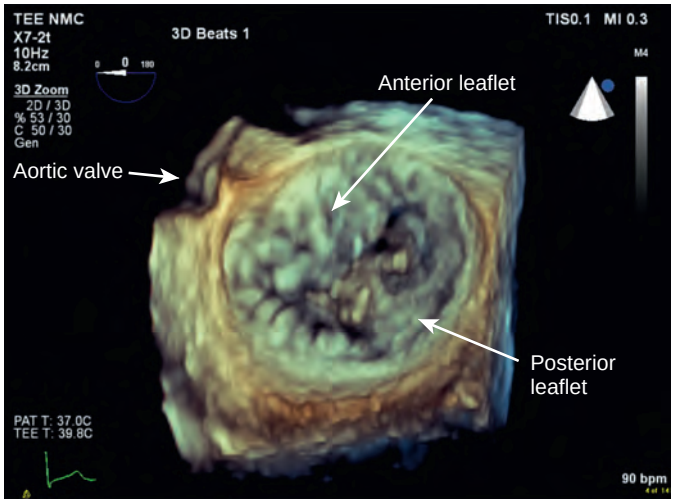

Fig. 15.7 Three-dimensional transesophageal echocardiographic image of the mitral valve displayed in the surgeon's view.

as good as that obtained by cardiac computed tomography (CT).[15] Further research in this field will undoubtedly lead to increased understanding of perioperative RV function.

Mitral Valve Apparatus

To ensure a high success rate of MV reconstruction, the cardiac anesthesiologist must have detailed understanding and insight into the mechanisms responsible for regurgitant lesions and must be able to identify these echocardiographically. The MV apparatus can best be viewed by utilizing the 3D zoom mode. The data block should be spatially oriented to view the MV from the left atrial (LA) perspective, with the aortic valve (AV) positioned at the top of the monitor (12 o'clock). This orientation, commonly referred to as the *surgeon's view,* puts the MV in an anatomically correct position (Fig. 15.7). This mode is especially useful in patients with atrial fibrillation, an arrhythmia frequently encountered in patients with MV disease, because it represents a live and instantaneous imaging mode not influenced by gating artifacts. Occasionally, in patients with Barlow disease, the valve is so grotesquely enlarged that temporal resolution suffers from the large sector required to image the entire valve. In these cases, a full-volume mode allows the imager not only to visualize the entire valve but also to maintain acceptable image and temporal resolution.

Although a comprehensive 2DE examination can help the physician identify the mechanism of MR in most cases, 3DE can not only help identify the mechanism but also provide information with regard to annular and leaflet geometry, which cannot be obtained by 2D imaging. Measurements that can be obtained easily include (1) the major anatomically oriented 3D axes of the annulus, anteroposterior

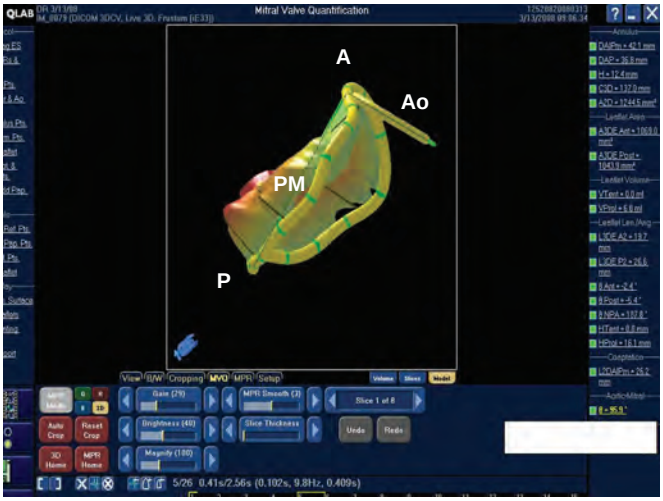

Fig. 15.8 Mitral valve quantification showing the aortomitral angle of 95.9 degrees. Patient at increased risk for development of systolic anterior motion after mitral valve repair surgery. *A*, Anterior; *Ao*, aorta; *P*, posterior; *PM*, posteromedial.

and anterolateral-posteromedial diameters, as well as annular height; (2) 3D curvilinear leaflet lengths and areas of all segments (A_1, A_2, A_3, P_1, P_2, P_3); (3) total and functional anterior and posterior leaflet surface areas; and (4) the angle between the AV annulus and the MV annulus (aortomitral angle). A narrow angle should alert the imager to the possibility of systolic anterior motion during the period after repair (Fig. 15.8).

Aortic and Tricuspid Valves

Unlike with the MV, acquiring high-quality images of the AV and the tricuspid valve (TV) represents a more difficult undertaking. The explanation lies, on the one hand, in the thinner leaflet tissue that generally comprises both the AV and the TV and, on the other hand, on the orientation of the tissue as a reflector. Because these factors result in weaker acoustic signal strength, the 3D volume renderer is more apt to tag these as transparent and render the voxels as blood—that is, invisible. Caution must be taken by the echocardiographer not to misdiagnose these imaging artifacts as perforations. Both the AV and the TV should be displayed in the surgical view, as shown in Figs. 15.9 and 15.10, respectively. A description of these views can be found in this text's companion textbook, Reich and Fischer's *Perioperative Transesophageal Echocardiography: A Companion to Kaplan's Cardiac Anesthesia*.[16]

Congenital and Interventional Procedures

Congenital heart disease is complex and characterized by multiple variants. Three-dimensional echocardiography can facilitate improved understanding of the anatomic features of congenital heart disease. The ability to spatially orient the data block to allow for views of atrial or ventricular septal defects (VSDs) and their relation to adjacent structures represents a milestone in improving understanding of these complex disease processes. The size and location of intracardiac shunts are crucial parameters when evaluating whether to pursue an interventional procedure. The understanding of congenital valvular pathology (eg, cleft MV, Ebstein's anomaly) can be greatly enhanced by 3DE. Thus, real-time 3DE offers improved insight for diagnosing valve defects and predicting the success of a surgical valve repair (Fig. 15.11).

Perioperative Echocardiographic Evaluation of Valves

Echocardiography has many roles and applications that provide healthcare professionals with invaluable information about patients with new murmurs, arrhythmias, thromboembolic events, and/or heart failure.

For patients with suspected valvular dysfunction, echocardiography is the method of choice for the detection, diagnosis, and subsequent follow-up evaluations.[17–20] An understanding of valvular dysfunction and resultant hemodynamic and cardiopulmonary effects is crucial to patient care.

The same principles and techniques used in the assessment of native valves apply to the echocardiographic assessment of prosthetic

valves; the latter are much more demanding because of specific differences among types of valve prostheses, including flow patterns, expected Doppler velocities, and regurgitant flows.[21,22] In addition, artifacts produced by prosthetic materials may obstruct imaging, thereby requiring the echocardiographer to view the prosthesis from multiple angles. Knowledge of the normal functions of each prosthetic valve is necessary.

Whereas the evaluation of native and prosthetic valves is primarily focused on the valve itself, the examiner must still perform a comprehensive examination of the surrounding cardiac tissues to assess for coexisting disease or secondary abnormalities and dysfunction.[23] Clinical decisions are based on symptoms, severity of valve dysfunction, and the ability of the heart to compensate.[24–27]

Valve dysfunction involves three pathophysiologic conditions: regurgitation, stenosis, and endocarditis/masses/embolic events. In most cases, however, valve dysfunction occurs as a result of endocarditic masses; however, some patients may have only mild regurgitation.

General Points Regarding Valve Assessment

General echocardiographic principles guide the assessment of the heart valves, in that a comprehensive examination is performed that uses all modes of imaging from multiple echocardiographic windows and multiple angles (see Chapter 14). In so doing, a 3D construct of the valve apparatus is formed. With advancements in technology, live imaging, reconstructed 3D imaging, or both are a routine part of the echocardiographic examination.

An understanding of valvular anatomy, function, and dysfunction helps explain cardiac hemodynamics, secondary cardiac changes, and patient presentations. In addition to assessing the degree of dysfunction, evidence of decompensation can guide therapeutic decision making, including the type and timing of invasive care. Whereas acute valvular dysfunction is not well tolerated, chronic dysfunction allows the heart to compensate and better tolerate pressure and/or volume loading conditions. Compensatory mechanisms initially include hypertrophy and increases in contractility in the presence of pressure and/or volume overload. Further progression causes increasing degrees of hypertrophy, dilation, and dysfunction until clinical decompensation occurs. Obstructive lesions result in relatively greater hypertrophy than dilation, whereas the opposite is true for regurgitant lesions.

Valvular dysfunction has numerous causal factors, some of which are common across all four valves, and others which are specific.[17–22] Causal factors can be grouped by valve, acuity, valvular disorder, or nonvalvular disorder (Tables 15.1 and 15.2). Valvular disorders may be described by leaflet mobility, as is the case for MR and aortic regurgitation (AR). Echocardiography is the mainstay of diagnostic imaging to assess and quantify valvular function and dysfunction as well as the degree of cardiac compensation, allowing healthcare professionals to

better manage, treat appropriately, and, ideally, prevent, reverse, or reduce long-term dysfunction.

General Considerations With Prosthetic Valves

Types of Prosthetic Valves

Prosthetic valves are usually broadly grouped as biologic or mechanical.[21,22] Bioprosthetic valves (Fig. 15.12) are composed of three biologic cusps with an anatomic structure similar to the native valve annulus. All bioprosthetic valves are similar in that the trileaflet valve opens to create a circular orifice with a flow pattern that is similar to the native valve. For imaging purposes it is useful to know whether the valve is stented or stentless.

Stented bioprostheses are composed of three tissue cusps/leaflets that are sewn into a fabric-covered metal support. This support/stent may cause shadowing or reverberations during ultrasound imaging. The manufacturer's valve size refers to the external diameter of the sewing ring, not the actual diameter of the valve orifice.

Stentless bioprostheses include all replacements without a prosthetic stent. Examples include St Jude Medical and Medtronic valves

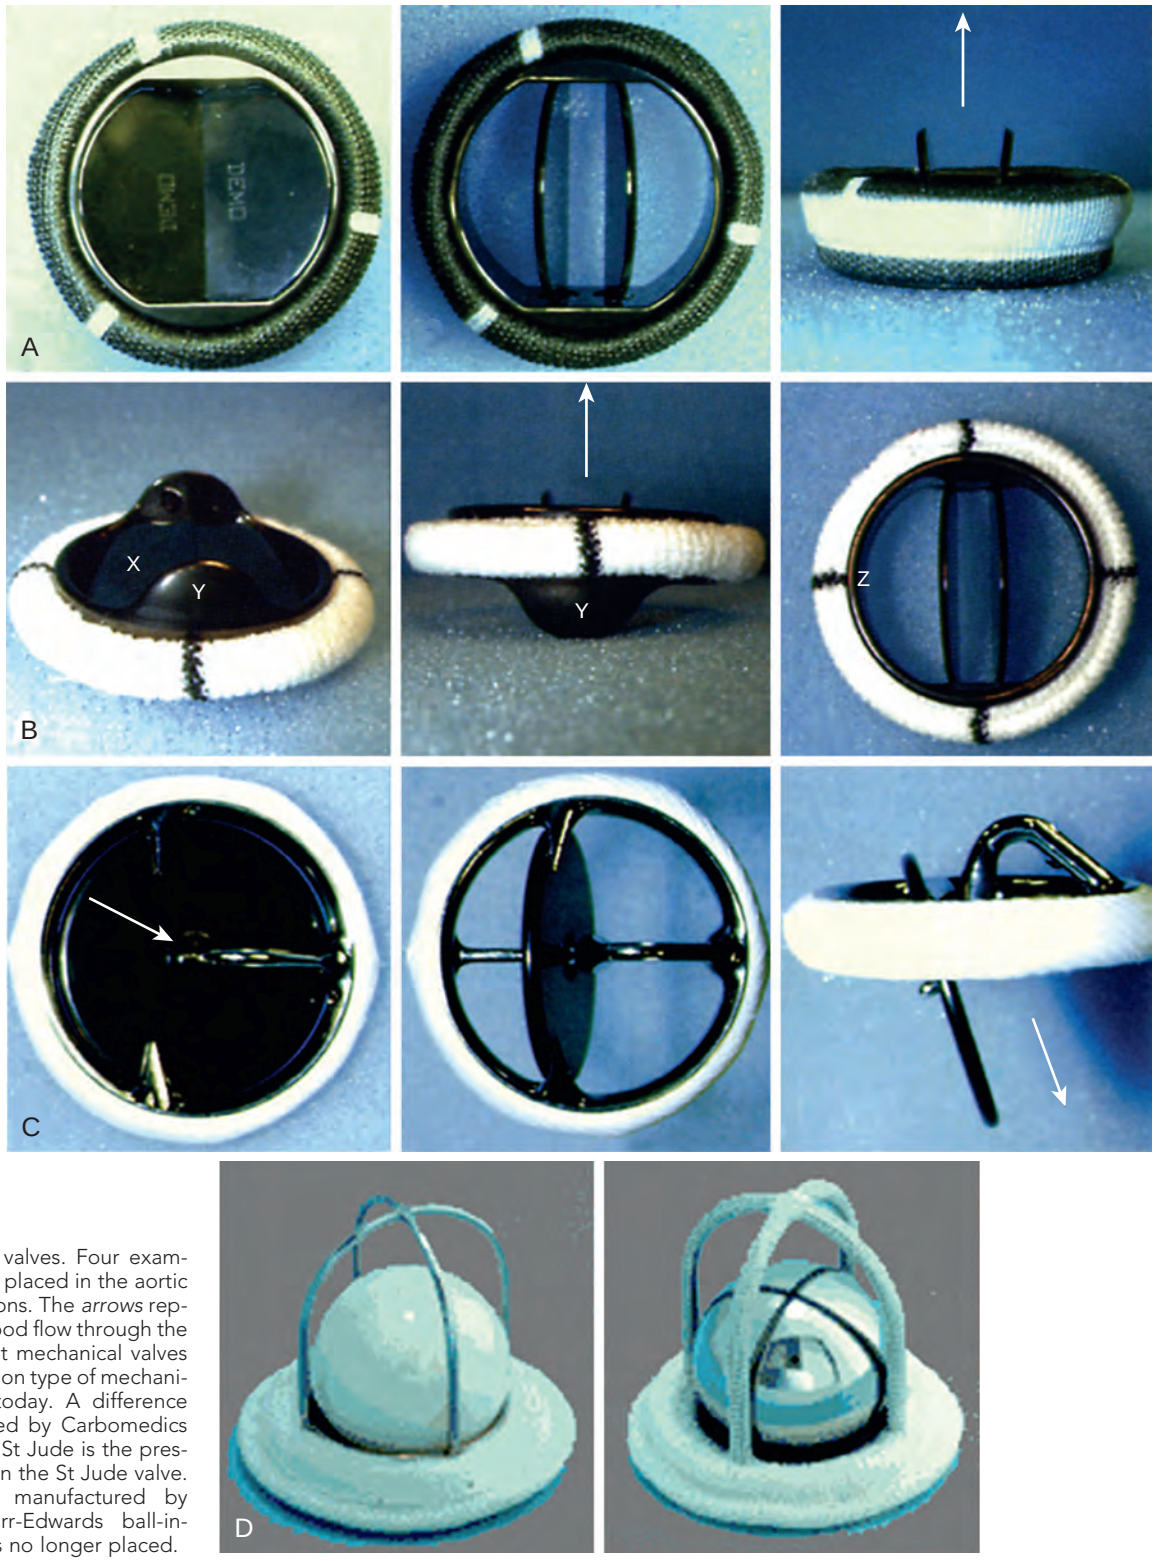

Fig. 15.13 Mechanical valves. Four examples of mechanical valves placed in the aortic and/or mitral valve positions. The *arrows* represent the direction of blood flow through the valve. (A) and (B) Bileaflet mechanical valves represent the most common type of mechanical heart valve placed today. A difference between (A) manufactured by Carbomedics and (B) manufactured by St Jude is the presence of a pivot guard *y* on the St Jude valve. (C) Single-leaflet valve manufactured by Medtronic-Hall. (D) Starr-Edwards ball-in-cage valve, a valve that is no longer placed.

(see Fig. 15.12). Stentless valves are considered xenografts consisting of either a preparation of porcine aorta or sculpted bovine pericardium without any added strut support. Xenografts differ in method of preservation of valve cusps, anticalcification regimens, and composition, as well as designs of stents and sewing rings. There also are cadaveric human AVs or pulmonary valves (PVs) that are cryopreserved shortly after being harvested. Typically the valve is harvested along with some of the respective ventricular outflow tract and great vessel, preserved as a block, and trimmed at surgery before implantation. Homografts are used only in the aortic and pulmonary positions as well as in valved conduits.

A wide variety of mechanical valves (Fig. 15.13) are currently available. Although variations exist, they all share similarities. The most commonly implanted is a bileaflet valve in which two semicircular disks rotate around struts that are attached to the valve housing. These open to form two large lateral orifices and a smaller central orifice.

BOX 15.1 CAUSES OF PROSTHETIC VALVE REGURGITATION

- Paravalve
  - Calcification
  - Abscess
  - Dehiscence
- Leaflet pathology: excess mobility
  - Abscess
  - Tears
  - Degeneration
  - Endocarditis
    - Bioprosthetic valves: leaflet perforation/destruction
    - Mechanical valves: interference with valve opening/closing
- Leaflet pathology: restriction/distortion
  - Suture
  - Thrombus
  - Pannus
  - Preserved leaflet valve apparatus interfering with closure of mechanical leaflets
  - Stuck leaflet

BOX 15.2 CAUSES OF PROSTHETIC VALVE STENOSIS/OBSTRUCTION

- Prosthetic valve stenosis
  - Stuck leaflet
  - Thrombus
  - Pannus
- Nonvalvular obstruction
  - Dehiscence
  - Obstructing retained native tissue
  - Suture causing restriction of leaflet
  - Subvalvular obstruction (aortic and pulmonary valves)
  - Systolic anterior motion (aortic and pulmonary valves)
  - Supraannular narrowing (aortic and pulmonary valves)
- Doppler issues/artifacts/errors: normal prosthetic valve function
  - Sampling of other flow (ie, sample mitral regurgitation during assessment of the aortic valve)
  - Subvalvular obstruction
  - High cardiac output
  - Significant aortic valve insufficiency
- Patient-prosthesis mismatch
- Compliance issues (net changes) affecting pressure half time

TABLE 15.3 Expected Ranges of Areas and Pressure Gradients for Prosthetic Valves in the Aortic and Mitral Positions

The data highlight the variability of reported data reflecting a host of operator variables and assumptions of physical principles. The data also provide practitioners with a reference to determine which prosthetic valve size is most appropriate for the individual patient to avoid patient-prosthesis mismatch. Similar data are applied when right-sided valves are being replaced as similar valves are employed; however, clinical echocardiographic data are not similarly available.

Several other types of mechanical valves were implanted in the past and will be encountered in patients. The ball-in-cage valve houses a spherical occluder contained within a metallic cage. This occluder fills the cage orifice in the closed position but rides above the orifice during antegrade flow. Single tilting disk valves contain a single circular disk controlled by a metal strut that opens at an angle to the annulus plane.

Since prosthetic valves share commonalities regarding function and normal flows, there also are similar causes of dysfunction (Boxes 15.1 and 15.2).

Doppler Echocardiography for Prosthetic Valves

Compared with a normal native valve, prosthetic valves have a smaller effective orifice area (EOA). Antegrade velocities and pressure gradients across a normally functioning prosthetic valve are higher than a normal native valve in the same space. Knowledge of normal hemodynamics for native and prosthetic valves is important for determining normalcy of each valve. Manufacturers publish data on the flow characteristics of each specific prosthetic valve and its various sizes (Table 15.3). After valve placement, cardiologists can use these data to determine what constitutes normal function for each type and size of prosthetic valve.

Whereas Doppler-derived peak and mean pressure gradients across native and bioprosthetic valves are consistent for flow moving through a single orifice, the Doppler-derived pressure gradients across dual orifices (eg, mechanical valves) present a more complex clinical scenario (Figs. 15.14 and 15.15). In the latter, flow and pressure gradient through and across each orifice are dependent on orifice size and geometry. Although it has not been thoroughly studied, since pressure and flow are directly related, it is possible to obtain accurate data regardless of whether or not the Doppler beam is parallel to a larger or smaller orifice. The bileaflet prosthetic valve has been studied in flow models (Figs. 15.14 through 15.16). Two semicircular disks hinge open to form two larger semicircular lateral orifices and a smaller slit-like central orifice. In the narrow central flow stream, higher blood velocities occur as a result of local acceleration forces. Whether or not continuous-wave Doppler–obtained transvalvular velocities are different across the central and peripheral orifices is unknown. Theoretically, similar to the dual orifice valve, the pressure gradient across a narrower

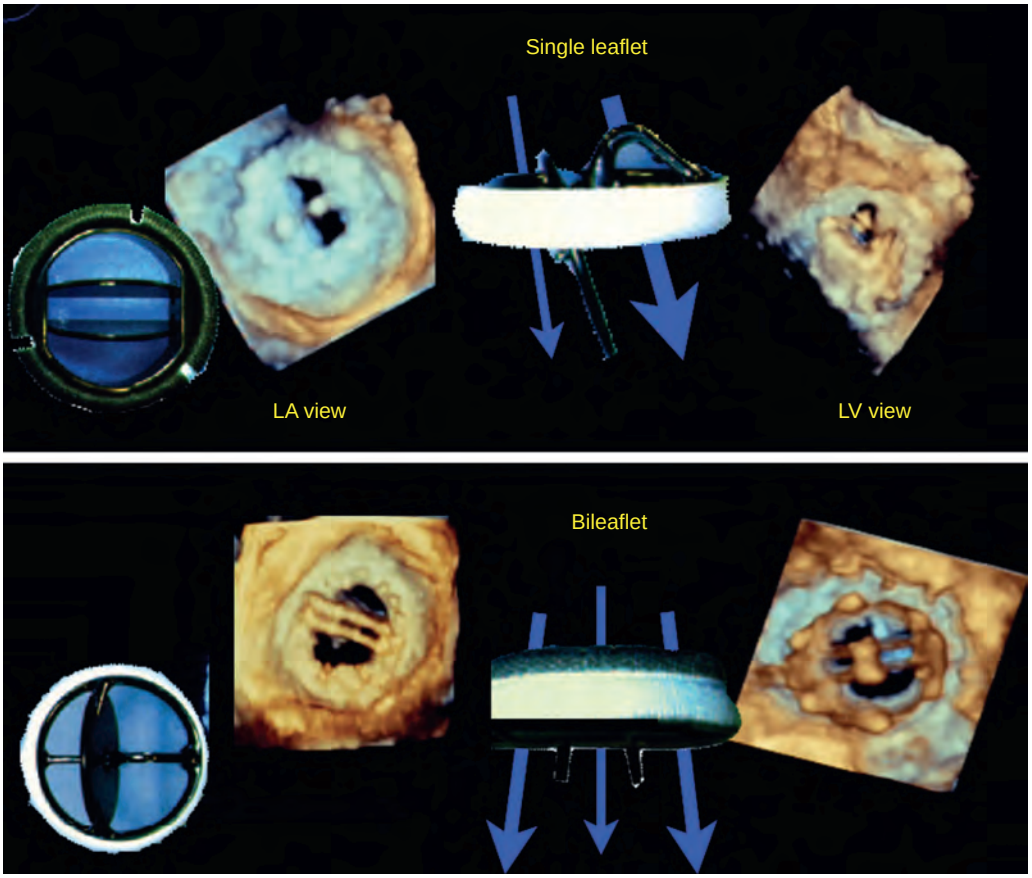

Fig. 15.14 Flows across mechanical prosthetic valves. This figure highlights the differences in both appearance and flow across a single-leaflet and a bileaflet mechanical prosthetic valve. Three-dimensional echocardiographic imaging shows valves, in mitral position, from the perspectives of the left atrium *(LA)* and left ventricle *(LV)* and highlights the paths through which blood flows while traversing the valve.

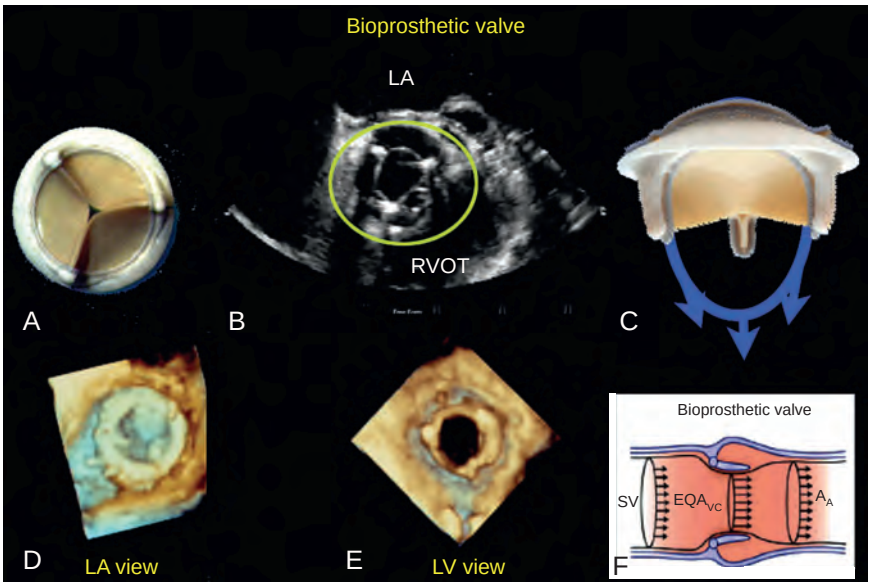

Fig. 15.15 Flows across bioprosthetic valves. The figure highlights the appearance and flow across a bioprosthetic valve. The valve is shown in the mitral and aortic positions. (A) and (B) Valve in short-axis view looking from downstream. (C) View highlighting the main single forward flow pattern. (D) and (E) Three-dimensional echocardiographic views of the mitral position from the left atrial *(LA)* perspective during systole and the left ventricular *(LV)* perspective during diastole. (F) Another view highlighting the main single forward flow pattern. A_A, Ascending aorta; EQA_{VC}, estimated qualitative area vena contracta; *RVOT*, right ventricular outflow tract; *SV*, stroke volume.

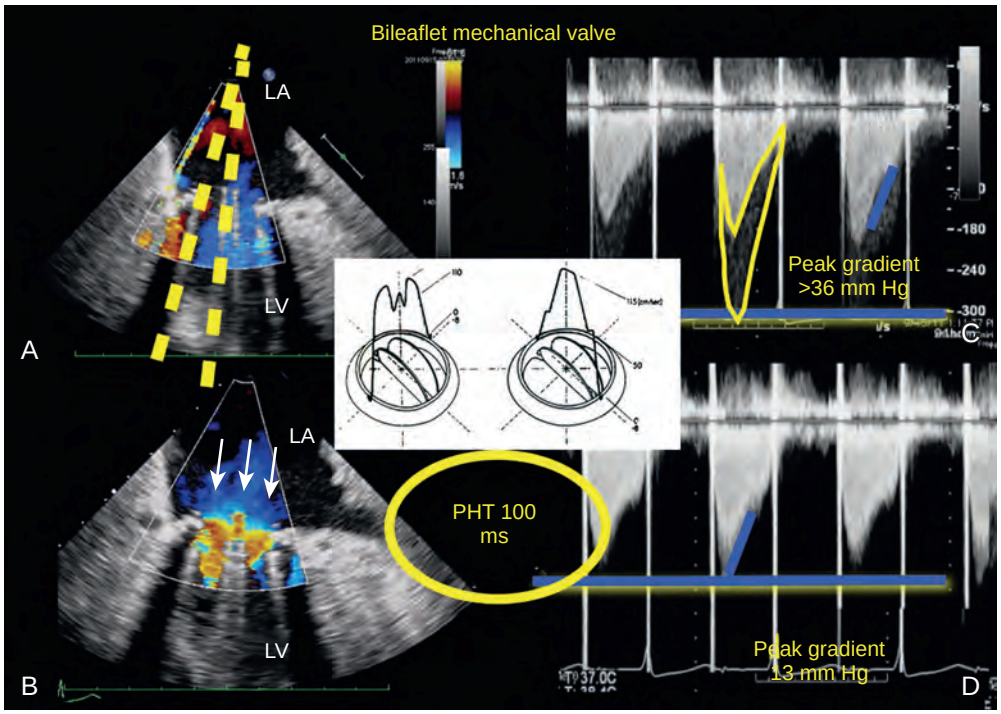

Fig. 15.16 Normal flows across a bileaflet mechanical valve. (A) and (B) Imaging of a bileaflet mechanical valve perpendicular to the leaflets. Three forward jets of blood flow through the two lateral and one central orifice. Flow through these orifices is on a slight stagger, as seen in the schematic in the middle. (C) The flow through the middle orifice passes with a higher velocity and may record a higher gradient than what is truly representative of the valve. The Doppler profile shows two components: a lower and more dense profile, which suggests the large majority of flow, that represents flow through the lateral orifices, and a faster less dense profile (fewer blood cells) that comes from the central orifice. The Doppler profile records a high peak gradient (>36 mm Hg) from the central orifice that does not accurately reflect the mitral valve area measured by the pressure half time *(PHT)* technique (220/100 ms = 2.2 cm^2). (D) The more dense profile from a lateral orifice is more consistent with a larger valve area recorded using the PHT. *LA*, Left atrium; *LV*, left ventricle.

orifice will be identical to the peripheral ones since blood flow through the orifices is directly related to the orifice size.[21,22,28]

Given the wide range of pressure gradients across any specific prosthetic valve, determining the valve EOA, or a dimension-less index, adds useful information. Measuring valve area is, at minimum, complementary to more basic Doppler velocity and pressure gradient data. Indexing the valve areas to individual body surface area (BSA) allows an assessment of the valve relative to the patient's size. A relatively small valve area (relative to the BSA) is called *patient-prosthesis mismatch (PPM)*.[29] PPM is more commonly described and discussed in the context of AV surgery. PPM is associated with short- and long-term adverse outcomes.[29]

Color-Flow Doppler

Normal native valvular flows have relatively low velocity. More than 70% of patients with normal valvular flow display trace or mild mitral, tricuspid, and PV regurgitation without obvious defect.[20] By contrast, only about 15% of patients display trace or mild aortic insufficiency (AI) in the absence of disease.[20]

All *mechanical valves* display normal regurgitant jets, sometimes referred to as *washing jets* (Fig. 15.17).[20–22,28] These flows are thought to prevent the formation of thrombi at sites of blood flow stasis. These jets are typically small (vena contracta < 3 mm) and low velocity, have a uniform color pattern (minimal aliasing at most), and do not extend far from the valve plane. The patterns of regurgitation detected by color-flow Doppler (CFD) are distinct (signature patterns) for each mechanical valve type, corresponding to their fluid dynamics. While casting an identifiable signature pattern of "regurgitant plumes," the associated regurgitant fraction is less than 10% to 15%.[21]

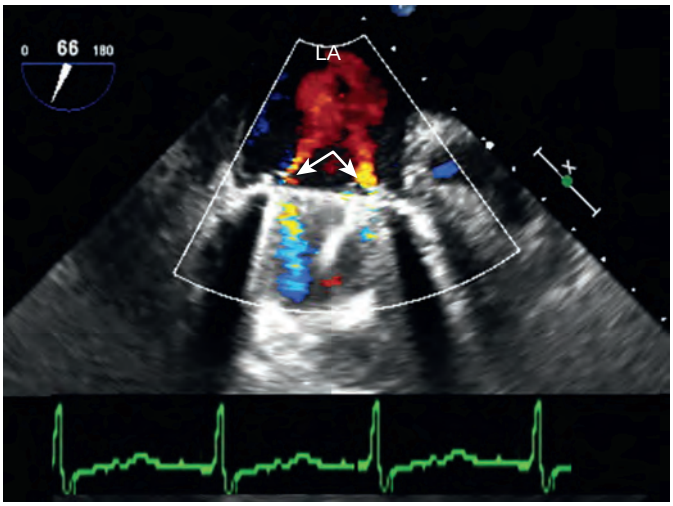

Fig. 15.17 Flow profile of a bileaflet mechanical valve. Image of a bileaflet mechanical valve parallel to the leaflet demonstrates the signature regurgitant washing jets for the bileaflet mechanical valve *(white arrows)*. When imaging in parallel to the mechanical leaflets, two inward directing jets can be seen. *LA*, Left atrium.

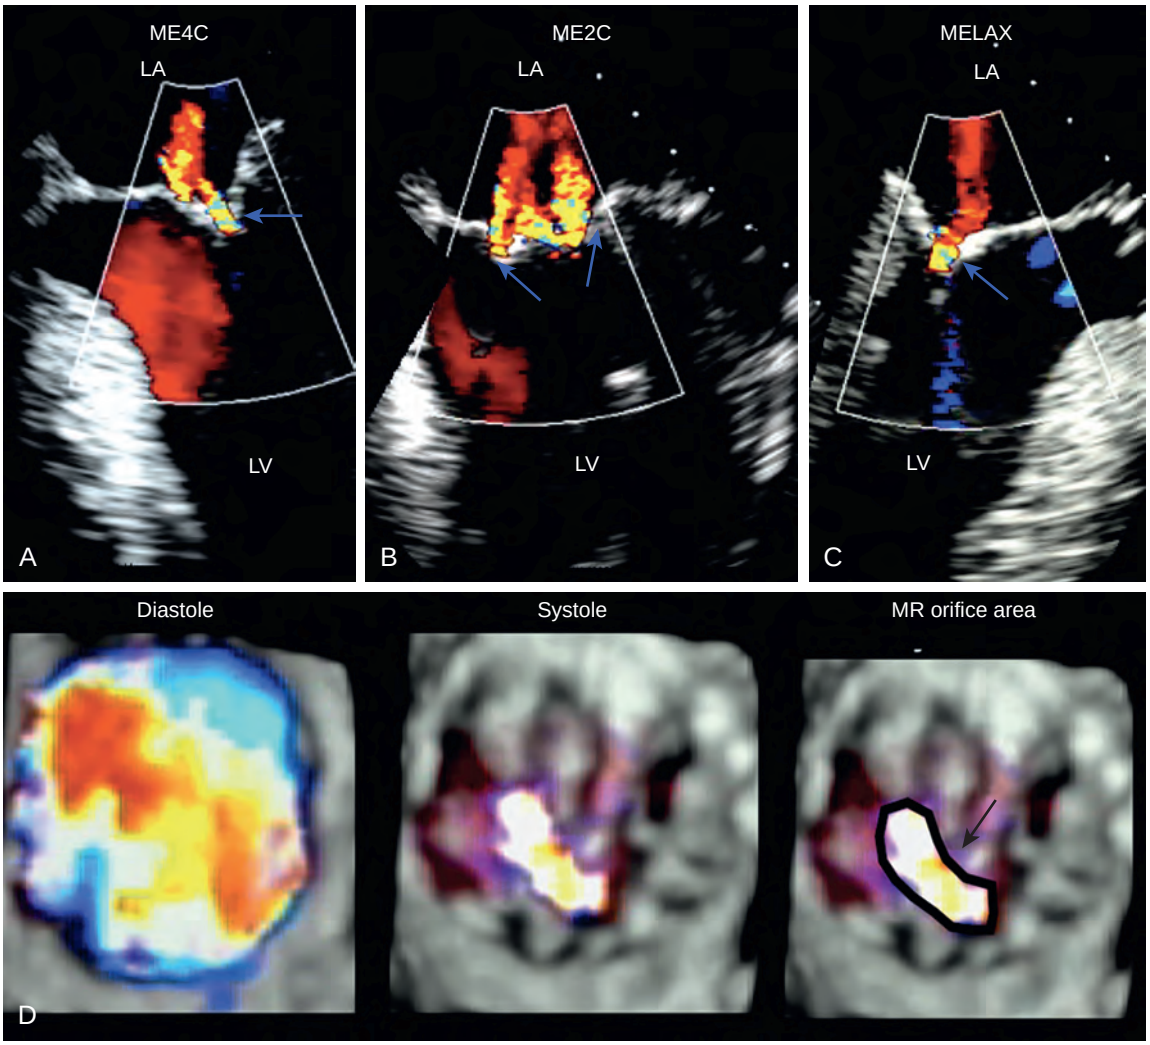

Fig. 15.18 Three-dimensional (3D) image of the regurgitant orifice. (A–C) Two-dimensional appearances of the same mitral regurgitant jet from three different midesophageal *(ME)* echocardiographic windows: four-chamber *(4C)*, two-chamber *(2C)*, and long-axis *(LAX)*, respectively. Vena contracta measurements from the ME4C and MELAX views are more accurate correlates of mitral regurgitation *(MR)* severity as they measure perpendicular to the MR jet, while the ME2C window views parallel to the MR jet. (D) This is confirmed using 3D imaging of the regurgitant jet during diastole *(left)* and systole *(middle)* from the left ventricular *(LV)* perspective. The shape of the regurgitant orifice, during systole on the *right*, is elliptical. The implications are that the effective regurgitant orifice is not circular and the flow convergence (proximal isovelocity surface area [PISA]) is not hemispherical as the principle behind the equation assumes it to be, creating errors in the PISA method. Three-dimensional imaging, when feasible, allows a direct measure of the regurgitant orifice area shown in black *(right)*.

A ball-in-cage valve in the open position shows antegrade blood flow around all sides of the ball occluder and across the cage orifice.[21,22] In the closed position, CFD demonstrates a small regurgitant jet circumferentially around the ball as it seats in the cage orifice. Antegrade blood flow across a single tilting disk prosthetic valve is characterized by a CFD across a major and a minor orifice. CFD indicates nonlaminar and asymmetric flow as blood accelerates along the tilted surface of the open disk. In the closed position, a single tilting disk normally demonstrates a regurgitation jet directed away from the sewing ring starting at the edge of the major orifice. Surgical preference on implantation determines the open disk position and hence the direction of the regurgitant jet normally seen on disk closure. The bileaflet valve has a complex blood flow profile on CFD imaging (see Fig. 15.16). In the open position, CFD shows antegrade flow through two larger lateral orifices and a small central orifice. When a bileaflet mechanical valve is imaged in the closed position, multiple washing jets of regurgitation are normally seen in the plane parallel to the leaflet-opening plane. All the regurgitant jets are located inside the sewing ring, with two jets originating from where the leaflets meet the housing and a third, central jet originating where the leaflets meet each other.

Bioprosthetic valves also display characteristic flow patterns. Stented and stentless valves display antegrade flow patterns closer to that of a normal native valve through a single orifice. Normal retrograde or regurgitant jets are centrally directed and do not extend far from the closed valve, are limited in jet area, and are homogenous in color.

Although generally accurate, recent data using 3D imaging suggested that geometric assumptions about the shape of the proximal isovelocity surface area (PISA) may be erroneous; that is, it is not necessarily hemispherical and the defect may not be circular (Fig. 15.18).[30] Three-dimensional imaging with CFD highlights important details of both stenotic and regurgitant jets and helps to explain why simpler 2D assessments may not provide the same accuracy (Figs. 15.19 through 15.21). Specifically, geometric assumptions required for several of the equations and principles are not always accurate. Visualizing the flow

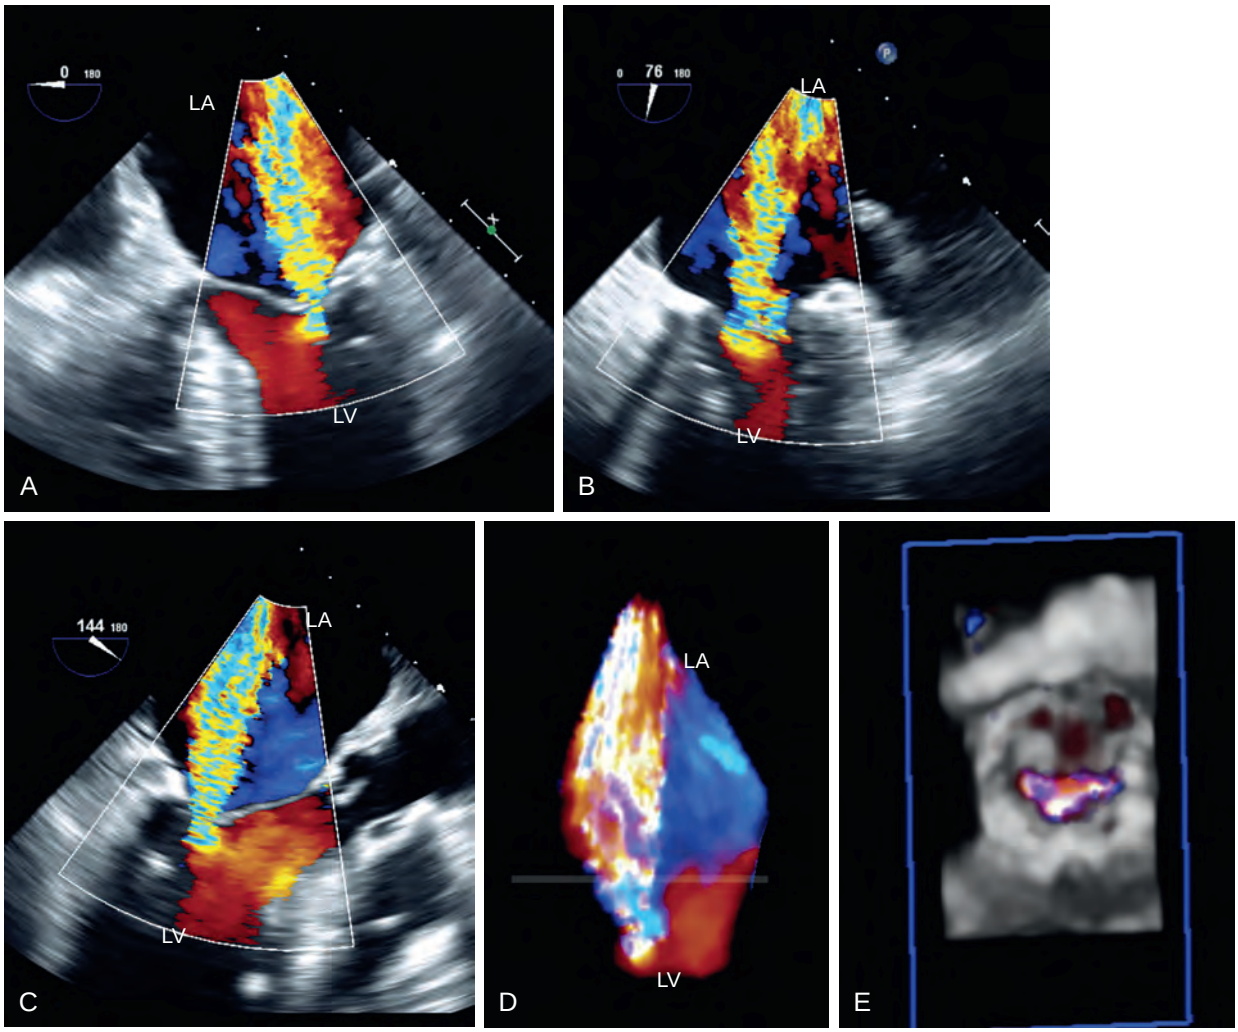

Fig. 15.19 Assessment of mitral regurgitant (MR) jet. (A–C) Two-dimensional (2D) color Doppler views of a centrally directed MR jet. (D) and (E) Three-dimensional (3D) color Doppler assessment of the same regurgitant flow. (D) The MR jet on three levels (below, above, and at the level of the mitral valve) demonstrates the expansion of the regurgitant jet immediately after it passes through that regurgitant orifice (ie, entrainment). (E) Similar to Fig. 15.16, this shows an elliptical regurgitant orifice that is not similarly highlighted in the 2D color Doppler evaluations (A–C). Assumptions made regarding the shape of the MR jet, centrally or eccentrically directed, may not be accurate as evidenced by 3D imaging. Using 3D color Doppler imaging, planimetry of the regurgitant orifice area can be measured. *LA*, Left atrium; *LV*, left ventricle.

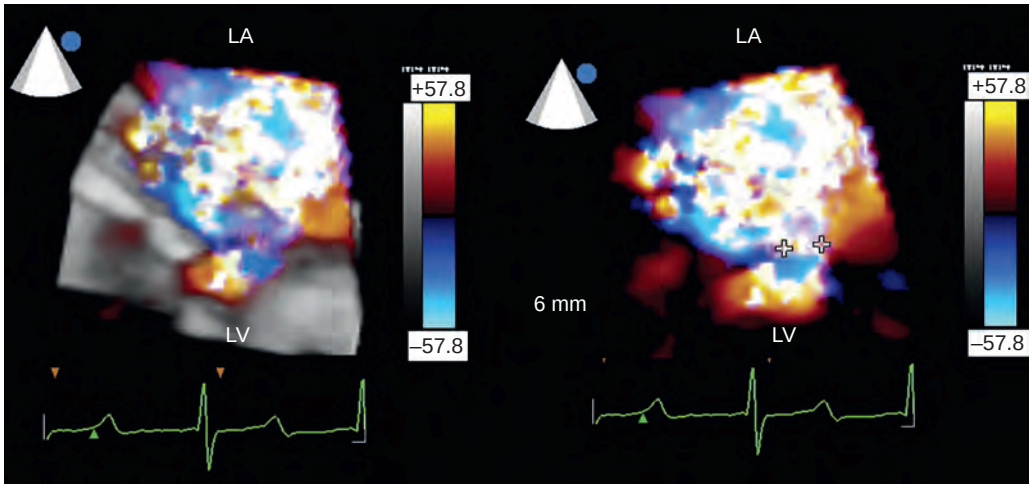

Fig. 15.20 Three-dimensional (3D) color Doppler imaging of a regurgitant mitral jet. The two images demonstrate the use of 3D color Doppler imaging to image flow from multiple levels to see the full shape of, in this case, regurgitant flow. Shown is the evaluation of a paravalvular regurgitant jet of a prosthetic mitral valve. The regurgitant jet is seen below, at, and above the valve to allow a more accurate measure of the vena contracta. As seen in Fig. 15.18, expansion of the regurgitant jet is seen on the atrial side. This expansion helps to understand why the regurgitant jet area may not reflect the regurgitant orifice accurately. In the case, the 3D view of the regurgitant flow aided in determining the size and number of occluder devices. *LA*, Left atrium; *LV*, left ventricle.

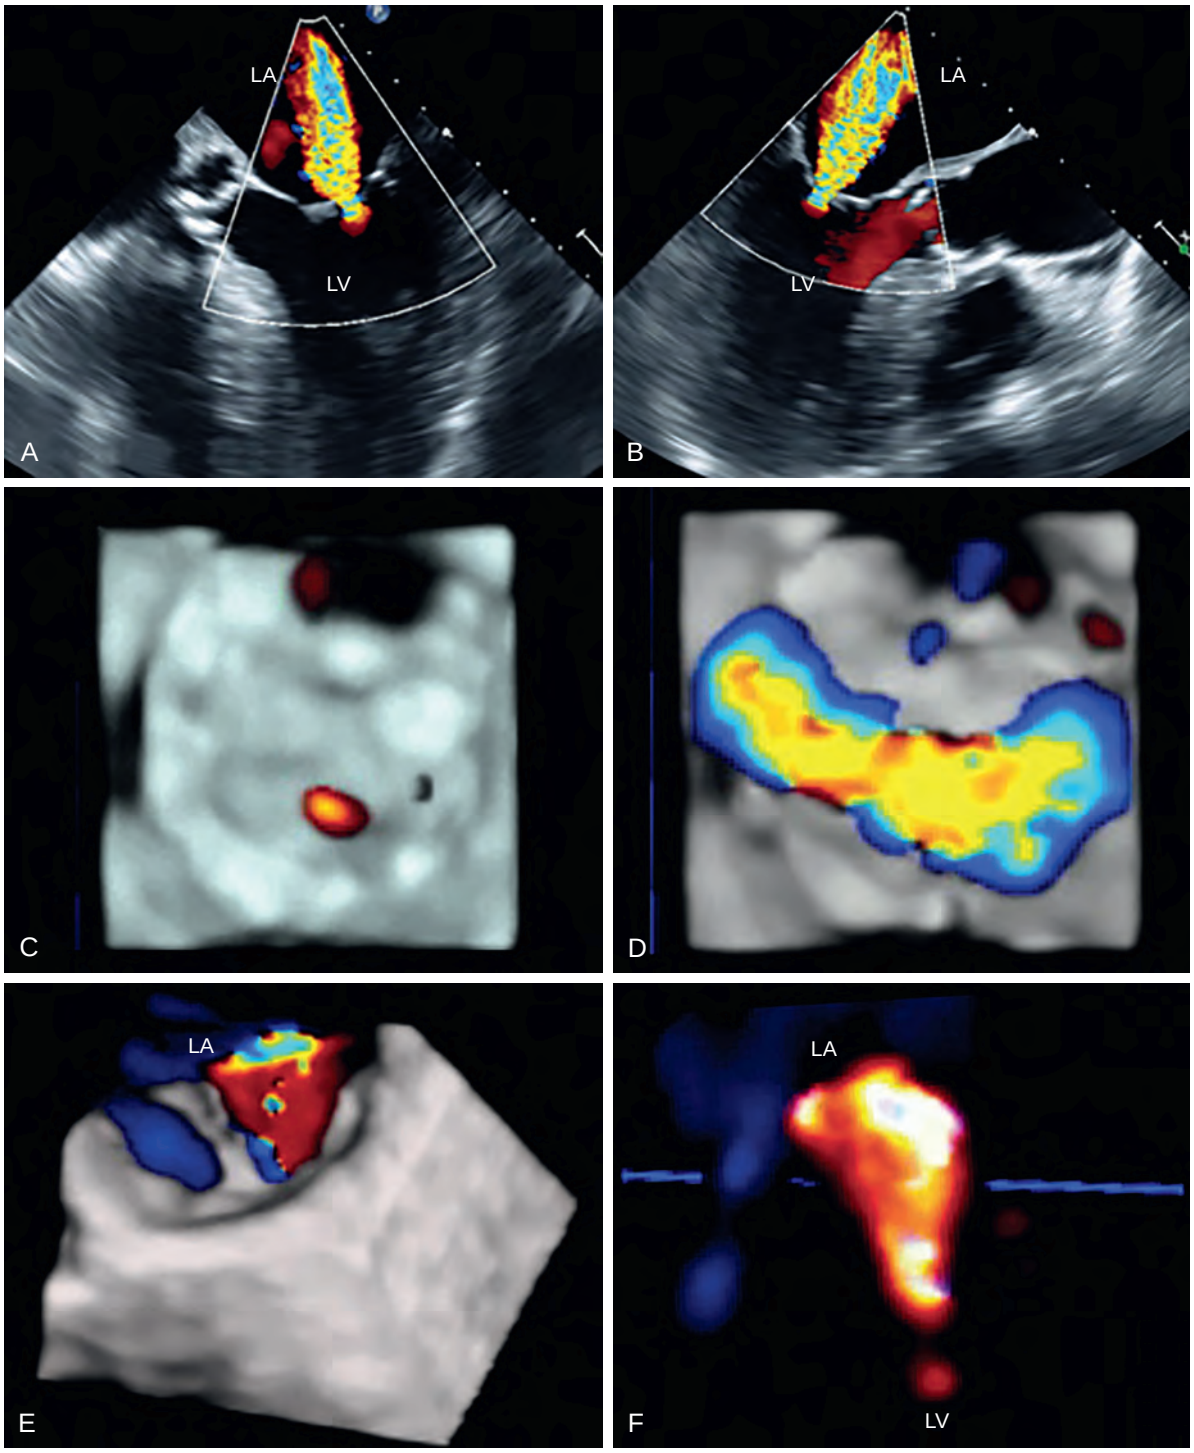

Fig. 15.21 Entrainment of the regurgitant jet. (A) and (B) Centrally regurgitant jet from the mid-esophageal windows. (C) The regurgitant orifice from the left ventricular perspective during systole. (D) Flow during diastole. (E) and (F) Three-dimensional shape of the regurgitant jet on multiple levels as it passes through the regurgitant valve orifice. The jet appears to expand as a result of entrainment. This explains why the vena contracta is a better reflection of the regurgitant orifice than the subsequent jet area, the latter overestimating the regurgitant orifice area due to entrainment. *LA*, Left atrium; *LV*, left ventricle.

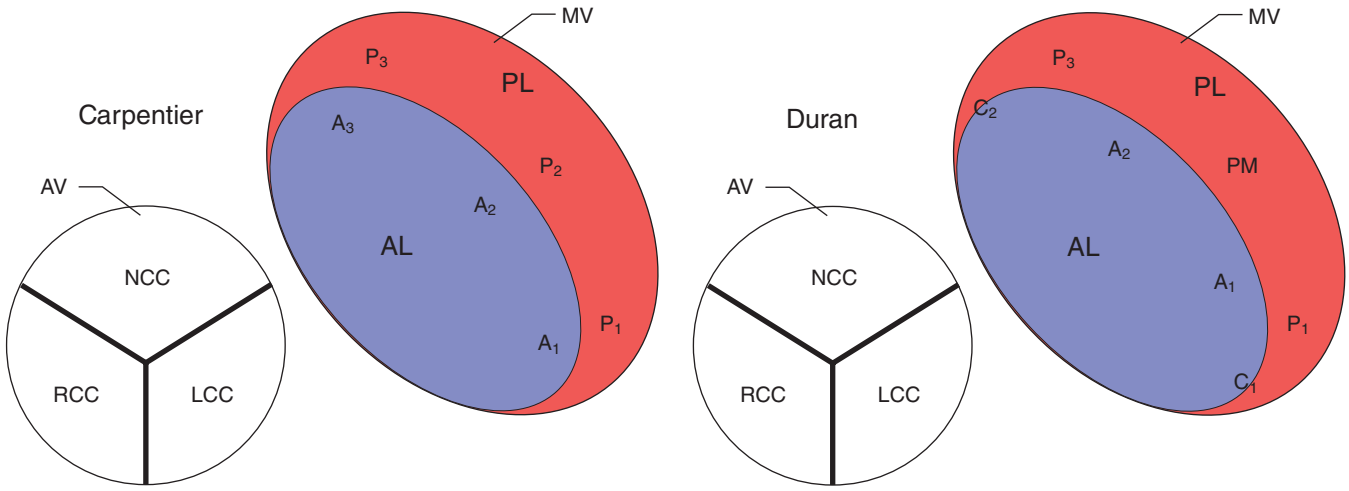

Fig. 15.22 Schematic showing the Carpentier and Duran nomenclatures of the mitral leaflet scallops. Whereas both recognize the posterior leaflet as having three scallops (P_1, P_2, P_3), the Duran labeling distinguishes the anterior leaflet as an anterior lateral section (A_1) and a posteromedial section (A_2) and two commissural areas on the periphery (C_1 and C_2). In contrast, the Carpentier nomenclature identifies three scallops on the anterior leaflet (A_1, A_2, A_3) corresponding to those on the posterior leaflet. *AL,* Anterior leaflet; *AV,* aortic valve; *LA,* left atrium; *LAA,* left atrial appendage; *LCC,* left coronary cusp (of the aortic valve); *LV,* left ventricle; *MV,* mitral valve; *NCC,* noncoronary cusp; *RCC,* right coronary cusp; *PL,* posterior leaflet.

profile on three levels—prevalve, valve, and postvalve—displays the characteristics of flow and the orifice through which blood flows (see Figs. 15.19 through 15.21). The equations apply well to mild and severe defects, but they are less accurate for moderate dysfunction. Although the flow convergence method provides more detail regarding this range of dysfunction, it is now known that inaccuracies exist. The recent advancements in 3D imaging allow a more accurate area measurement using planimetry (see Fig. 15.21), when feasible.

The following sections apply these echocardiographic principles toward assessing valvular function. Similar principles apply across the different valves. As a general fact, validation of analyses is greater for left-sided heart valves than for those on the right side.

Mitral Valve

Normal Anatomic and Functional Features of the Native Valve

The anatomic and functional features of MV have been reviewed extensively (see Chapter 14), and understanding of MV function and failure has contributed to the success of MV repair.[31,32] The normal MV is a thin bileaflet (each <2 mm thick) valve, of which the anterior and posterior leaflets insert into their respective annuli. Each of the leaflets is divided into segments or scallops, which have been defined by Carpentier and Duran (Fig. 15.22).[33–38] Both investigators describe the posterior leaflet as having three scallops or segments; anterolateral and superior (P_1), middle (P_2), and posteromedial and inferior (P_3). Duran divides the anterior leaflet into two larger segments (anterior [A_1] and posterior [A_2]) and two smaller commissural segments (C_1 and C_2). By contrast, Carpentier describes the anterior leaflet with relation to the posterior leaflet; A_1, A_2, and A_3 lying in the same respective planes. Although the posterior annulus covers two-thirds of the annular circumference, the posterior leaflet covers one-third of the coapting area, while the anterior leaflet is responsible for two-thirds of this space (see Fig. 15.22). Functionally, it appears that the posterior leaflet provides a coapting surface for the larger anterior leaflet. During coaptation the leaflets overlap by at least 6 mm and the base of the coaptation point lies within 6 mm of the annular plane but not above it. The importance of the leaflet heights or lengths and coaptation point is seen in their effect on blood flow direction into and out of the left ventricle.[39–42] During ventricular diastole the anterior leaflet is concave to the left atrium, directing blood flow toward the ventricular apex along the posterolateral wall (Fig. 15.23). Subsequently, before and during ventricular contraction, blood flow is directed toward the left ventricular outflow tract (LVOT) along the anteroseptal wall. During this latter time period the anterior leaflet is convex toward the left atrium enlarging the LVOT just before and during systolic ejection. This pattern of blood flow sets up a vortex with energy that drives flow up and toward the AV with minimal interference and maximum efficiency (see Fig. 15.23). Other anatomies or configurations or flow directions are less efficient.

The chordae connect the mitral leaflets to the two papillary muscles (anterolateral and posteromedial) and ventricular walls, and create important interactions between the mitral apparatus and the ventricular myocardium (Fig. 15.24). The anterolateral papillary muscles connect to the more anterior and lateral portions of each leaflet and the posteromedial papillary muscle connects to the more posterior and medial portions. The primary purpose is to prevent leaflet prolapse or flail by creating tension during papillary muscle contraction (ie, ventricular systole). There are multiple types of chordae. While the primary chordae prevent prolapse, other secondary, tertiary, and quaternary chords connect areas of the mitral leaflets to the ventricular walls. These chordae help maintain both function and shape of the ventricle.

The normal mitral annulus is a 3D saddle-shaped dynamic structure (Fig. 15.25).[39,43] Its shape and position change throughout the cardiac cycle to optimize forward flow into the ventricle, prevent regurgitant flow, and accommodate ventricular systolic outflow. During diastole the mitral annulus is more planar and forward toward the ventricular cavity opening up wide and directing flow toward the posterolateral ventricular wall creating a vortex and vortical forces, resulting in flow toward the apex and then anteroseptal toward the LVOT prior to systolic ejection. In conjunction with the end of diastole and onset of systole, the mitral annulus contracts posterolaterally toward the membranous portion and superiorly toward the atrium, both actions increasing size of the LVOT, increasing its reservoir capacity prior to ejection, and minimizing interactions between systolic outflow and the mitral leaflets.

Prosthetic or Repaired Mitral Valve

It is important to know the details of the surgical procedure including what kind of valve was placed or how the valve was repaired. Previous

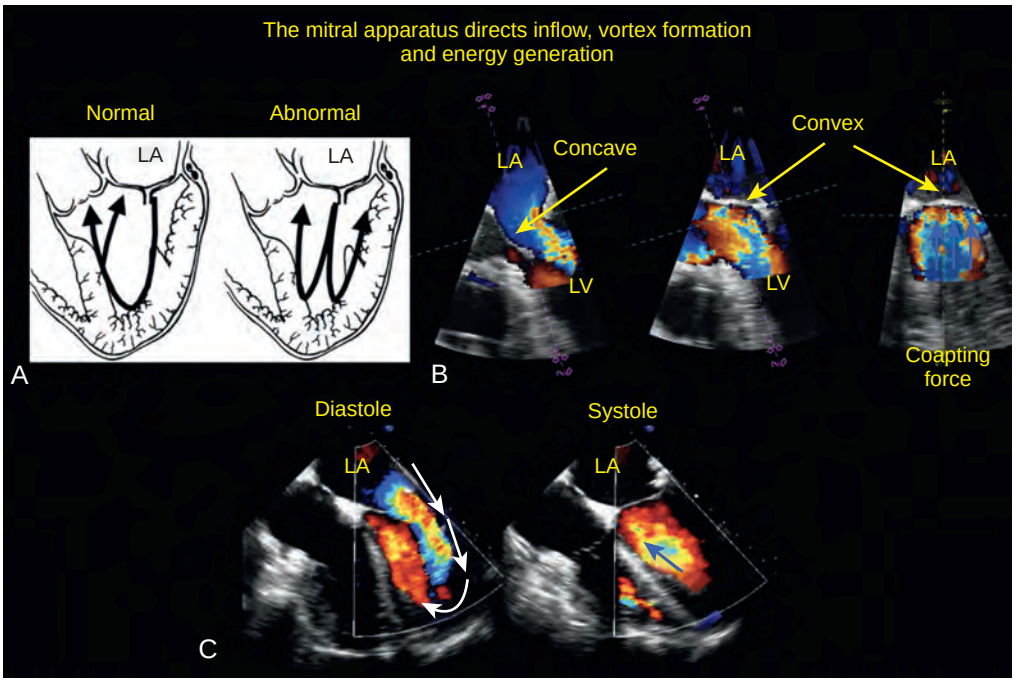

Fig. 15.23 Flow directions of transmitral and intracavitary flows. (A) Schematic showing normal and abnormal patterns. The normal pattern consists of transmitral flow directed toward the left ventricular apex along the posterolateral wall, which is followed by flow directed toward the left ventricular outflow tract along the anterior and anteroseptal walls. This normal pattern is associated with the development of normal flow vortexes, which creates energy, all contributing toward more efficient flow, which minimizes the chance of systolic outflow interacting with slack mitral leaflet portions, thereby increasing the risk of systolic anterior motion (SAM). By contrast, the abnormal flow patterns create less energy and are less efficient. Furthermore, its flow directions have potential implications when the different flows potentially interact with slack mitral leaflets and increase the chance of SAM. (B) and (C) Movement of the anterior leaflet and how it directs blood flow into the left ventricle. Normal changes in the mitral leaflets create normal flow patterns resulting in normal flow configurations. *LA,* Left atrium; *LV,* left ventricle.

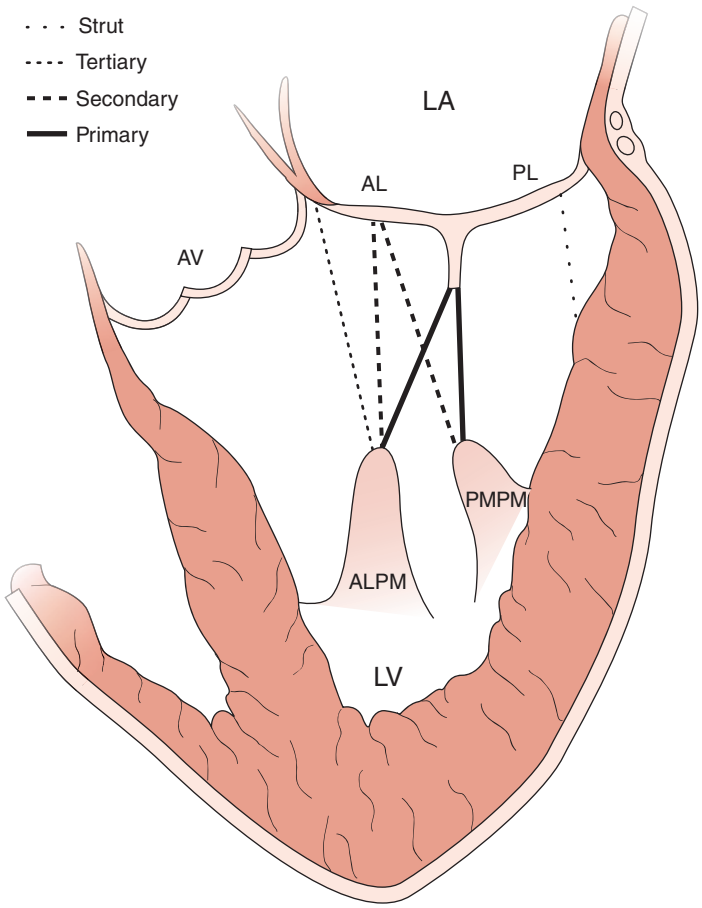

Fig. 15.24 Chordal anatomy. Schematic shows the four main categories of chordae tendineae that allow the mitral valve to function normally, which includes its affect on left ventricular shape and function. The primary chords are responsible for normal coaptation. The secondary chords associated with the tethering phenomenon seen during left ventricular remodeling have been a target of repair (cutting) for type IIIb mitral regurgitation. The tertiary chords attach from the papillary muscle to the base of the anterior leaflet, while the strut chords connect that base of the posterior leaflet to the posterolateral left ventricular wall. *AL,* Anterior leaflet; *ALPM,* anterolateral papillary muscle; *AV,* aortic valve; *LA,* left atrium; *LAA,* left atrial appendage; *LV,* left ventricle; *PL,* posterior leaflet; *PMPM,* posteromedial papillary muscle.

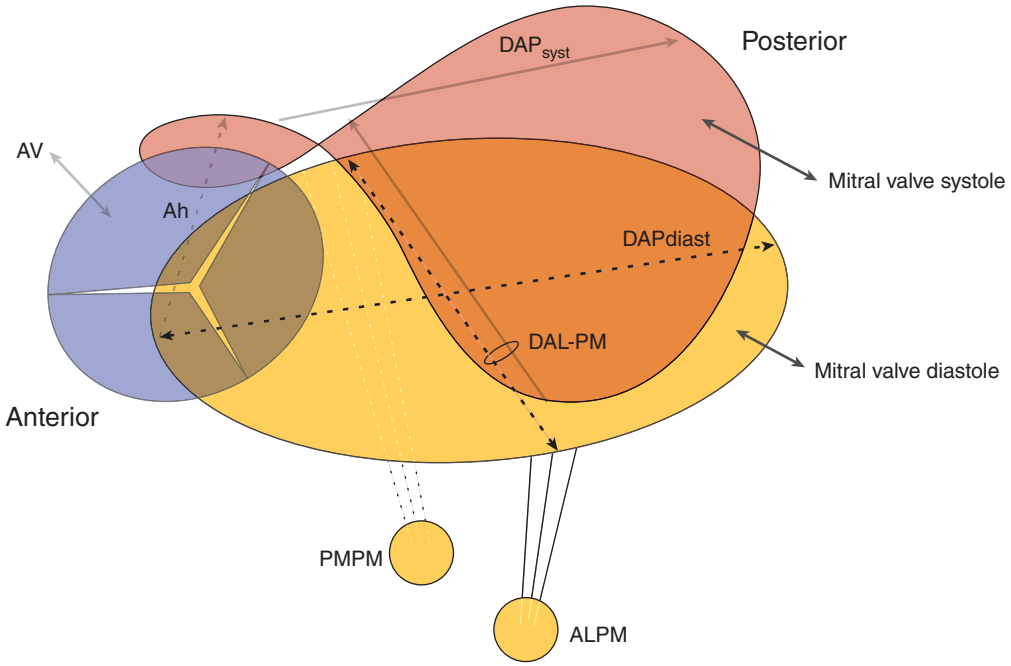

Fig. 15.25 Annular changes. Schematic shows three measures of the mitral annulus and how they change during the cardiac cycle. The *black dashed arrows* represent the annular dimensions at end-diastole. During ventricular systole the anteroposterior distance (DAPsyst) decreases and moves laterally (ie, away from the left ventricular outflow tract [LVOT]). The intercommissural line (DAL-PM) decreases and moves posterior. The annular height increases and moves the anterior portion of the annulus away from the LVOT. Altogether, the mitral annular area declines during ventricular systole, and moves away from the LVOT to allow for unhindered systolic outflow. *Ah,* Annular height; *ALPM,* anterolateral papillary muscle; *AV,* aortic valve; *DAP,* anterior posterior diameter; *diast,* diastole; *PMPM,* posteromedial papillary muscle; *syst,* systole.

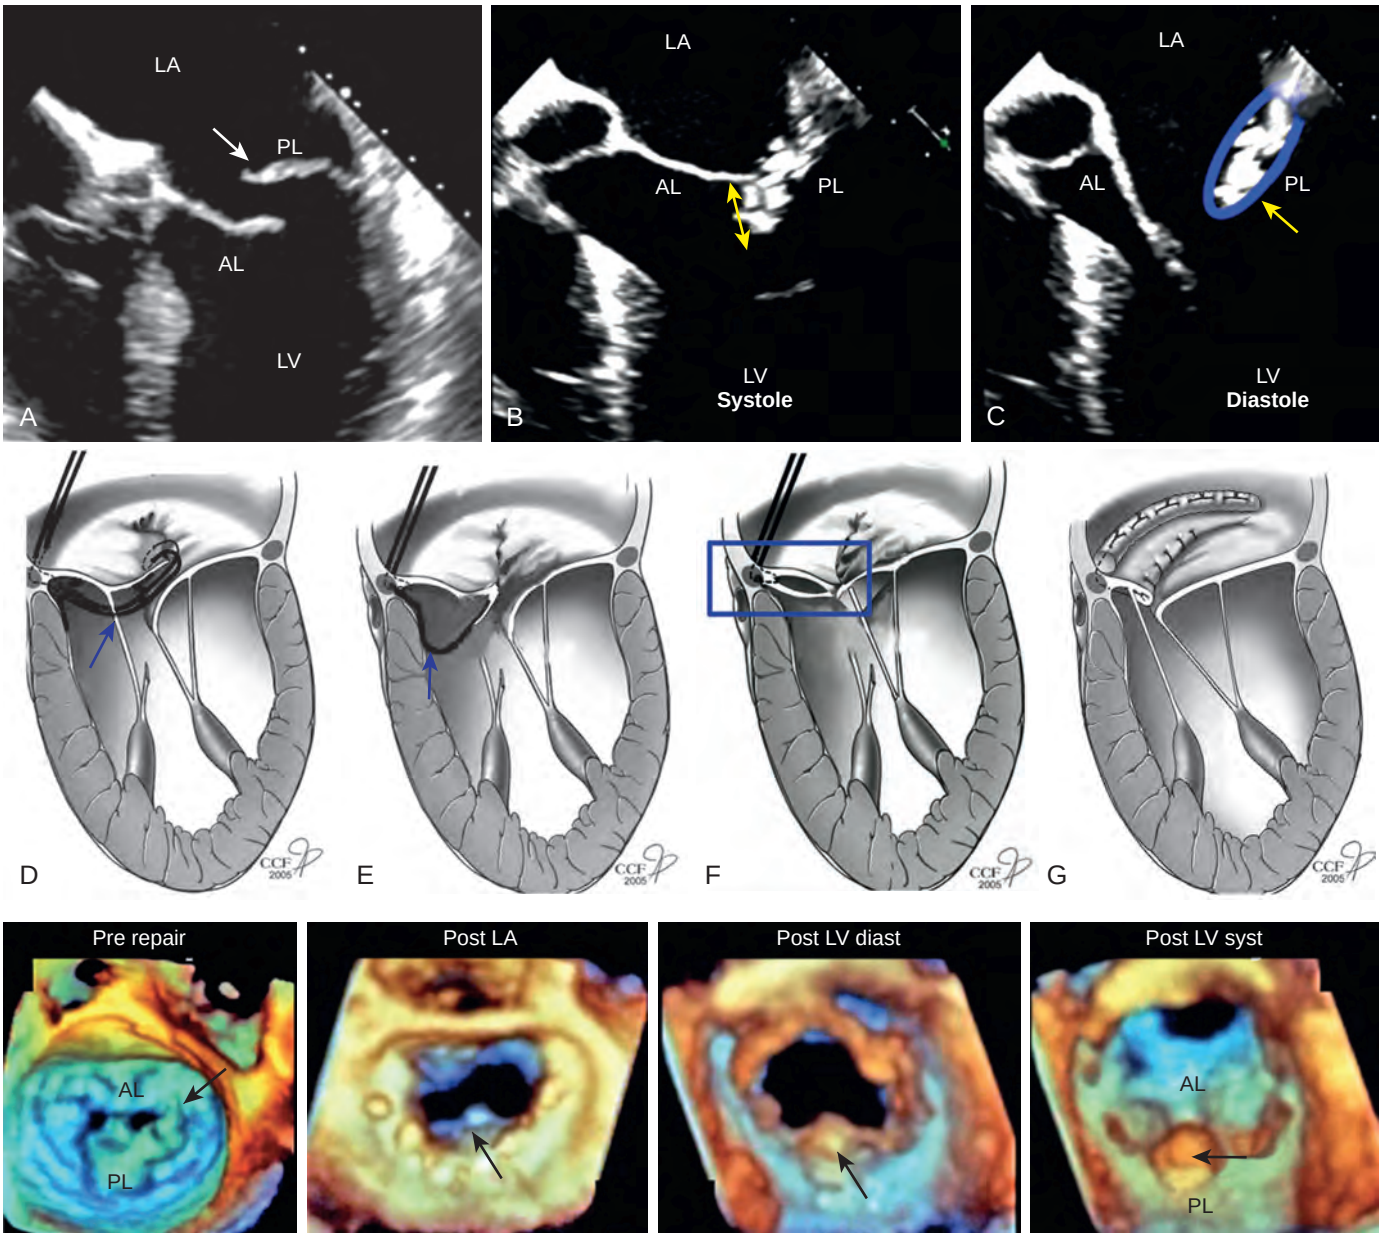

Fig. 15.26 Before and after valve repair. The folding leaflet plasty is a repair technique that reduces posterior leaflet *(PL)* height without resecting the leaflet. Suture is placed on the edge of the prolapsing scallop, passed below (left ventricle [*LV*] side) the leaflet and then through the respective annular segment. The leaflet is pulled down and folded over itself to produce a significant coapting surface for the anterior leaflet. (A) Patient with a flail PL. (B) and (C) Same patient postrepair image obtained during LV systole *(syst)* and diastole *(diast)*, respectively. (B) shows the coaptation zone *(yellow arrow)* created by the folding plasty, which can be seen in (C) *(blue surround* that is pointed to by the *yellow arrow)*. (D) and (E) Path of repair suture *(blue arrow)*, until (F) leaflet is folded *(blue box)*. (G) Annuloplasty ring supporting the repair. The lower series of images are three-dimensional views of the repair. The *black arrow* in the first image on the left shows the flail PL and torn chord *(thin black arrow)*, while the next three show the repair with the folded PL highlighted by the *black arrows*. *AL*, Anterior leaflet; *LA*, left atrium.

knowledge of normal echocardiographic findings for specific valves and/or successfully repaired valves helps delineate what is normal and what is not. Details include whether or not a bioprosthetic or mechanical valve was placed, and what kind and how many leaflets. For valve repairs, information regarding annulus type (flat vs saddle shaped, full vs partial), and leaflet resection, repair, or augmentation helps echocardiographers understand what they see during imaging.[21,31,32,44]

The repaired valve relies mostly on a normally mobile anterior leaflet that is adequate in size to cover the coapting surface (Figs. 15.26 and 15.27).[31,32] The primary role of the posterior leaflet is to provide a coapting surface for the anterior leaflet. Typically, the anterior leaflet in a patient with MV disease is minimally resected but otherwise repaired, whereas the posterior leaflet is often resected. Variations include repair or folding of the posterior leaflet to provide a larger coapting surface and a larger valve area (see Figs. 15.26 and 15.27). The Alfieri repair is an alternative repair procedure that reduces or prevents prolapse.[45–47] It is classically performed centrally, resulting in a figure-of-eight opening; however, it may also be performed peripherally along the commissures to form a dual figure-of-eight orifice in diastole (Fig. 15.28). For all echocardiographic assessments, recording

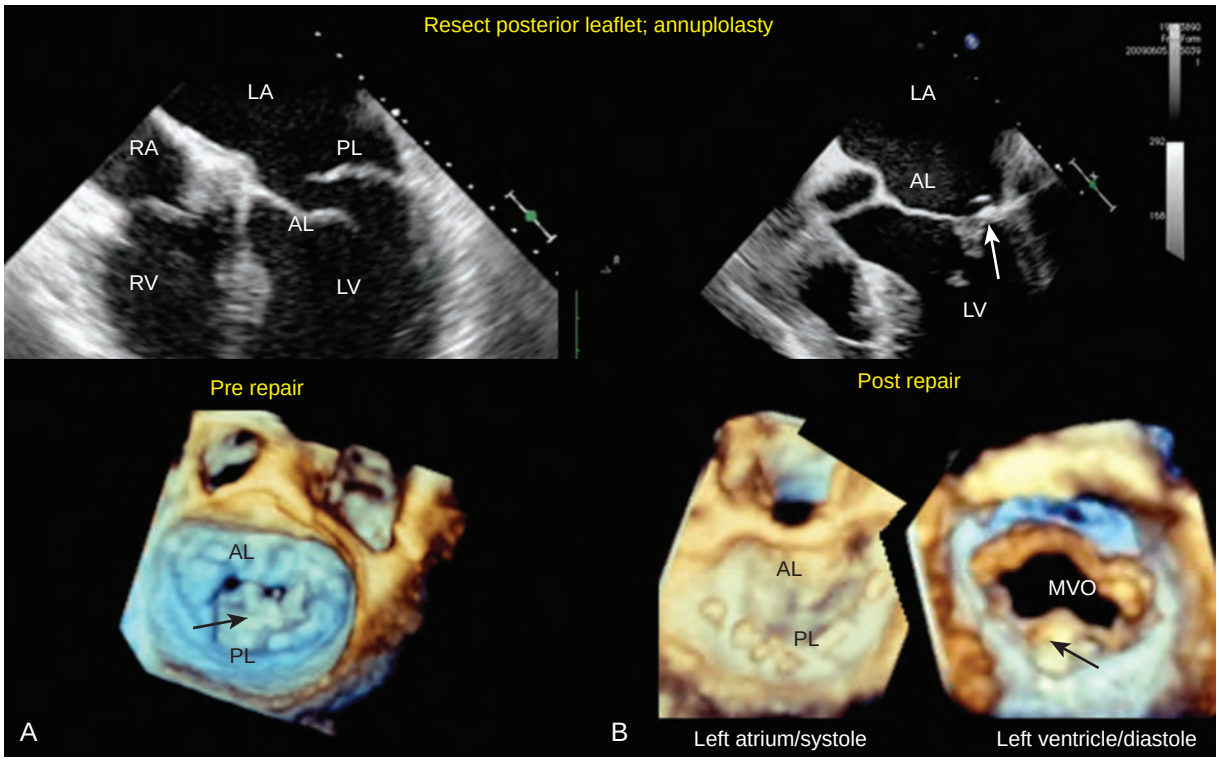

Fig. 15.27 Before and after mitral valve repair. (A) In the prerepair period, the posterior leaflet *(PL)* is seen as flail. The three-dimensional image similarly shows the flail scallop *(arrow),* which in this case, is the middle scallop of the posterior leaflet (P_2) with two torn chordae. (B) The repaired valve is mostly dependent on the anterior leaflet *(AL)* to cover the coating surface, while the PL covers a smaller portion of the coapting area but also provides a coapting surface for the larger and more mobile anterior leaflet *(arrow). LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

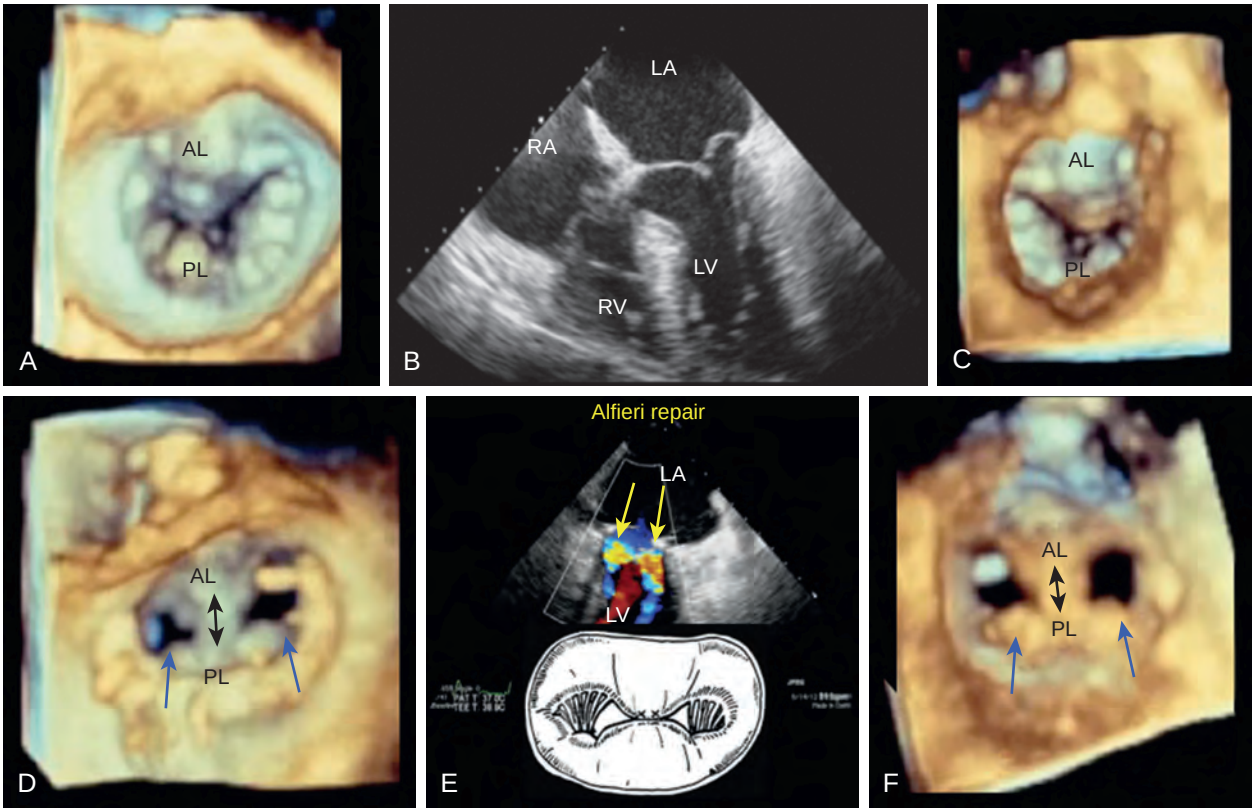

Fig. 15.28 Alfieri repair. (A) and (B) The case of a bileaflet prolapse or myxomatous disease is used to demonstrate the Alfieri repair, in which a running suture (*small black arrow* in [D] and [F] and middle schematic [E]) is classically placed centrally but may also be placed peripherally. The centrally placed suture creates a figure-of-eight orifice as compared to (A–C) the single orifice. (D–F) After Alfieri repair. Three-dimensional views from (D) the left atrial and (F) ventricular perspectives show a figure-of-eight orifice. (E) Two-dimensional image shows the color Doppler display of two separate jets.

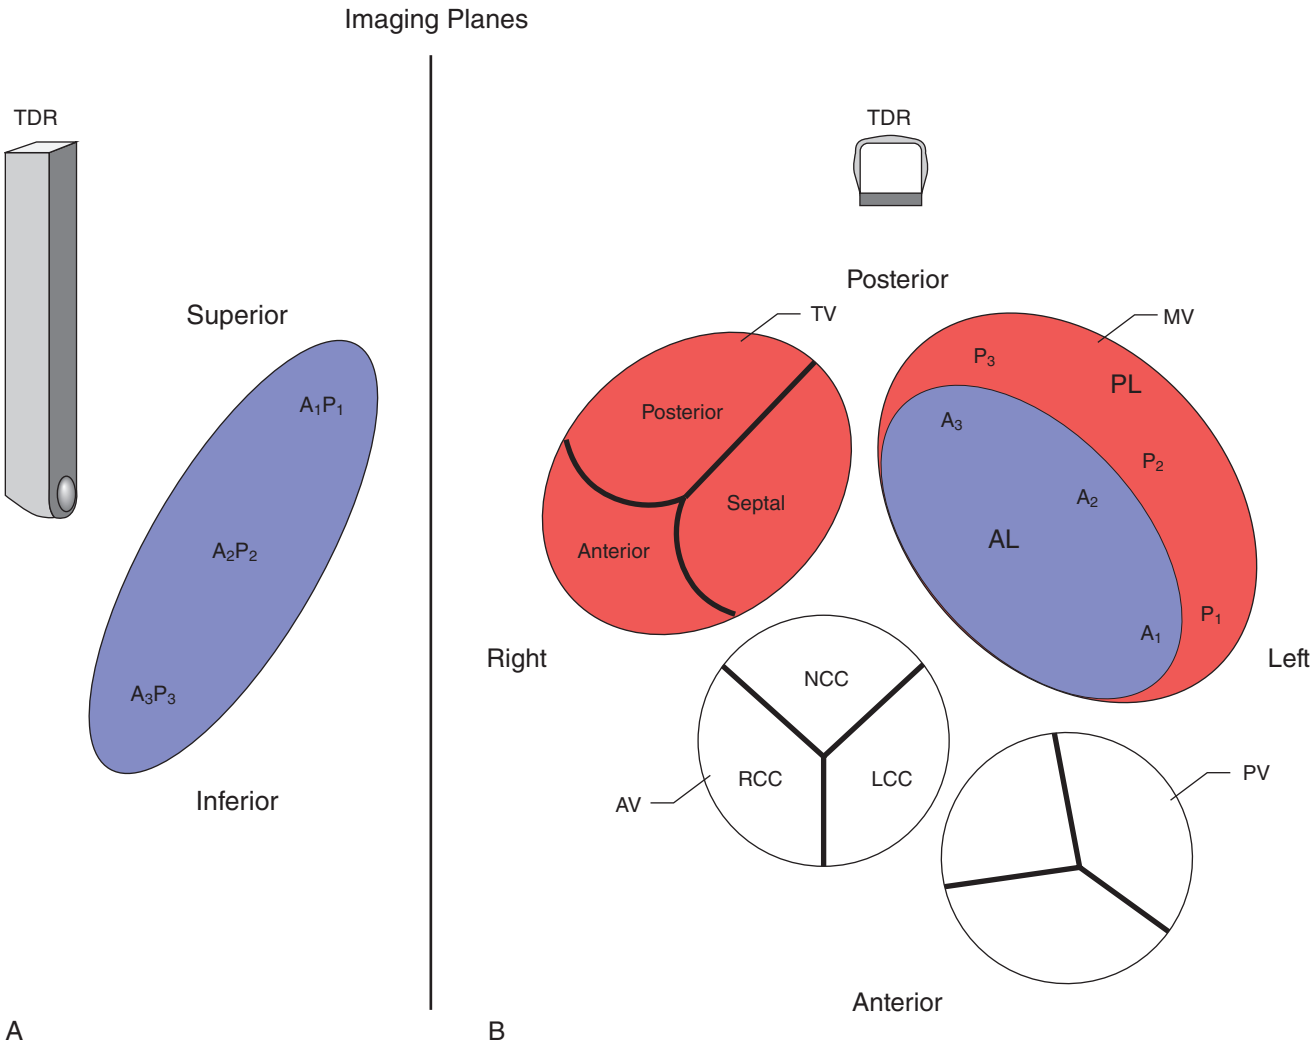

Fig. 15.29 Imaging planes. Schematics showing the vertical (A) and horizontal (B) position of the mitral valve, the latter in relation to other surrounding structures and as would be seen by the transducer positions. *A_1, A_2, A_3,* Anterior leaflet scallops; *AL,* anterior leaflet; *AV,* aortic valve; *LA,* left atrium; *LAA,* left atrial appendage; *LCC,* left coronary cusp (of the aortic valve); *LV,* left ventricle; *NCC,* noncoronary cusp; *P_1, P_2, P_3,* posterior leaflet scallops; *PL,* posterior leaflet; *PV,* pulmonary valve; *RCC,* right coronary cusp; *TDR,* transducer; *TV,* tricuspid valve.

of the patient's hemodynamic status improves the perspective at the time of evaluation.

The Echocardiographic Examination

The 2D and Doppler examinations are accomplished from a number of echocardiographic windows, with emphasis on mid-esophageal (ME) windows (0–150 degrees), to analyze the native valve before and after repair and/or the prosthetic MV (Figs. 15.28 through 15.31).[21,22,31–33] Although transgastric (TG) views may complement imaging of the valve, it may be more useful to visualize the LVOT as well as the subvalvular apparatus (see Figs. 15.31 through 15.33).

Evaluation is made of leaflet mobility (normal, excessive, restrictive), thickness, and any associated mobile structures, the latter of which may represent suture materials; fractured calcium deposits; and retained chordae or leaflet or endocarditis. Imaging of the subvalvular apparatus identifies thickening or suspected calcification, mobility or flail of the chordae and/or papillary muscles. The valve should appear stable and secured in the surrounding tissues. Echocardiographic lucency of the surrounding tissues may suggest infection or abscess, dehiscence, or rupture (Fig. 15.34).

For mechanical prosthetic valves, imaging perpendicular to the leaflets allows seeing the opening and closing of the leaflet edges while parallel imaging facilitates viewing of signature regurgitant jets. Viewing from multiple windows improves the completeness of the examination and the diagnostic abilities (Figs. 15.14, 15.17, 15.35–15.38). Additional concerns regarding bioprosthetic valves are positioning of the struts or, more specifically, if they lay near or in the LVOT, potentially causing obstruction to systolic outflow (Fig. 15.39).

The Doppler examination assesses, both qualitatively and quantitatively, the presence, direction, and width of normal and abnormal blood flows of the native, prosthetic, and repaired valves. Imaging from multiple windows improves the assessment and ability to differentiate between normal and abnormal forward and regurgitant jets. The ME windows offer the best proximity of the valve to the transducer and of alignment between blood flow and the ultrasound beam. Although qualitative CFD assessments may suggest high velocities based on the presence of aliasing (turbulence), this may or may not indicate abnormal flow. Further quantitative analysis should be performed to clarify the flow.

Different prosthetic valves have signature flow profiles.[21,28] Bioprosthetic valves allow a large central forward flow and, for some

Lower panel shows three-dimensional images from the left ventricular and atrial perspectives during diastole and systole. *Asc Ao,* Ascending aorta; *LA,* left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

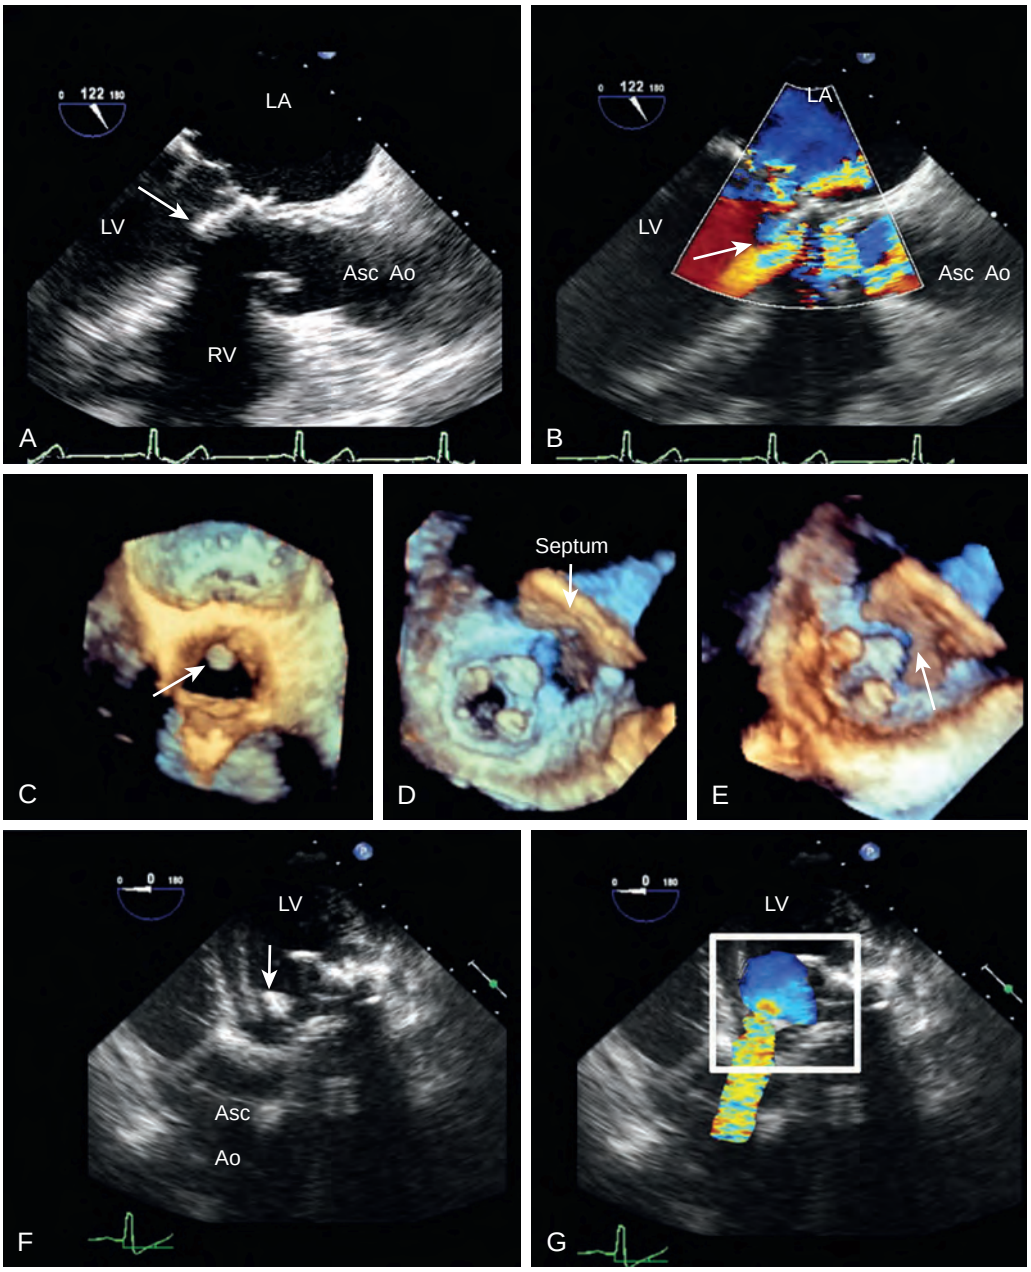

Fig. 15.39 Imaging of the bioprosthetic mitral valve in relation to the left ventricular outflow tract (LVOT). (A) Two-dimensional (2D) and (B) color Doppler midesophageal long-axis views, showing the strut *(arrow)* of a bioprosthetic valve in close proximity to the LVOT. The color Doppler image shows turbulence *(black arrow)* in the LVOT. Three-dimensional views from (C) the aortic side of the aortic valve and from the LV perspective in (D) diastole and (E) systole. (D) shows a circular appearing echo density *(arrow)* on the LVOT side This is the tip of the more anterior prosthetic strut in close proximity to the LVOT. (E) During systole the anterior strut *(arrow)* of the bioprosthetic valve is in close proximity to the ventricular septum. (F) 2D and (G) color Doppler images from transgastric windows, showing both proximity of the strut *(arrow)* to the LVOT and color Doppler turbulence at this site. (G) The narrowing is significant enough to create flow convergence *(white box)*. *Asc Ao,* Ascending aorta; *LA,* left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

TABLE 15.4 Mitral Regurgitation: Degrees of Severity

	Mild	*Moderate*	*Severe*
Angiographic grade	1+	2+	3–4+
Color Doppler jet area (cm^2)	<4 or <25% of LA area		>7 or >50% of LA area
Vena contracta width (cm)	<0.3	0.3–0.69	>0.7
Regurgitant orifice area (cm^2)[a]	<0.20	0.20–0.49	≥0.50
Regurgitant volume (mL)[a]	<30	30–60	>60
Regurgitant fraction (%)[a]	<30	30–50	>50
Pulmonary venous flow	Systolic dominance	Systolic blunting	Systolic flow reversal
Secondary findings	LAE, LVE, LVSD, PHTN		

[a]Measured with proximal isovelocity surface area.
LA, Left atrium; *LAE,* left atrial enlargement; *LVE,* left ventricular enlargement; *LVSD,* left ventricular systolic dysfunction; *PHTN,* pulmonary hypertension.

prostheses, a small central regurgitant jet (see Figs. 15.35 through 15.38). A single tilting disk or bileaflet mechanical valve consists of two or three forward jets and signature regurgitant jets (see Fig. 15.38). Single-leaflet valves typically display one or two small regurgitant jets (one significantly larger than the other) directed centrally. Bileaflet mechanical valves have two centrally directed equal regurgitant jets.

Flow across the repaired valve depends on the repair technique. Typically a large singular jet directed toward the posterior and lateral walls toward the apex followed by flow toward the LVOT along the anterior and septal wall is seen, which is not dissimilar to the normal native valve (see Fig. 15.23). Any other flow pattern may increase risk of systolic anterior motion. Alternatively, a central Alfieri repair, which results in a figure-of-eight orifice, provides two forward moving jets of flow (see Fig. 15.28).

Mitral Regurgitation

Normal native mild MR occurs in up to 75% of patients without clear dysfunction or abnormality of the mitral apparatus, and is, therefore, considered normal. Abnormal MR occurs as a result of dysfunction of one or more of the components of the mitral apparatus (Table 15.4). MR can be grouped into three types: those with normal leaflet mobility (type 1) (see Fig. 14.87; Video 14.64), those with excessive leaflet mobility (type 2) (see Fig. 14.83; Video 14.61), or those with restrictive leaflet mobility (type 3).[31,32,37,38] The latter group can be further distinguished based on the timing of the cardiac cycle to which leaflet mobility is impaired. Type 3a involves restriction during the diastolic phase or during both systole and diastole as seen in rheumatic disease with involvement of leaflet and chordae (see Fig. 14.84; Video 14.62). Type 3b involves restriction during the systolic phase of the cardiac cycle as seen in patients with functional MR as a result of either myocardial ischemia/infarction or cardiomyopathy during which tethering and/or remodeling has occurred (see Fig. 14.85; Video 14.63). The types of MR are summarized in Fig. 14.86.

Type 1 MR can be seen in the presence of annular dilation or leaflet perforation. In the former, the annulus is more likely to dilate along the posterior and lateral annular areas as these are mostly muscle and membranous tissues. As the annulus dilates (>4.0 cm), it becomes more circular and flatter. The regurgitant jet may be centrally or eccentrically directed. The greater the amount of annular dysfunction, the less likely that valve repair will provide long-term freedom from valve replacement. Leaflet perforation occurs in the presence of endocarditis and is more commonly found on the anterior leaflet.

For type 2 MR the leaflets are described by their systolic excursion relative to the annular plane. Prolapse is defined as a greater than 2-mm excursion above the annular plane with the leaflet tip pointing down. Flail is similarly described except with the leaflet tip pointing above the annular plane. Excessive leaflet mobility is often accompanied by redundant or torn chordae or, in the case of myocardial infarction (MI) or trauma, a torn or ruptured papillary muscle. Regurgitation caused by degenerative or myxomatous mitral disease is associated with either prolapse or flail of an isolated scallop or multiple scallops involving one or both leaflets. Excess mobility may result from redundant or torn chordae to leaflet thickening (ie, myxomatous changes). Most commonly, the posterior leaflet is involved with the middle scallop (P_2) being involved in more than 40% to 50% of the cases.[35,48–50] Next in incidence, the middle scallop of the anterior leaflet (A_2) is involved. Both leaflets are involved in up to 40% of cases. The delineation of the scallops is very important in determining the appropriate surgical procedure and whether or not a repair is feasible.

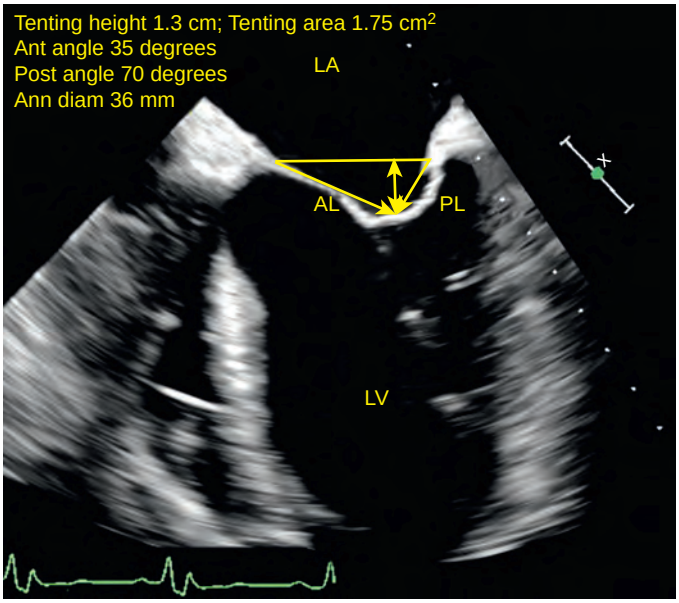

Fig. 15.40 Annular and leaflet measurements. A single view from the midesophageal window allows measurements of tethering and leaflet mobility and excursion. In this case, significant tethering has occurred as denoted by a tethering height greater than 1.0 cm, a tethering area greater than 1.6 cm^2, and a posterior angle greater than 60 degrees. *AL,* Anterior leaflet; *LA,* left atrium; *LV,* left ventricle; *PL,* posterior leaflet.

Type 3b MR seen with dilated cardiomyopathy (DCM) and/or ischemic cardiomyopathy may include normal appearing leaflets; however, reduced systolic return is decreased as a result of tethering.[49] Quantitative assessments help to determine the presence and extent of tethering and may predict outcome after valve repair. These assessments include tethering height and area, and angles of coaptation (Figs. 15.40 and 15.41). Tethering heights greater than 1 cm or tethering areas greater than 1.6 cm^2 are suggestive of severe long-standing changes and greater left ventricular dysfunction, dilation, and remodeling (Figs. 15.41 and 15.42).[51–53] With greater chronicity, leaflet compliance and mobility decline as well. Restriction of abnormal leaflets (type 3a) is seen with rheumatic valves or after radiation therapy. In these cases, the valve leaflets may be thickened, shortened, and/or the subvalvular apparatus (chord and papillary muscle) may be affected. Although rheumatic leaflets (anterior leaflet) may appear like a hockey stick during diastole, this finding is not necessary for the diagnosis to be considered.

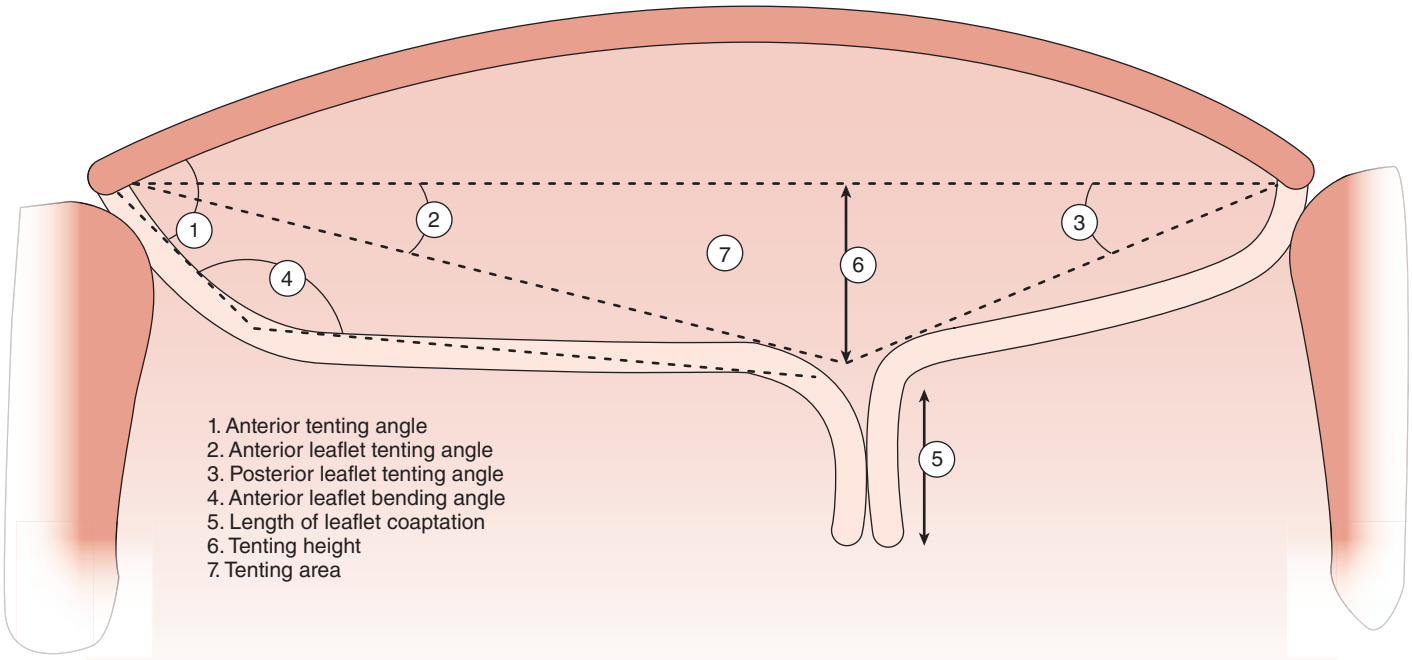

Fig. 15.41 Functional mitral regurgitation (MR): annular measurements. Although these seven annular measurements can be useful for all types of MR, they are particularly relevant for patients with functional MR as they highlight the extent of change in the mitral apparatus resulting from ventricular remodeling. Increases in all measures except for number 5 (coaptation zone/length) result from ventricular remodeling described by apical and lateral displacement of the papillary muscles and resultant tethering of the mitral leaflets. When this happens, the coaptation length or zone decreases in the valve becomes incompetent.

Prosthetic valves are associated with a normal signature of expected regurgitant jets and should be differentiated from abnormal flows (see Figs. 15.17, 15.32, and 15.36 to 15.38).[21,28] Normal or nonproblematic regurgitant jets are less than 3 mm in width and do not extend far from the valve.[54,55] All paravalvular regurgitant jets are considered abnormal. However, regurgitant jets less than 3 mm in width are not likely to pose a long-term problem, especially in the absence of clear disease (Fig. 15.43). Regurgitant jets greater than 3 mm in width and/or are eccentrically directed away from the middle carry a greater risk of MR progression and/or reintervention (Fig. 15.44).[56] These abnormal flows can result from a number of causes, including leaflet restriction or excess mobility, endocarditis, and/or annular dehiscence (Figs. 15.45 to 15.47).[19]

Repair of the MV generally is applied to regurgitant valves.[37,38] Although the goal is to eliminate regurgitation, mild or less is acceptable, while more than mild increases the risk of MR progression and reoperation (see Fig. 15.47). The location and direction of the regurgitant jet depends on the prerepair dysfunction and the repair technique.[31,32,37,38] Determining the cause of MR after repair is essential to decide whether or not additional repair is feasible or if replacement is warranted.

MR can also be described by its acuity. The importance of this distinction is related to the level of compensation or decompensation and clinical presentation. In the acute setting, LA and LV compliance have not adapted; this can result in elevated chamber pressures, which are transmitted backward to the pulmonary vasculature increasing pulmonary vascular pressures, causing pulmonary edema. Ventricular and atrial dilation may not be present. Chronic MR is accompanied by cardiac changes or compensation to allow maintenance of forward flow. Initial compensation includes hypertrophy and dilation of the left ventricle to compensate for MR. Initially, the left ventricle ejects against a lower total resistance as a result of the backward ejection into the low resistance atrial chamber and pulmonary vascular bed. A normal left ventricular ejection fraction (LVEF) in the presence of severe MR is greater than 60%. With continued or worsening MR, dilation becomes more prominent, followed by contractile dysfunction. This is coincident with clinical decompensation. Ultimately, with continued volume overload and increased chamber pressure and stress, LA dysfunction ensues, pulmonary vascular pressures and resistances increase, and, finally, right-sided heart dysfunction occurs. Arrhythmias reflect these cardiac changes and decompensation.

Two-dimensional quantitative analysis of the native valve helps determine outcome for valve procedures.[31,32,34,35,37,38] For regurgitant valves, echocardiographic imaging helps the practitioner predict feasibility and technique of valve repair. For stenotic valves, the examination helps the practitioner determine whether or not valvuloplasty is a viable option.

Measurements guiding valve repair of the regurgitant valve include annular dimensions, leaflet lengths (anterior leaflet, posterior leaflet), coaptation height (tenting height or area), various angles of coaptation, and relations between the leaflets (coaptation) and the ventricular cavity, or specifically, the ventricular septum (see Figs. 15.40 through 15.42, 15.48).[31,32] Data may help the practitioner predict risk of postrepair complications such as SAM and LVOT obstruction (see Fig. 15.48).[57] In general, the more complicated the repair is, the greater is the likelihood of complications and need for reoperation.

Predictors of repair failure differ for patients with functional or ischemic MR versus those with degenerative disease.[31,32,51–53] For all patient types, severe annular dilation (>50 mm) represents prolonged MV dysfunction (ie, end-stage disease) and a greater risk of repair failure. For functional or ischemic MR, the greater the amount of prerepair tethering or remodeling, the more likely that MR will recur (Figs. 15.41, 15.42, and 15.49). These include a tenting height greater than 1.0 cm or area greater than 1.6 cm^2, a posterolateral coaptation angle greater than 45 degrees, inferior and lateral wall motion abnormalities, dilated LV (LV end-diastolic diameter > 65 mm; LV

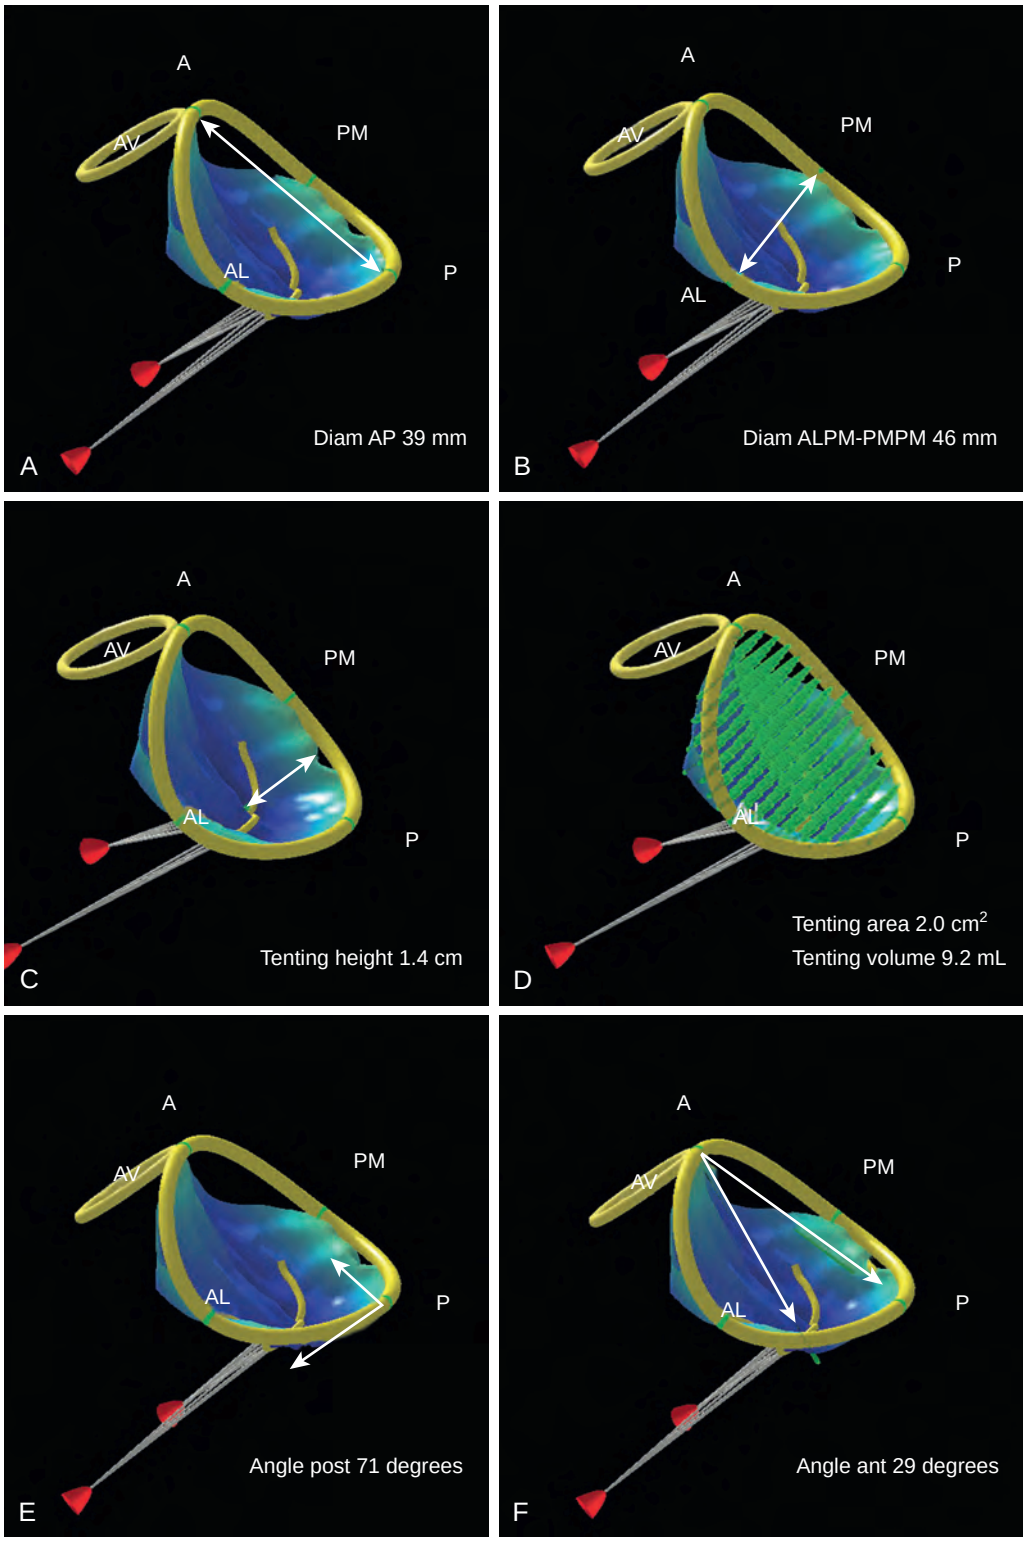

Fig. 15.42 Functional mitral regurgitation QLAB measurements. From the volumetric three-dimensional data set, a number of measurements can be performed using QLAB (Philips Healthcare, Andover, Mass). Measurements that appear in this figure include (A) anteroposterior annular diameter, (B) anterolateral-posteromedial annular diameter, (C) tenting height, (D) tenting area/volume, (E) posterior annular angle, and (F) anterior annular angle. The case depicted in the figure is consistent with severe tethering suggested by the larger annular diameters, a tenting height greater than 1.0 cm, a tenting area greater than 1.6 cm^2, and a posterior annular angle greater than 45 degrees. *A,* Anterior; *AL,* anterolateral; *AV,* aortic valve; *P,* posterior; *PM,* posteromedial.

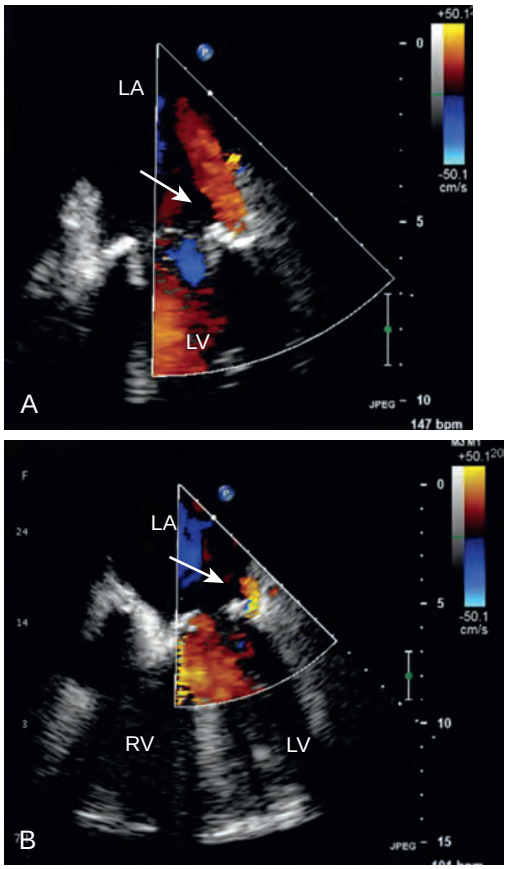

Fig. 15.43 Paravalvular leak after mitral valve replacement. Bioprosthetic valve with a decreasing paravalvular leak (left to right). (A) Jet appears to be nonturbulent or of lower velocity. (B) Color Doppler jet area shows a significant reduction in the regurgitant after administration of protamine. *LA,* left atrium; *LV,* left ventricle; *RV,* right ventricle.

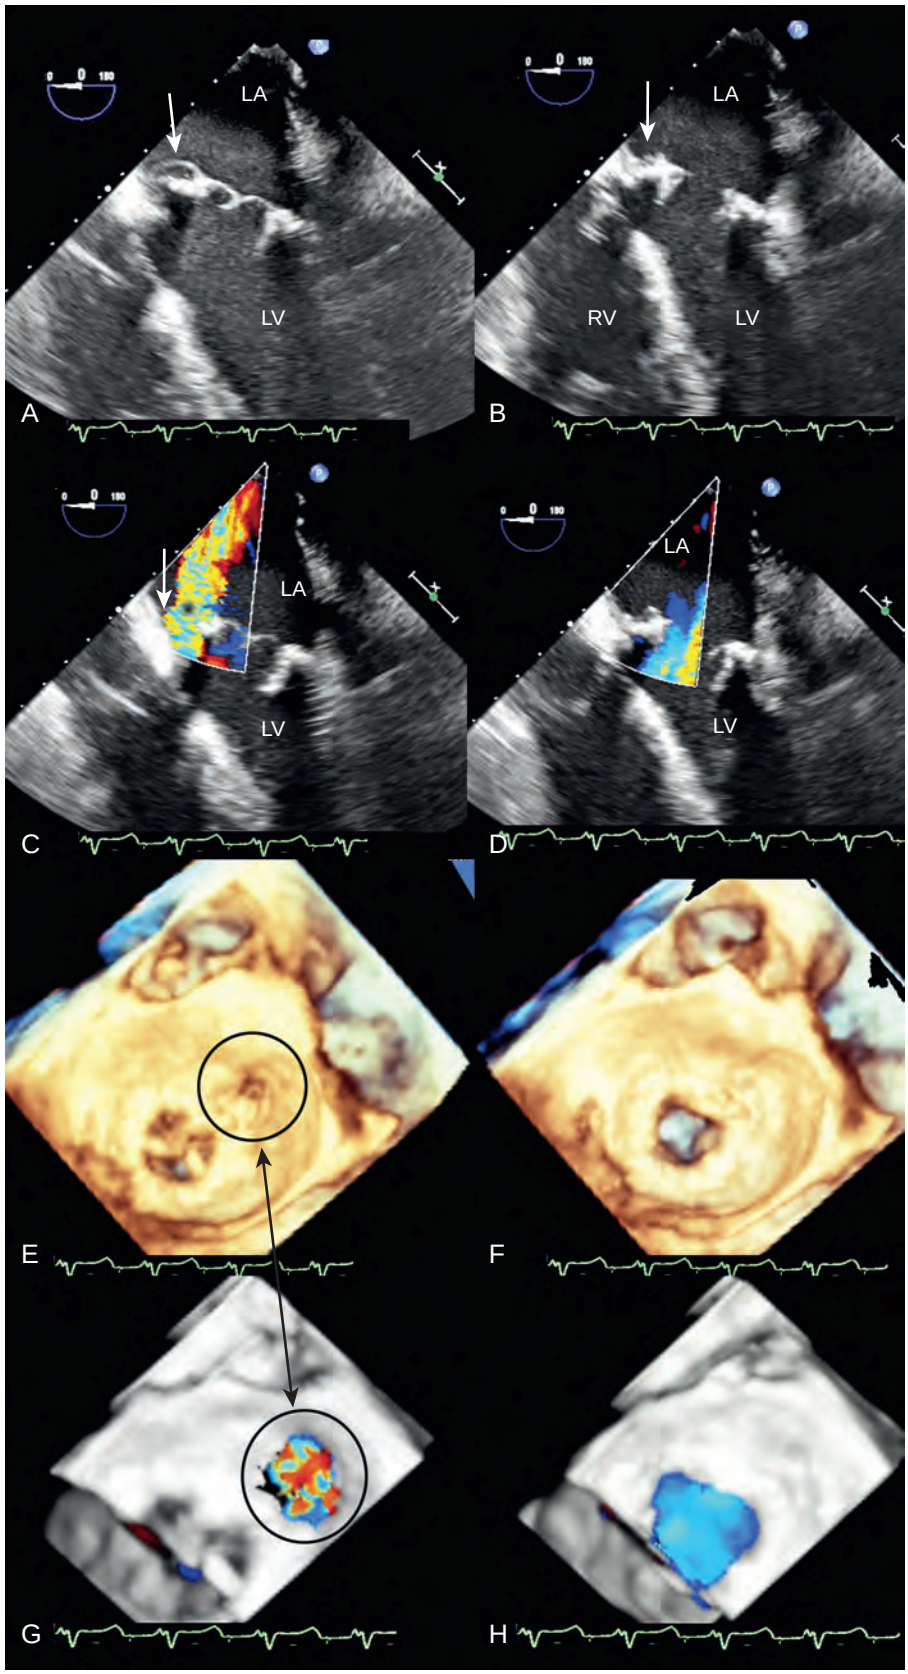

Fig. 15.44 Large paravalvular leak following mitral valve replacement. Large paravalvular regurgitant jet along the septal border *(white and black arrows)* of the prosthetic valve during (A and C) systole and (B and D) diastole. (C) Large jet of regurgitation. (E–H) The defect *(black circle)* is further qualified (and subsequently quantified) in three-dimensional imaging during systole (E) and (F). (F) and (H), obtained during diastole, show that the defect is not seen. *LA,* left atrium; *LV,* left ventricle; *RV,* right ventricle.

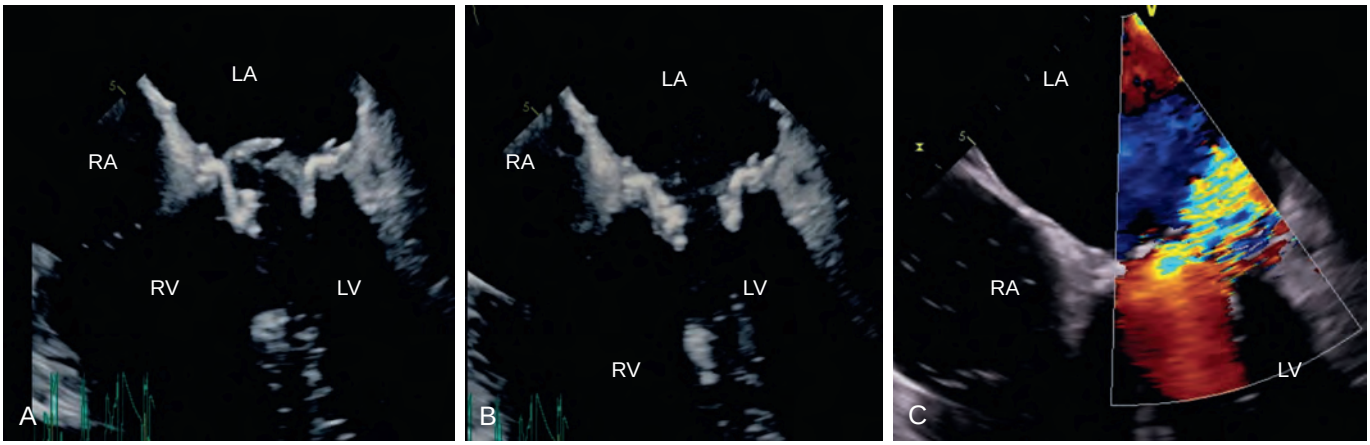

Fig. 15.45 Prosthetic valve endocarditis. (A) and (B) A mobile (above the annular plane) echodensity seen during systole on this bioprosthetic valve is associated with (C) significant mitral regurgitation. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

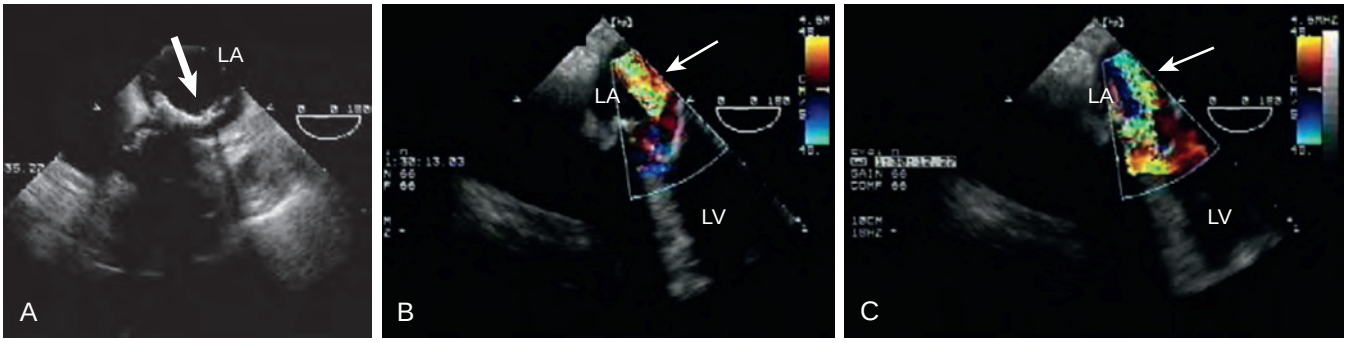

Fig. 15.46 Bioprosthetic valve dehiscence along the posterior mitral annulus. (A) Echo clear *(arrow)* space below the annular prosthesis with advancement of the transesophageal echocardiography probe. (B) and (C) Associated severe mitral regurgitation *(white arrow). LA,* Left atrium; *LV,* left ventricle.

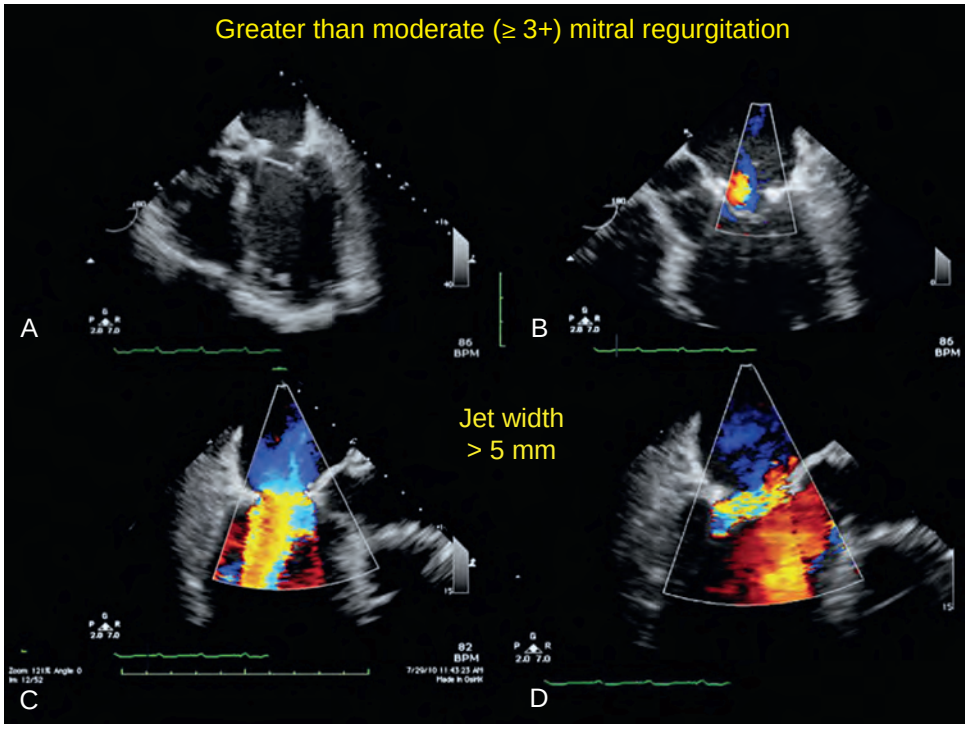

Fig. 15.47 Mitral regurgitation (MR) assessment immediately after mitral valve repair. (A) and (B) Leaflets are seen in the closed position with (B) a mild amount of MR. (C) and (D) Follow-up shows (D) a significant amount of MR defined by a jet width greater than 5 mm.

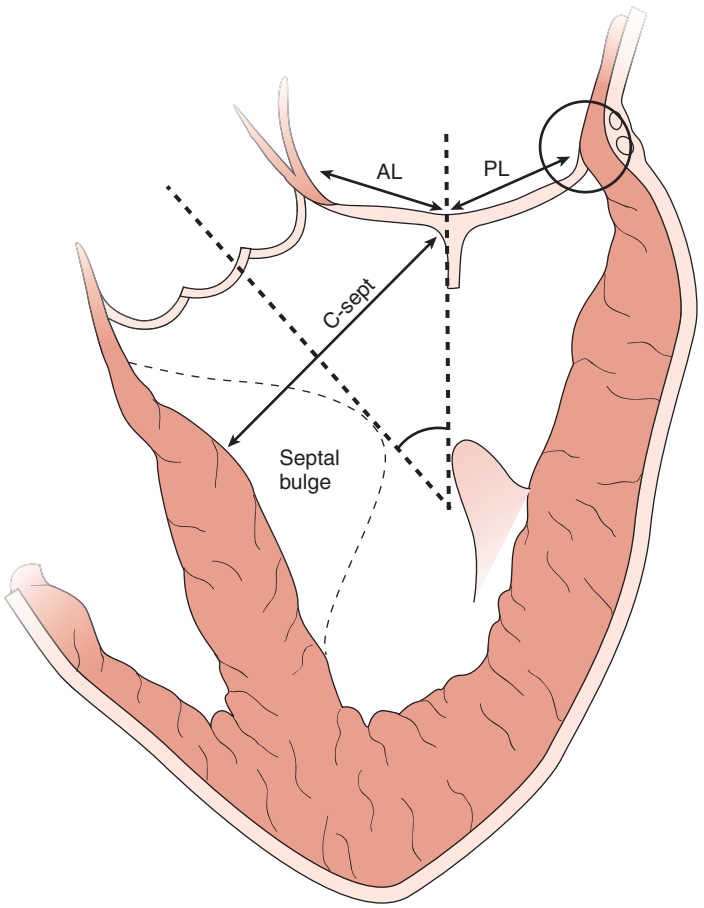

Fig. 15.48 Predictors of systolic anterior motion (SAM). While a greater number of predictors of SAM have been described, the schematic highlights six that seem to be more commonly encountered and/or described. The ratio and heights of the anterior *(AL)* and posterior *(PL)* leaflets contribute toward a greater amount of slack leaflet portions in closer proximity to the left ventricular outflow tract (LVOT). This may also be seen as a shorter distance between the coaptation point and the ventricular septum *(C-sept)*. The presence of a prominent septal bulge also narrows the LVOT, which brings the mitral leaflets closer and/or creates higher jet velocity, which might create a venturi effect to drag the slack mitral leaflet portions toward the LVOT. The mitral inflow: aortic outflow angle *(right dotted lines)* might describe an anatomy that either brings the leaflet tips closer to the LVOT or one that affects transmitral and subsequent intraventricular flow directions such that systolic outflow may (with a greater angle) interact more with mitral leaflets. Finally, impairment of the normal annular systolic motion may decrease the LVOT area and the distance between the mitral leaflets and the LVOT. The *black circle* around the posterior and lateral annulus represents calcification of the annulus and a reduction in posterior and lateral annular contraction.

end-systolic diameter > 50 mm, or LV end-systolic volume > 75 mL/m^2), and/or a sphericity index higher than 0.7. These values reflect significant ventricular dysfunction and remodeling. Although repair of papillary muscle rupture has been reported, such cases are generally managed with valve replacement.

Predictors of repair failure for degenerative valve dysfunction include multiple scallops involved, anterior leaflet disease, bileaflet disease, and endocarditis with leaflet destruction.[48,58–61] These valves may require complicated repair techniques. In addition, severe MR in the presence of a normal annular diameter, or short anterior (<26 mm) and posterior (<10 mm) leaflets, is more difficult to repair. These latter predictors reflect the importance of identifying something repairable and of having adequate leaflet heights after repair.

Other predictors of difficult repair or adverse outcome include rheumatic origin; MR caused by radiation therapy; severe calcification of either the valve, the annulus, and/or the subvalvular apparatus; and atrialization of the coaptation points (Figs. 15.50 and 15.51).[48,59,60] The former three reflect either the absence of repairable tissues or the lack of adequate leaflet lengths. The latter reflects an end-stage degenerative state.

Assessing Severity of Regurgitant Flow

The procedure for assessing severity of regurgitant flow in the native versus the prosthetic MV is similar (see Table 15.4). The examination includes diagnosis, detection, and severity assessment of MR. This is supported by assessing the secondary effects on other cardiac functions, which support the severity assessment as well as determining treatment options. The finding of contractile dysfunction (LVEF < 60%), LA and LV chamber dilation (LV end-systolic volume > 70 mL/m^2), elevation in left-sided heart pressures, the presence of pulmonary hypertension, and right-sided heart dysfunction suggest either more severe, chronic, and/or decompensated MR. The examination demands a comprehensive review using all modes of imaging.

Identifying and determining leaflet anatomy and mobility, as well as assessing the annulus and subvalvular tissues are important to identifying the cause of MR and the possibility of repairing the valve if surgery is necessary. The stability of the valve determines the integrity of the surrounding tissues. A valve that appears to rock or one that has an echocardiographic lucent space within the annulus or between the prosthesis and surrounding tissues might suggest infection or abscess or, in the case of a prosthesis, dehiscence. Dehiscence for an MV prosthesis is more likely to happen along the posterior and lateral annular areas where surgical exposure is less and concern exists over interfering with left circumflex coronary arterial flow (see Fig. 15.46).

The Doppler examination identifies regurgitant jets and determines whether or not they are within normal range for a native valve or are considered the normal (or abnormal) signature for a prosthetic valve. Eccentric jets are considered abnormal.

Severity assessment reflects the regurgitant orifice area (ROA) either indirectly or directly. Measurement of the regurgitant jet area is neither specific nor sensitive enough to diagnose the severity of MR.[62–64] Jet areas of eccentric jets underestimate severity, whereas those of central jets may overestimate severity. However, a regurgitant jet that has a large area (>7 cm^2 vs <4 cm^2), extends toward the posterior wall (>50%), or covers more than 50% of the

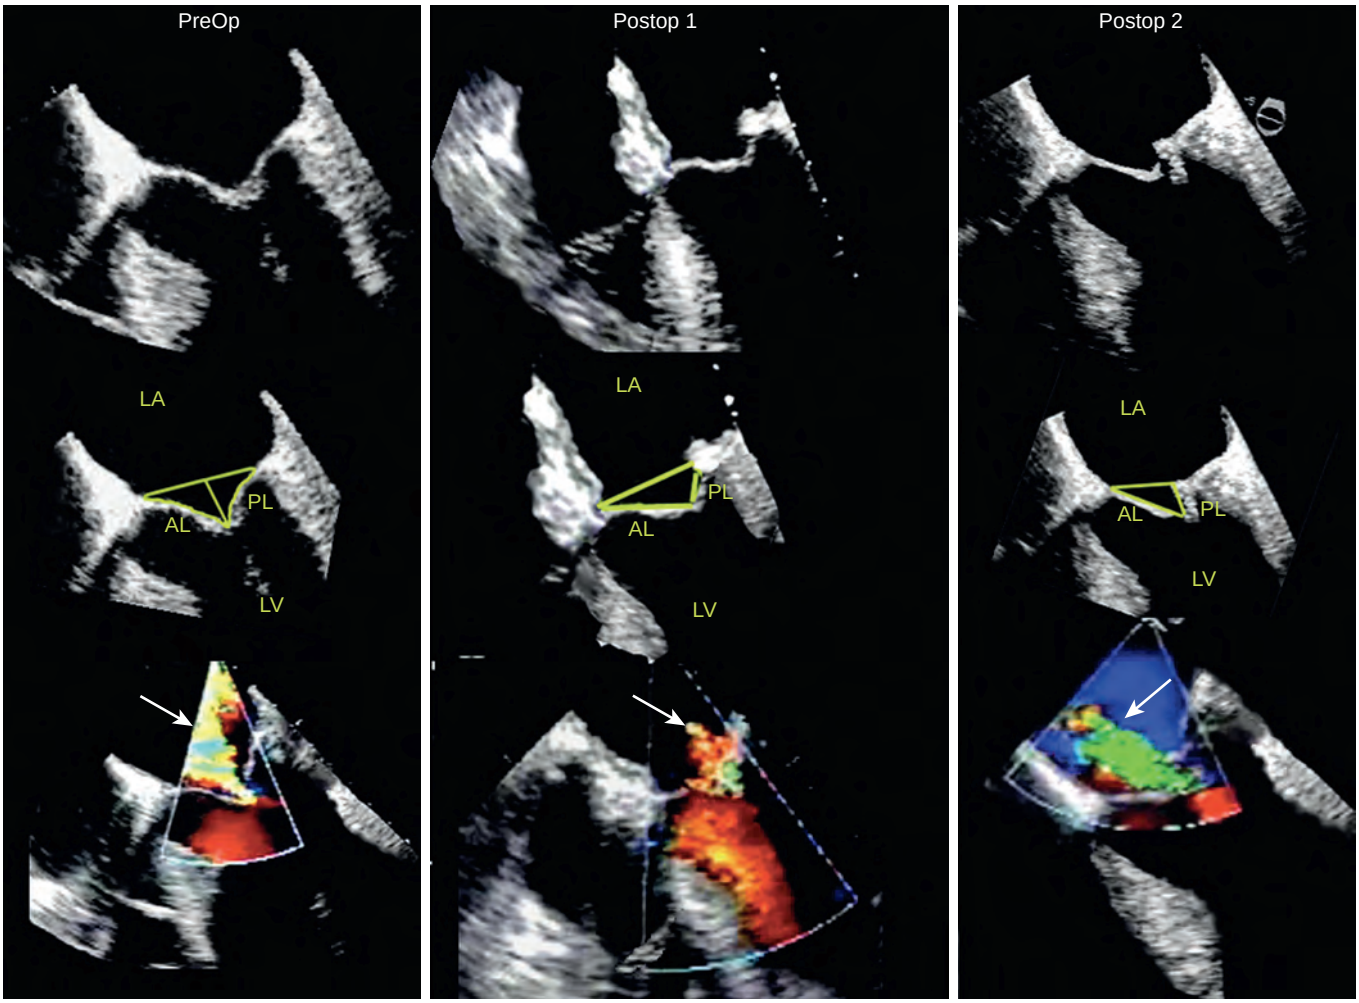

Fig. 15.49 Repair of type IIIb mitral regurgitation (MR): annuloplasty. This case shows the preoperative, intraoperative, and second preoperative (reoperation) echocardiographic images. The preoperative images show the tethered leaflets *(yellow triangle, middle figure)* and MR *(white arrow, lower image)*. After placement of an annuloplasty ring, the intraoperative images show a reduced tethering *(yellow triangle, middle image)* with reduced MR *(white arrow)*. As is reported with repair of type IIIb MR, the images to the right show the recurrence of MR *(white arrow)*. *AL,* Anterior leaflet; *LA,* left atrium; *LV,* left ventricle; *PL,* posterior leaflet.

LA area is considered moderate or greater.[18–21] This determination is further supported by the presence of flow convergence. Moderate or worse MR is suspected by a pulsed-wave Doppler profile of the pulmonary vein showing blunting or reversal of the systolic component (see Fig. 14.91). A dense and more complete continuous-wave Doppler flow profile of the regurgitant jet also supports moderate or greater MR.

More accurate quantitative assessments include measurements of the VC width, ROA, regurgitant volume, and regurgitant fraction, which are detailed in Chapter 14. The latter three are obtained using the flow convergence or PISA method, or the continuity equation. Although the VC measurement is relatively easy to obtain, its accuracy is mainly useful for either mild or severe MR, but it varies for moderate degrees of MR.[20,30,65–70] It is also important to measure the width of the VC perpendicular to the regurgitant jet and not in parallel (see Fig. 15.18). For the native valve, the VC should be obtained either in the ME four- or five-chamber or long-axis windows, but not in the ME two-chamber or bicommissural image, as the latter has been shown to overestimate MR severity. A VC width less than 3 mm or greater than 6 mm is consistent with mild and severe MR, respectively.[20,30,65–70]

The flow convergence method or PISA can be used qualitatively or quantitatively.[17,18,20,21,30,71–73] The absence of a large flow convergence (especially with Nyquist limit of <20 cm/s) supports the determination of moderate or less MR. The corollary is that the presence of a PISA at a Nyquist limit greater than 40 cm/s is consistent with moderate/severe to severe MR.

Flow convergence data that report an ROA greater than 40 mm^2 and/or a regurgitant volume greater than 60 mL is consistent with severe MR. The accuracy of the flow convergence method assumes that the PISA shells are hemispherical and the ROA is circular. Three-dimensional imaging shows that these assumptions are not always correct. A benefit of 3D color imaging is to allow direct measure of the ROA by planimetry.

Simplifications of the flow convergence method can be made if the Nyquist limit is set at 40 cm/s and it is assumed that the peak MR velocity is 5 m/s. If this were the case, then the ROA is equal to:

$$r^2/2$$

If the Nyquist limit were 30 cm/s, then this would be $r^2/3.8$.

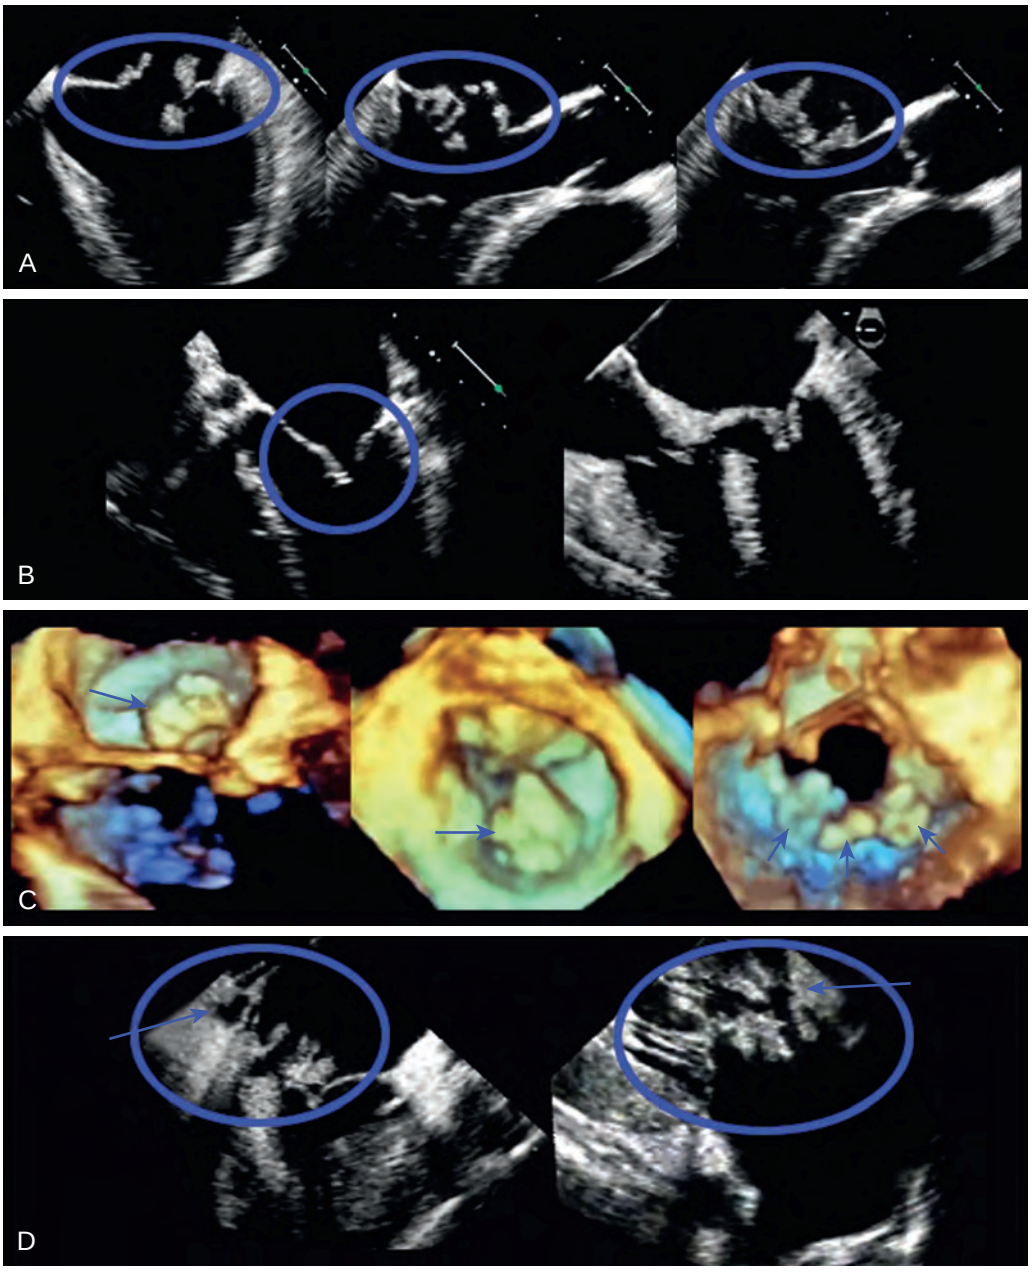

Fig. 15.50 Difficult repair or no repair examples. Although not an absolute contradiction to repair, extensive infection increases the difficulty of repair and reduces the long-term durability. (A) Extensive leaflet destruction. (B) Rheumatic velvets; typically replaced as the risk of mitral regurgitation recurrence and reoperation is high (approximately 25%). (C) Three-dimensional images highlighting extensive annular calcification *(blue arrows)*. (D) Significant leaflet destruction and annular involvement.

A dimensionless index is the ratio of the time-velocity integral (TVI) of the MV to that across the AV.

$$(TVI_{MV}/TVI_{AV})$$

In the absence of significant AI, a value less than 1 or greater than 1.4 is consistent with mild and severe MR, respectively.

Data have been published to predict outcome for varying degrees of MR. Severe MR is defined by an effective ROA greater than 40 mm^2 and is associated with early and late mortality.[64,74] Whereas severe MR requires therapy, it is less clear how milder degrees of MR should be managed. In the same study, an effective ROA (20 to 39 mm^2) was also associated with a worse outcome, but it was not significant until after 2 to 3 years.[64,74]

Surgical Indications

In the presence of severe MR, surgery should be performed if the patient is symptomatic[24–26] (Fig. 15.52). For an asymptomatic patient with severe MR, surgery should be considered if a durable repair is likely; if LV decompensation is present (LVEF <60%; LV end-systolic diameter >45 mm), especially if it is refractory to medical therapy; if it is thought that the MR is causing or contributing to arrhythmias and/or pulmonary hypertension (systolic pulmonary artery [PA] pressure >50 mm Hg); or if LA enlargement is significant and coupled with arrhythmias and pulmonary hypertension. For patients with moderate MR, surgery should be considered if that patient is presenting for other cardiac surgical procedures, especially if it is thought that repair is feasible and to provide long-term reduction in MR (>5–10 years).

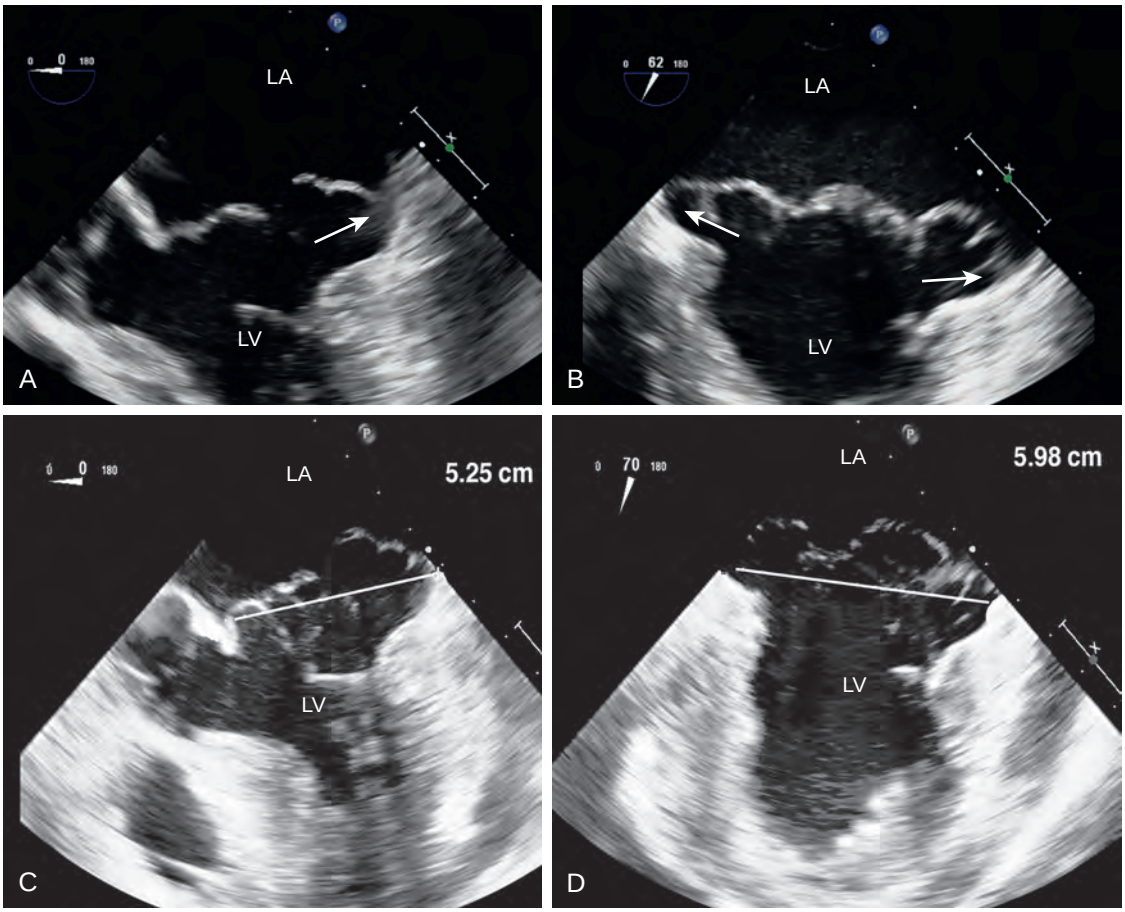

Fig. 15.51 End-stage or atrialization of mitral leaflets. (A–D) Significant bileaflet prolapse, as well as the appearance of atrialization of the leaflet insertion *(arrows)*. When coupled with severe annular enlargement (5.25 cm), these findings are consistent with severe, perhaps late-stage myxomatous disease, with all findings suggesting a difficult repair with questionable durability. *LA,* Left atrium; *LV,* left ventricle.

TABLE 15.5 Mitral Stenosis: Degrees of Severity

	Mild	*Moderate*	*Severe*
Peak jet velocity (m/s)	<1.8	1.8–2.2	≥2.2
Peak pressure gradient (mm Hg)	<12	12–18	>18
Mean pressure gradient (mm Hg)	<6	6–10	>10
MV area (cm^2) pressure half time continuity equation planimetry	>2.0	1–2	<1.0
MV area index (cm^2/m^2)	<1.25		
Velocity ratio (TVI_{MV}/TVI_{LVOT})	<2.2	2.2–2.5	>2.5
Pressure half time (ms)	<130	130–200	>200

LVOT, Left ventricular outflow tract; *MV,* mitral valve; *PHTN,* pulmonary hypertension; *RAE,* right atrial enlargement; *RVE,* right ventricular enlargement; *RVSD,* right ventricular systolic dysfunction; *TVI,* time-velocity integral.

Mitral Stenosis

The normal mitral valve area (MVA) ranges from 4 to 6 cm^2 and transmitral flow velocities are less than 1 m/s (Table 15.5). The more common causes of mitral stenosis (MS) include rheumatic stenosis, calcific MS, and, less commonly, congenital MS. The echocardiographic examination incorporates 2D and Doppler technologies to diagnose and assess for the presence and severity of MS (see Figs. 15.53 and 15.54).

Rheumatic valvitis is the most common cause of MS, causing commissural fusion, chordal shortening/fusion, and leaflet thickening, all complicated by calcification of the structures. The leaflet tips are fused, resulting in stenosis. While stenosis is more common in the rheumatic MV, the leaflet and chordal abnormalities can also be associated with significant MR (Carpentier type IIIa). In addition, involvement of other cardiac tissues and valves are not uncommon, including AV insufficiency and tricuspid regurgitation (TR).

Calcific mitral degeneration mainly affects the mitral annulus and uncommonly results in stenosis unless associated with leaflet thickening.

Patients with MS may be asymptomatic or may have varying degrees of LV and RV failure and arrhythmias depending on the severity and chronicity of the disease. With greater decompensation, forward flow across the valve and into the left ventricle declines, while LA pressure, size, and function continue to deteriorate. With time, the pulmonary vascular pressures and gradient rise, causing pulmonary edema and significant right-sided heart afterload, dilation, and dysfunction. Patients experience fatigue, hemoptysis, and right-sided heart failure. TR may result either from primary rheumatic involvement and/or secondary to pulmonary hypertension. Atrial fibrillation and stroke may be initial presenting signs, the latter, in part, resulting from development of atrial appendage thrombus. The chest x-ray and electrocardiogram show a dilated left atrium and right side of the heart and pulmonary edema.

Part of the assessment of the stenotic MV is geared toward determining the need for and timing of invasive procedures, the latter being either valvuloplasty or valve replacement. The Wilkins score was proposed and now used to predict outcome after valvuloplasty. The score includes assessment of leaflet thickening, mobility, and calcification, as well as subvalvular thickening, each of which is scored from 1

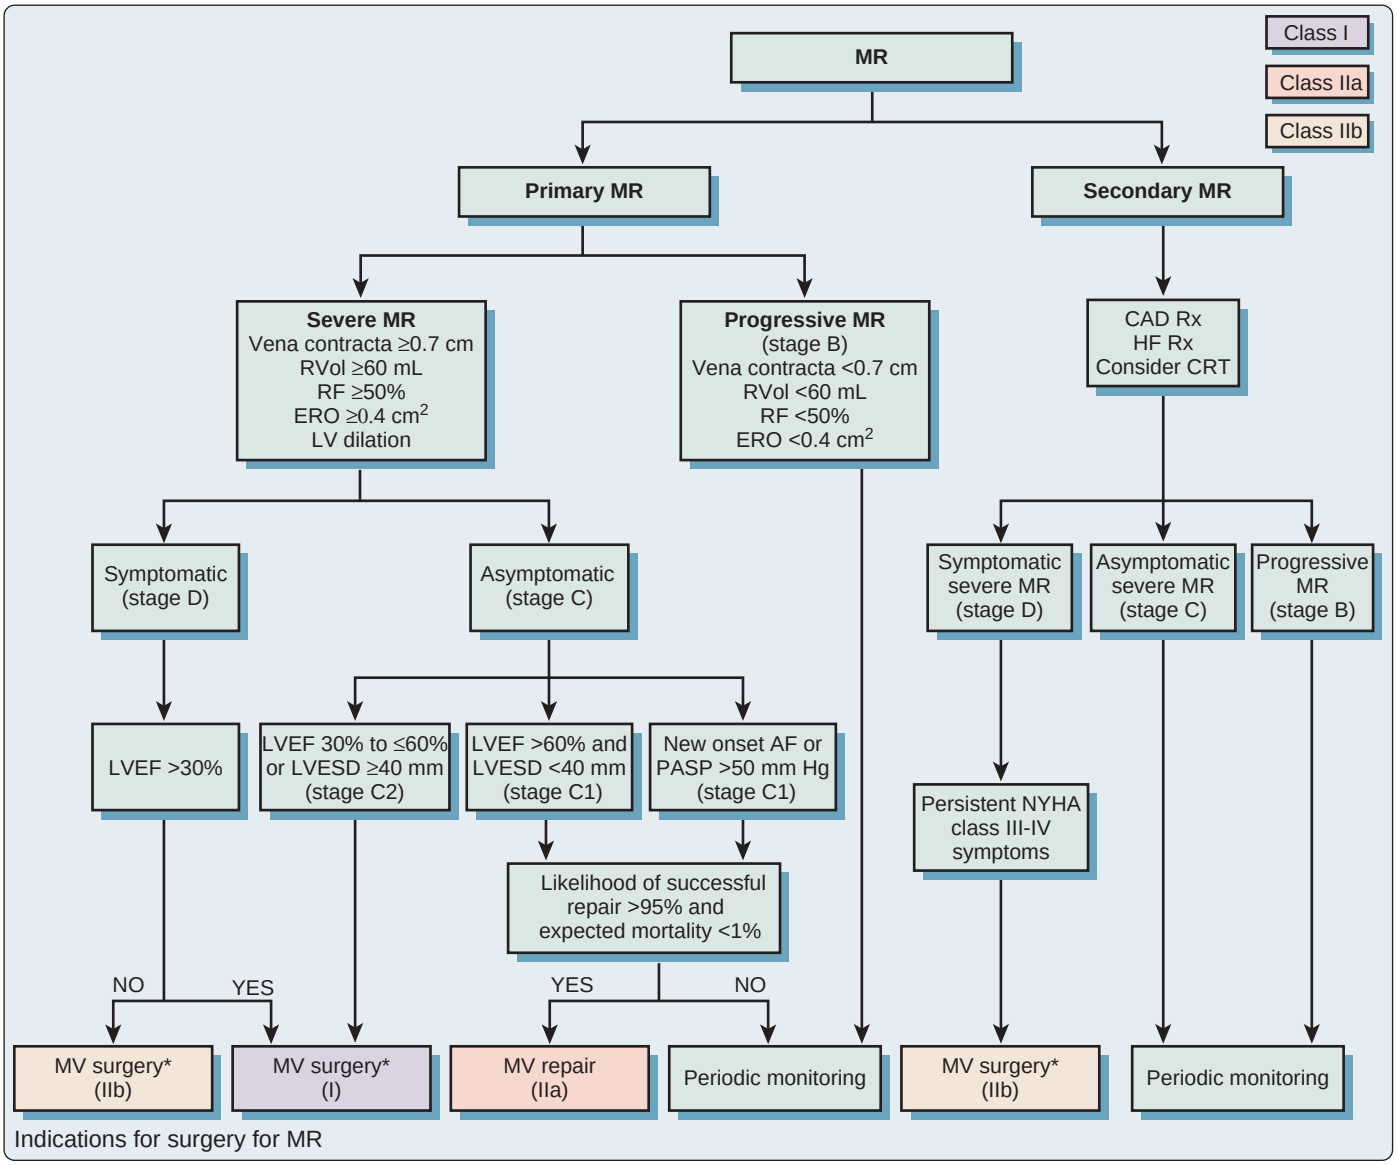

Fig. 15.52 Decision algorithm for mitral regurgitation *(MR)*: timing of intervention. The decision algorithm was taken as a consensus by an expert panel and based on outcome data and interpretation. Decisions are classified as class I, class IIa, class IIb, the former being supported by sufficient evidence such that intervention should be performed, while the latter two are supported by evidence that suggests that the benefits of intervention outweigh the risks and that intervention is reasonable based on multiple (IIa) or isolated trials or nonrandomized data (IIb). Intervention for MR is based on a number of considerations including cause, presentation (symptoms), changes in cardiopulmonary function, and timing (ie, whether other cardiac surgical procedures are scheduled and how repairable the valve is). *AF,* Atrial fibrillation; *CAD,* coronary artery disease; *CRT,* cardiac resynchronization therapy; *ERO,* effective regurgitant orifice; *HF,* heart failure; *LV,* left ventricular; *LVEF,* left ventricular ejection fraction; *LVESD,* left ventricular end-systolic diameter; *MV,* mitral valve; *NYHA,* New York Heart Association; *PASP,* pulmonary artery systolic pressure; *RF,* regurgitant fraction; *RVol,* regurgitant volume; *Rx,* prescription. *(Reprinted with permission from Nishimura RA, Otto CM, Bonow RO, et al. 2014 AHA/ACC guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines.* J Am Coll Cardiol. *2014;63:e57–e185.)*

to 14.[64] A score less than 8 suggests that the valve is more amenable to valvuloplasty as compared to a score higher than 8. Variations on this score as well as others have been proposed, including one based on 3D imaging. Findings consistently show that the greater the amount of thickening, calcification, and immobility, the worse the outcome after valvuloplasty.[75]

Assessing forward flow across the prosthetic MV, to determine both whether or not it is normal and how severe the dysfunction is, is similar to that for the native valve. As described earlier, different prostheses have different forward flow projections. Bioprosthetic valves have a single forward flow, whereas mechanical valves will have two (single-leaflet) or three (bileaflet) forward projecting jets. The more information known about specific prosthesis, the easier it is to distinguish between normal and abnormal. Prosthetic valve stenosis is caused by leaflet restriction, thickening, and/or thrombosis (Figs. 15.55 and 15.56).

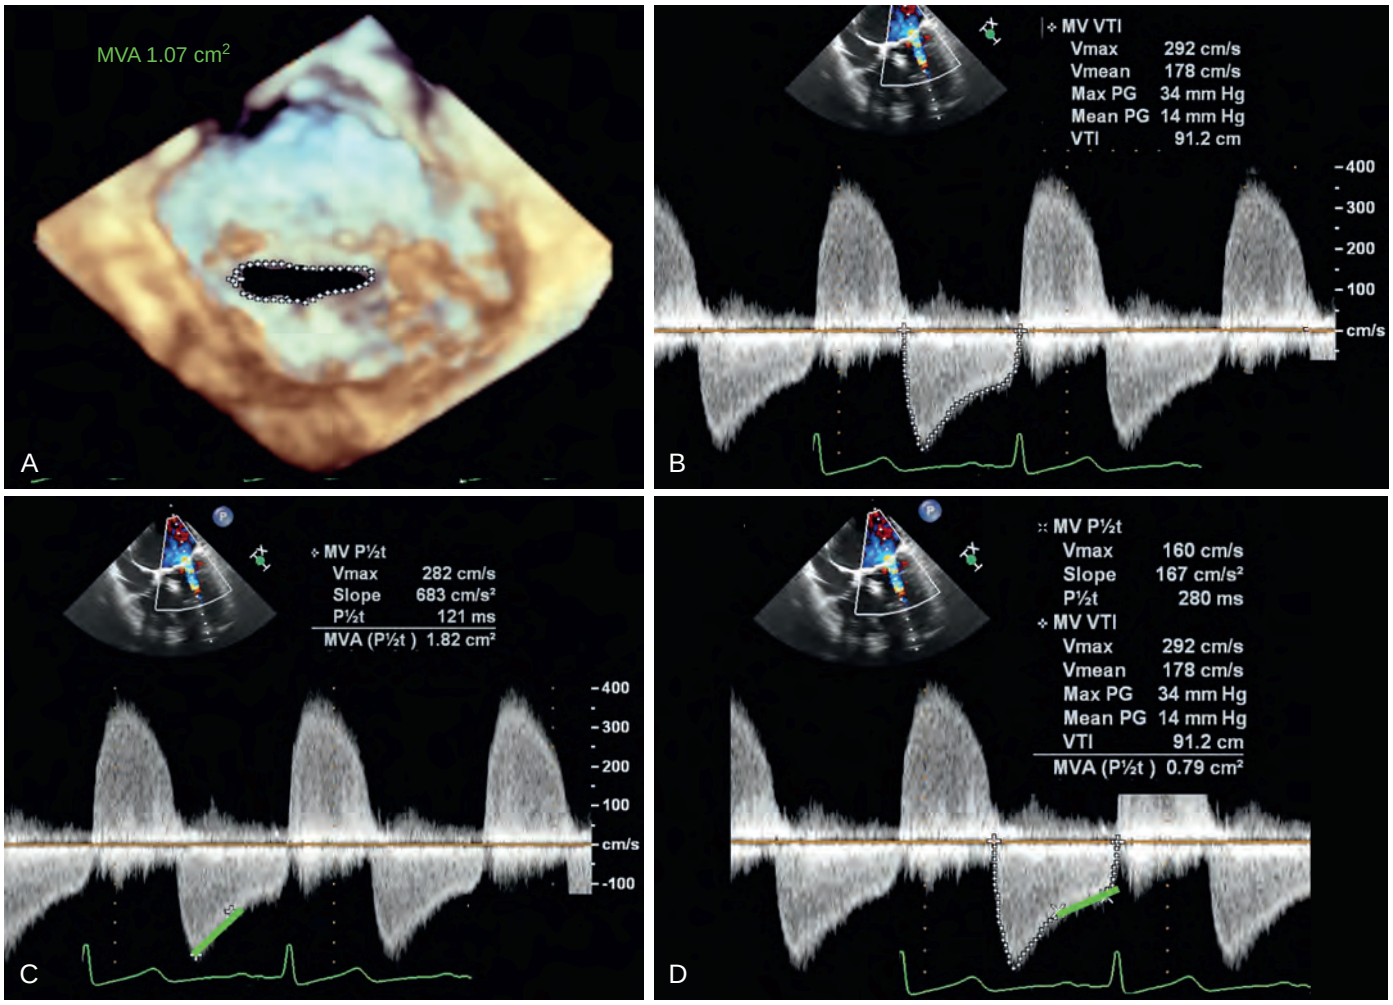

Fig. 15.53 Assessment of mitral stenosis (MS). Pressure gradients, pressure half time (PHT), and planimetry are the common assessments of the mitral valve area *(MVA)*. (A) Planimetry is performed from the three-dimensional view of the mitral opening seen from the left ventricular perspective. (B–D) Doppler profiles of flow across the valve. It is evident that mitral regurgitation coexists as seen by the upward systolic flow. Based on the downward deflection, MS also exists. The peak and mean gradients are 34 and 14 mm Hg, respectively. The forward flow profile across the valve, however, is biphasic. If the PHT were based on the initial phase, the MVA would be 1.82 cm^2. However, if based on the latter phase, the MVA would be 0.79 cm^2. Since the initial phase may represent initial opening velocity resistances, flow, and cardiac output, it is recommended to use the latter phase because it represents a more stable flow state and a better reflection of the effective orifice area.

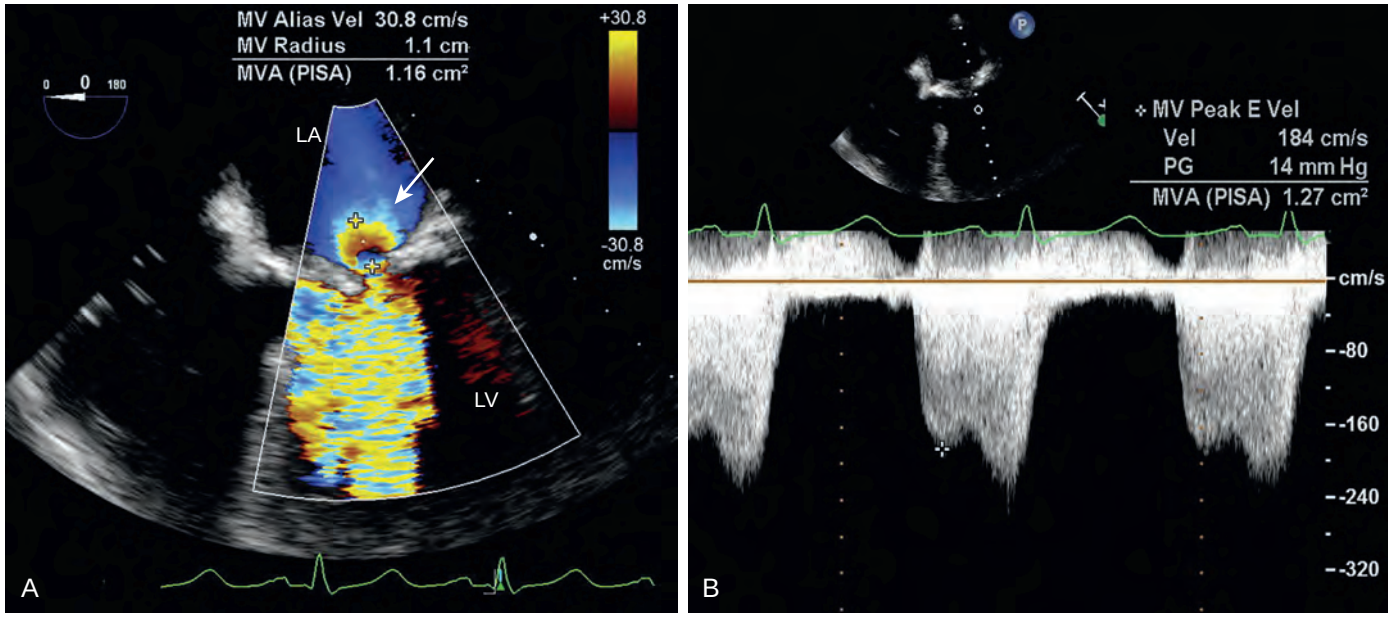

Fig. 15.54 Mitral valve area *(MVA)* with proximal isovelocity surface area (PISA). Flow through a relatively narrow orifice results in flow convergence. This can be the case for stenotic valves as well as regurgitant valves. The PISA method to assess effective orifice area can be employed to calculate the stenotic orifice in the same way it is used to calculate a regurgitant orifice. As shown in this figure the MVA is approximately 1.30 cm^2. *LA,* Left atrium; *LV,* left ventricle.

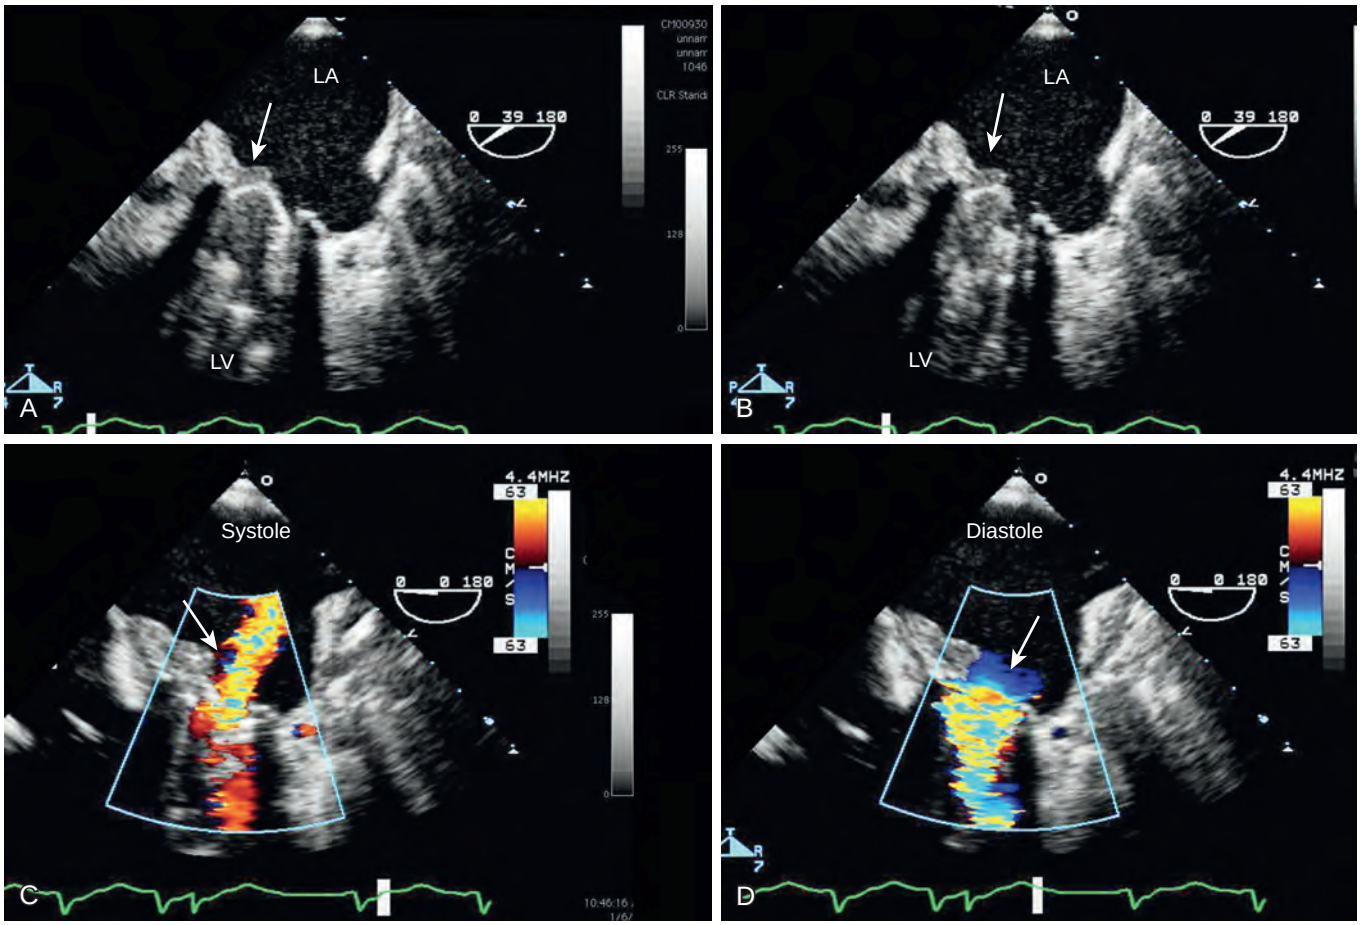

Fig. 15.55 After mechanical mitral valve replacement: stuck leaflet: thrombus. Stuck mechanical leaflet of a bileaflet mechanical valve in the mitral position, probably the result of thrombus. The medial leaflet *(white arrow)* appears to be stuck in a closed position and surrounded by thickening consistent with thrombus formation shown in (A) systole and (B) diastole. Color Doppler imaging demonstrates turbulent flow consistent with both (C) regurgitation and (D) stenosis. *LA,* Left atrium; *LV,* left ventricle.

Quantitative assessment of forward flow across the native versus prosthetic MV is similar and includes all modes of imaging. Measures include both indirect and direct assessment of the MVA (see Table 15.5). The most direct measurement is planimetry made possible by 2D or, more recently, 3D imaging.[76] Identifying and tracing the inner edges of the maximum opening of the MV allow measurement of the anatomic orifice area. This is more feasible and, perhaps, more accurate using 3D imaging.[77] Whereas 2D planimetry is performed from TG MV short-axis imaging, 3D planimetry is obtained using volumetric data from ME windows.

American Society of Echocardiography level 1 recommendations for assessing MV patency include peak transvalvular jet velocity, pressure gradients, and MVA calculated from the pressure half time (PHT) or measured by planimetry (see Figs. 15.53 and 15.54).[17,21,63,77] Peak pressure gradients are obtained from the peak transvalvular jet velocity using the simplified Bernoulli equation. Mean pressure gradients are obtained by tracing the TVI across the MV to integrate the various jet velocities allowing calculation of the mean gradient. Since the peak gradient is influenced more by the net compliance between the left atrium and left ventricle, the mean gradient is of greater importance.[78,79]

The Doppler data are affected by changes in cardiac loading conditions, as well as coexisting valvular or congenital lesions. In addition to changes in cardiac output (CO), these include changes in net compliances, coexistence of MR, AV dysfunction, and an atrial septal defect (ASD).[1,3] Variables that increase the LA pressure or reduce LV pressure and/or increase transmitral flow increase jet velocity and gradient measures and may overestimate MS severity.[24] Doppler measures of MS, including the PHT, are affected by these variables.[78,79] Variables that reduce LA pressure or increase LV pressure do the opposite. For example, an ASD with left-to-right flow, moderate or greater AI, or net positive change in the LV-LA compliance cause an overestimation of MVA by shortening the PHT. The calculation of the MVA from the PHT is done by applying an empirically derived value (see Fig. 14.81).

$$\text{MVA} = 220/\text{PHT}$$

The deceleration time (DT) is an extension of the PHT and is the time from the peak velocity to zero velocity across the orifice. Using the DT to calculate MVA requires knowing that PHT is 29% of the DT.

$$\text{PHT} = 0.29 \times \text{DT}$$

$$\text{Since MVA} = 220/\text{PHT},$$

$$\text{MVA} = 220/0.29 \times \text{DT or } 759/\text{DT}$$

The transmitral TVI may be bimodal with a more rapid initial deceleration followed by a slower decline in gradient. It is recommended to measure the PHT from the slower decline as it better reflects the contribution of the MVA.[80]

Degrees of MS follow similar charts for native and prosthetic valves. Significant (more than mild) MS is considered with a peak velocity greater than 1.8 m/s, a mean transvalvular gradient greater than 6 mm Hg, a peak gradient greater than 12 mm Hg, and/or an

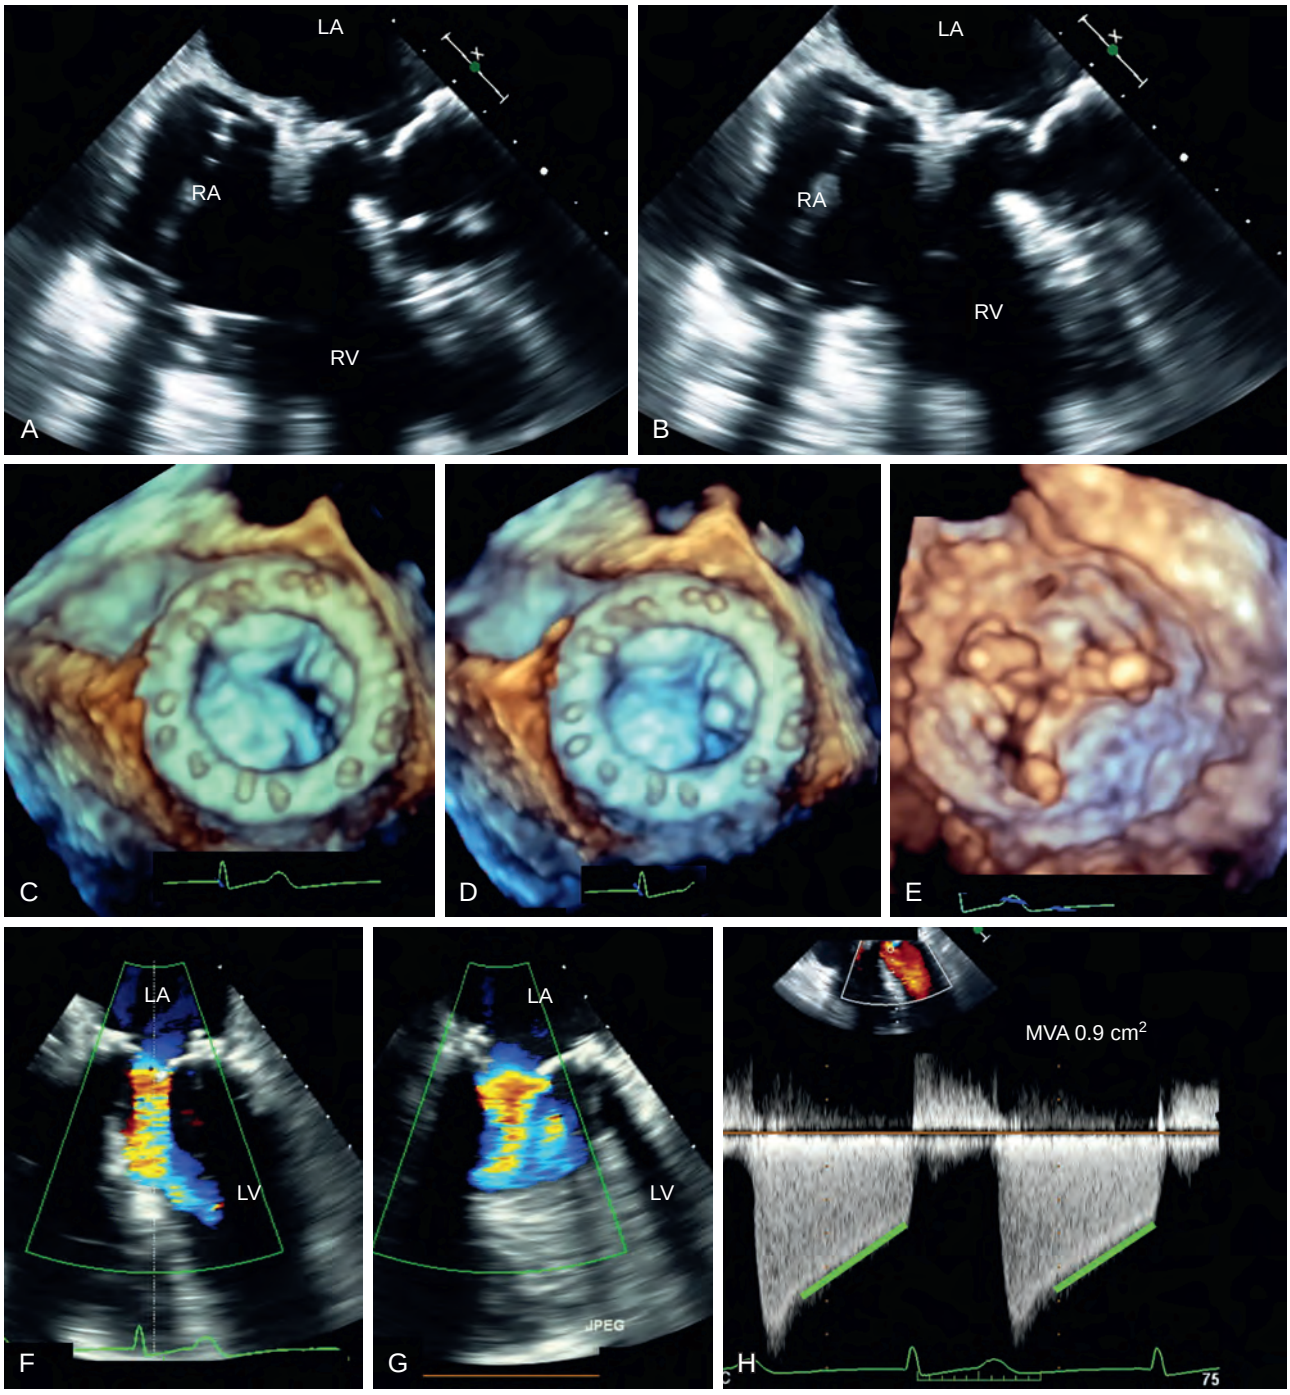

Fig. 15.56 After bioprosthetic mitral valve replacement: degeneration/thickening/restriction. These images demonstrate a complication of bioprosthetic valves in that the leaflets, likely due to inflammation, are thickened, less compliant, and less mobile. This case demonstrates significant mitral stenosis. (A) and (B) Two-dimensional images show echo-bright thickened and immobile prosthetic leaflets during both diastole *(left)* and systole *(right)*. (C) Three-dimensional image showing a very small opening in diastole from the left atrial perspective. (D) Valve in systole. (E) Three-dimensional image showing a very small opening in diastole from ventricular perspective. (F) and (G) Turbulent forward flow during diastole compared with stenosis and confirmed by (H) the continuous-wave Doppler profile. *LA,* Left atrium; *LV,* left ventricle; *MVA,* mitral valve area; *RA,* right atrium; *RV,* right ventricle.

MVA less than 1.5 to 2.0 cm^2. PPM has been described for prosthetic MVs.[81] PPM, for the MV, has been categorized as present or not, based on the indexed valve area (EOAi; $cm^2/BSA\ [m^2]$). PPM for the MV may be considered present when the EOAi is less than 1.25 cm^2/m^2. Different methods are used to assess the EOA, including the PHT, the continuity equation, and the flow convergence method. The continuity equation can be simply described by the following equation (Fig. 15.57)[82]:

$$EOA_{MV} = SV/TVI_{MV}$$

The stroke volume (SV) can be measured from a reference site using Doppler echocardiography (eg, PA or LVOT), a noninvasive

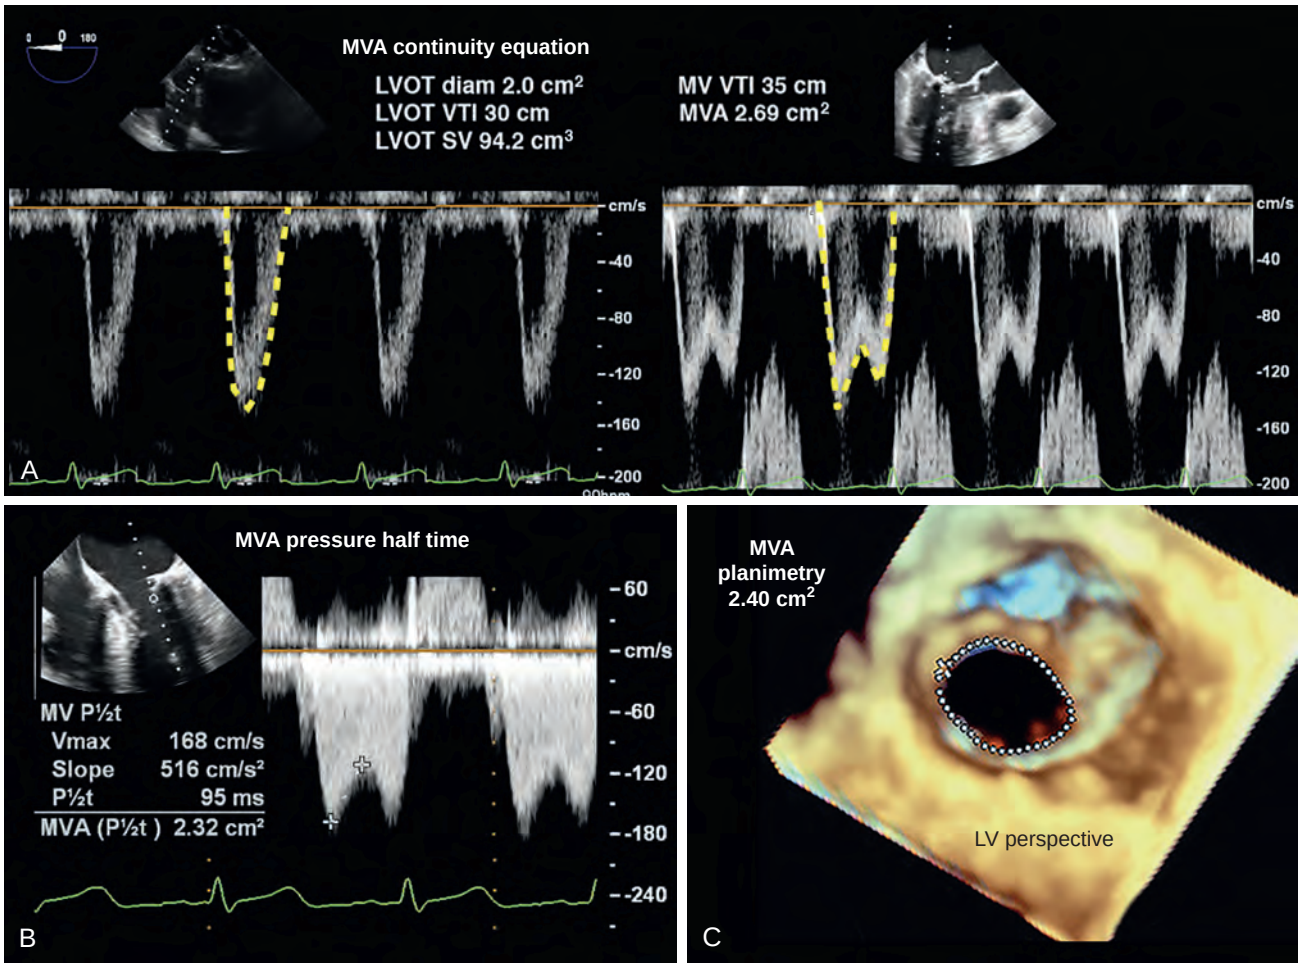

Fig. 15.57 Measures of mitral valve area *(MVA)*. The images show three different methods to measure MVA. (A) employs the continuity equation with the left ventricular outflow tract *(LVOT)* as a reference site. (B) employs the pressure half time equation, while (C) measures MVA by planimetry of the three-dimensional image.

method (eg, arterial waveform), or, in the presence of a PA catheter, can be measured using the thermodilution CO technique. Finally, the PISA, or flow convergence, method has been described in similar principle as above for assessment of MR and is, similarly, based on geometric assumptions that variably exist for native valves; this is perhaps not different for prosthetic valves (see Fig. 15.54).[83]

To avoid geometric assumptions and other variables listed, a Doppler velocity index (DVI) also may be used to assess prosthetic MV patency.[84]

$$TVI_{MV}/TVI_{LVOT}$$

A value < 2.2 is considered normal.

For cases in which imaging is difficult, a modified Gorlin equation can be employed. In this equation, the CO is divided by the square root of the peak transmitral pressure.[74]

Surgical Indications

Surgery, or percutaneous valvuloplasty, is indicated for symptomatic patients with severe MS (MVA< 1.5 cm^2)[24–27] (Fig. 15.58). Percutaneous mitral commissuroplasty (PMC) is preferred to open surgery, and surgery is only performed when PMC is contraindicated, which includes an MVA greater than 1.5cm^2, LA thrombus, significant MR (> 2+), unfavorable anatomy for PMC, and/or when patients are scheduled to undergo other cardiac surgery procedures.

Aortic Valve

Normal Anatomic and Functional Features of the Native Valve

The normal AV is a thin (<2 mm) three-leaflet semilunar valve with a normal EOA ranging from 2–4 cm^2. The three leaflets, or cusps, are equal in size and symmetric and labeled as left, right, and noncoronary cusps, depending on their association with a coronary artery.[17,20,21,85–87] The three leaflets cover an area that is 40% greater than the area of the open orifice, indicating significant overlap. The coapting length (ie, overlap between leaflets) is generally greater than 6 mm. The three leaflets coapt centrally along a thickened nodular area (Nodules of Arantius) above the annular plane (ie, no prolapse).

The AV is a part of the LVOT that extends from the subvalvular to supravalvular area, being defined as the region between the anterior mitral leaflet and the septum immediately below and extending to the sinotubular junction (STJ) within which the AV is attached (Fig. 15.59). The supravalvular tissues include the sinuses of Valsalva, and the STJ, which then extends into the ascending aorta. There are three sinuses of Valsalva: left, right, and non. Each is defined by the presence of the respective coronary ostia (right and left) or its absence (non). The sinuses appear as out-pouches and serve an important role, one of which is to provide a reservoir of blood during diastole to optimize coronary artery filling and flow.

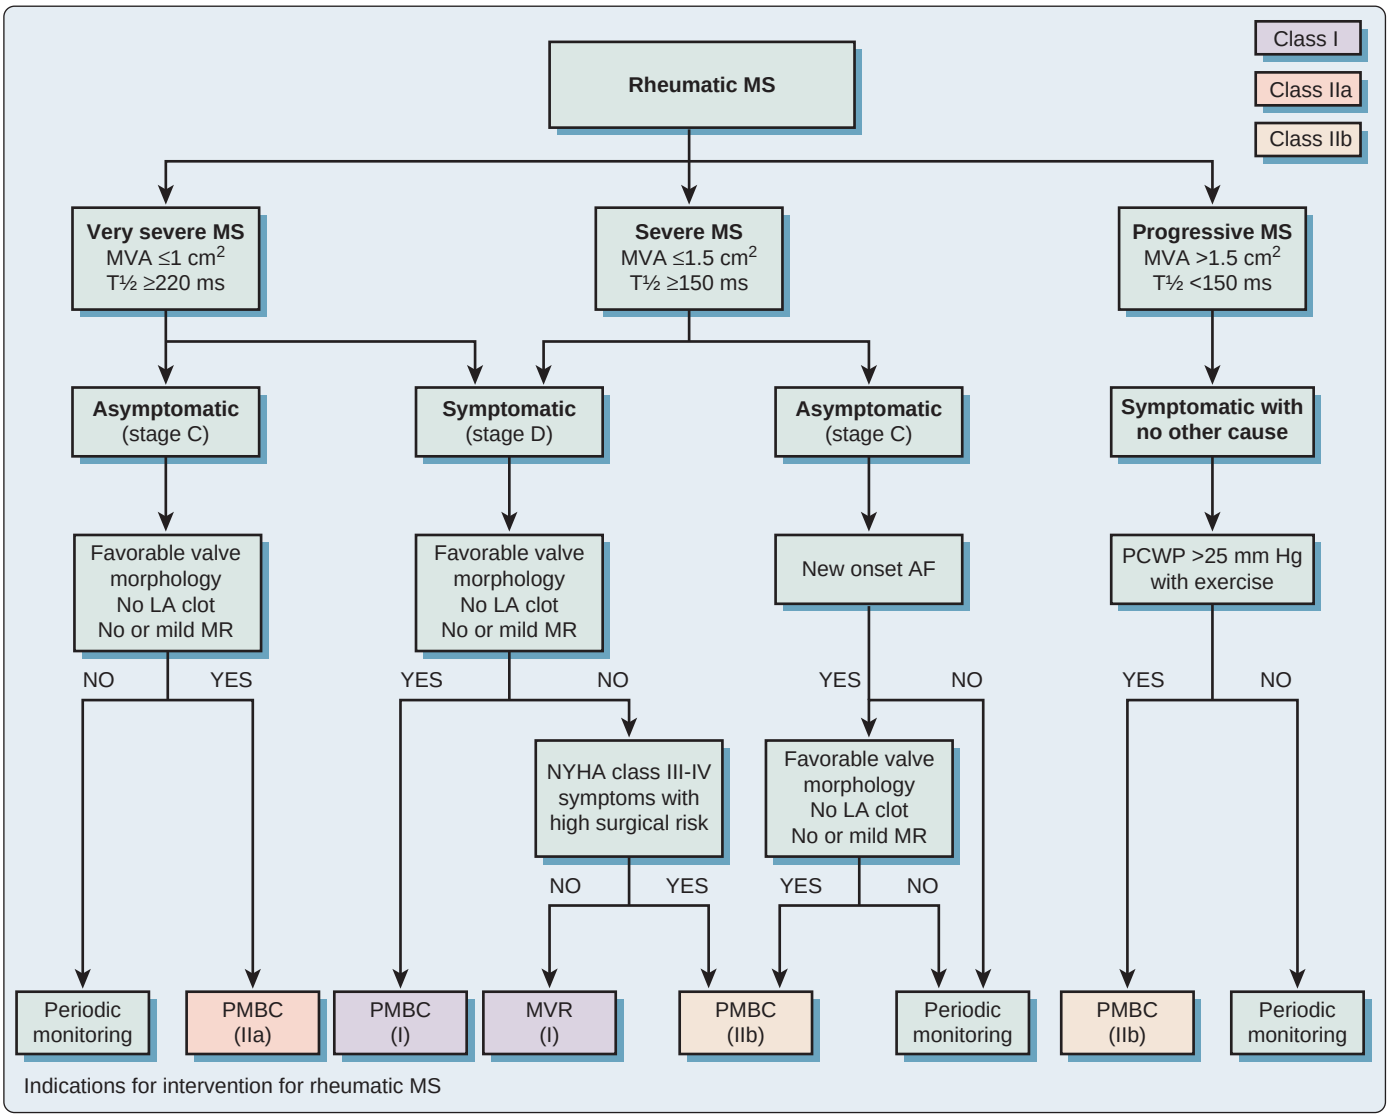

Fig. 15.58 Decision algorithm for mitral stenosis *(MS)*. The decision algorithm was taken as a consensus by an expert panel and based on outcome data and interpretation. Decisions are classified as class I, class IIa, class IIb, the former being supported by sufficient evidence such that intervention should be performed, while the latter two are supported by evidence that suggests that the benefits of intervention outweigh the risks and that intervention is reasonable based on multiple (IIa) or isolated trials or nonrandomized data (IIb). Treatment for MS usually includes percutaneous intervention. The decision is based on a number of considerations including severity, presentation (symptoms), changes in cardiopulmonary function, and whether valvuloplasty is feasible. *AF,* Atrial fibrillation; *LA,* left atrium; *MR,* mitral regurgitation; *MVR,* mitral valve replacement; *NYHA,* New York Heart Association; *PCWP,* pulmonary capillary wedge pressure; *PMBC,* percutaneous mitral balloon commissurotomy. *(Reprinted with permission from Nishimura RA, Otto CM, Bonow RO, et al. 2014 AHA/ACC guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines.* J Am Coll Cardiol. *2014;63:e57–e185.)*

The leaflets open (ventricular systole) and close (ventricular diastole) in accordance with changes in the pressure gradient between the aorta above and the left ventricle below. Although this is the main driving force guiding leaflet motion, the anatomic position and connection between the AV and surrounding tissues also contribute to the opening and closing of the valve. The interplay between the valve leaflets and surrounding tissues/muscle reduce resistance and tension on the leaflets to facilitate both opening and closing. Prior to ventricular ejection, the ascending aorta begins to enlarge and accounts for the initial leaflet separation. Prior to diastole, blood begins to pool in the coronary sinuses creating vortical forces and pressure, which initiate leaflet closure.

Prosthetic or Repaired Aortic Valve

Prior to the evaluation of the prosthetic or repaired AV, it is important to know the details of the surgical procedure, including what kind of valve was placed or how the valve was repaired.[21,22,87] Previous knowledge of normal echocardiographic findings for specific valves and/or successfully repaired valves help delineate what is normal and what is not for the surgical procedures. Knowledge of whether a mechanical or bioprosthetic valve was placed is important to predict what the echocardiographic appearance will look like. Each type of valve has specific appearances. For mechanical valves, the type and number of leaflets are important, while for bioprosthetic valves whether a stented or stentless valve is important to predict appearance

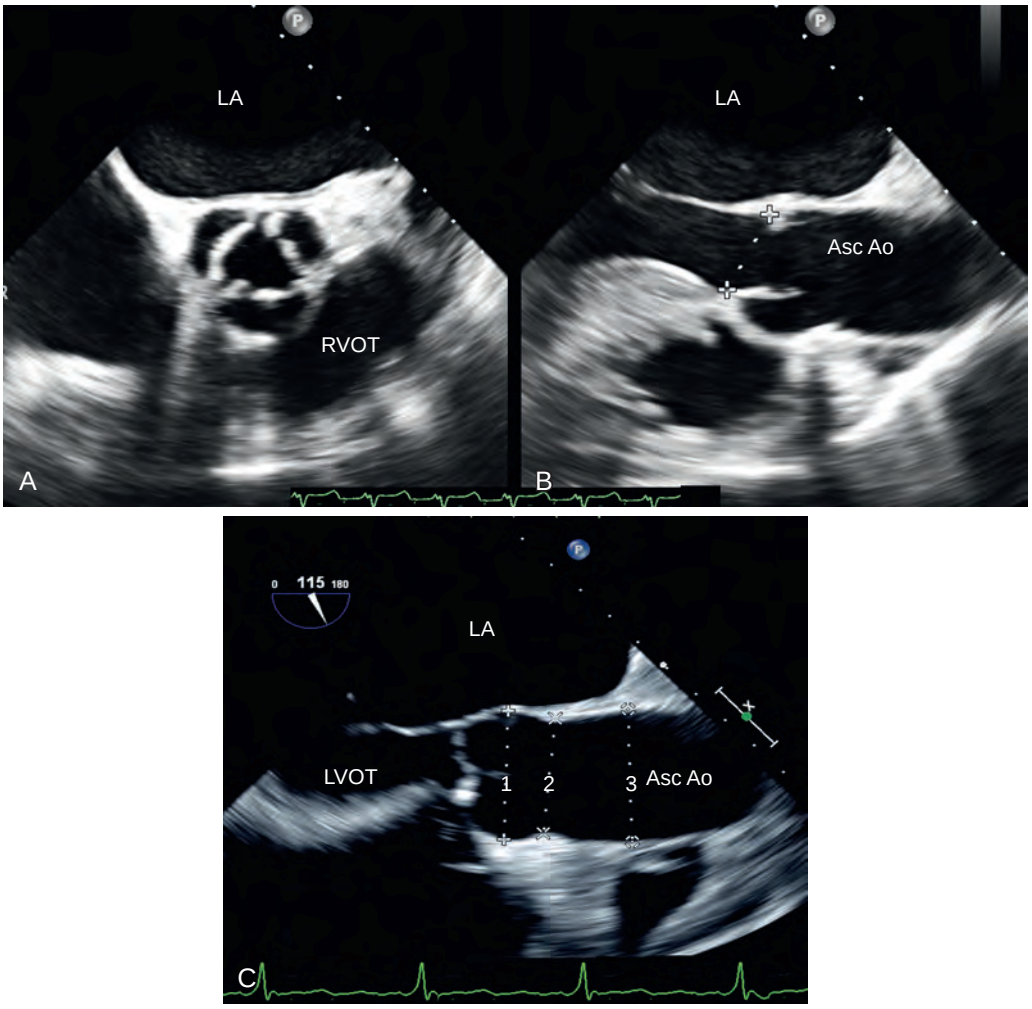

Fig. 15.59 Aortic root diameters. (A–C) The left ventricular outflow tract *(LVOT)* extends from the subvalvular area at the base of the anterior mitral leaflet to the sinotubular junction (STJ). Within this space the aortic valve is attached and distinctly separates the subvalvular from the supravalvular tissues. Important diameters include (B) the annulus, (C1) the sinuses, (C2) the STJ, and the (C3) ascending aorta. These measurements not only explain possible causes of aortic valve insufficiency but also help to guide therapy decisions, including surgical replacement. *Asc Ao,* Ascending aorta; *LA,* left atrium; *RVOT,* right ventricular outflow tract.

and flow profiles. Prosthetic valves are described by their annular size with 19, 21, and 23 mm valves being most commonly placed. In general 19, 21, and 23 mm valves result in EOAs of 1.1, 1.4, and 1.6 cm^2, respectively (see Table 15.3).[21,22,88–91] A normal functioning prosthetic valve yields a smaller EOA compared to a normal native valve in the same anatomic space.

For valve repairs, information of the prerepair disease and the repair itself helps explain the echocardiographic images. Repairs for congenital stenosis are described; however, most repairs are directed toward treating AI, especially for the adult population. Although the appearance of the repaired valve depends on the repair, by and large it should resemble a normal native valve. AV function and prediction of long-term function are the goals of the post- repair imaging. This includes assessment of length and level of leaflet coaptation and Doppler assessment of transvalvular flows. For all echocardiographic assessments, recording of the patient's hemodynamic status improves the perspective at the time of evaluation.

Echocardiographic Examination

The 2D examination of the AV also includes assessment of the supravalvular and subvalvular tissues. This is accomplished from a number of echocardiographic windows. Imaging from multiple sites and angles help to construct a 3D impression of the valve and flows, and helps delineate between normal and abnormal. Particular windows of importance include ME short-axis and ME long-axis windows to image the AV and the tissues above and below in short and long-axis views. Although TG windows are more useful for quantitative Doppler, the TG 2D examination also complements ME images, especially when imaging artifacts limit the latter.

A part of the examination is to determine the feasibility of repair for the regurgitant AV.[87] In doing so, the mechanism of AI has to be determined. Similar to other valves, dysfunction can be divided based either on mobility and/or leaflet pathology. *Type I dysfunction* includes AI due to aortic root dilation (Fig. 15.60). Root dilation includes those tissues extending to the STJ, but not beyond (ie, the ascending aorta).

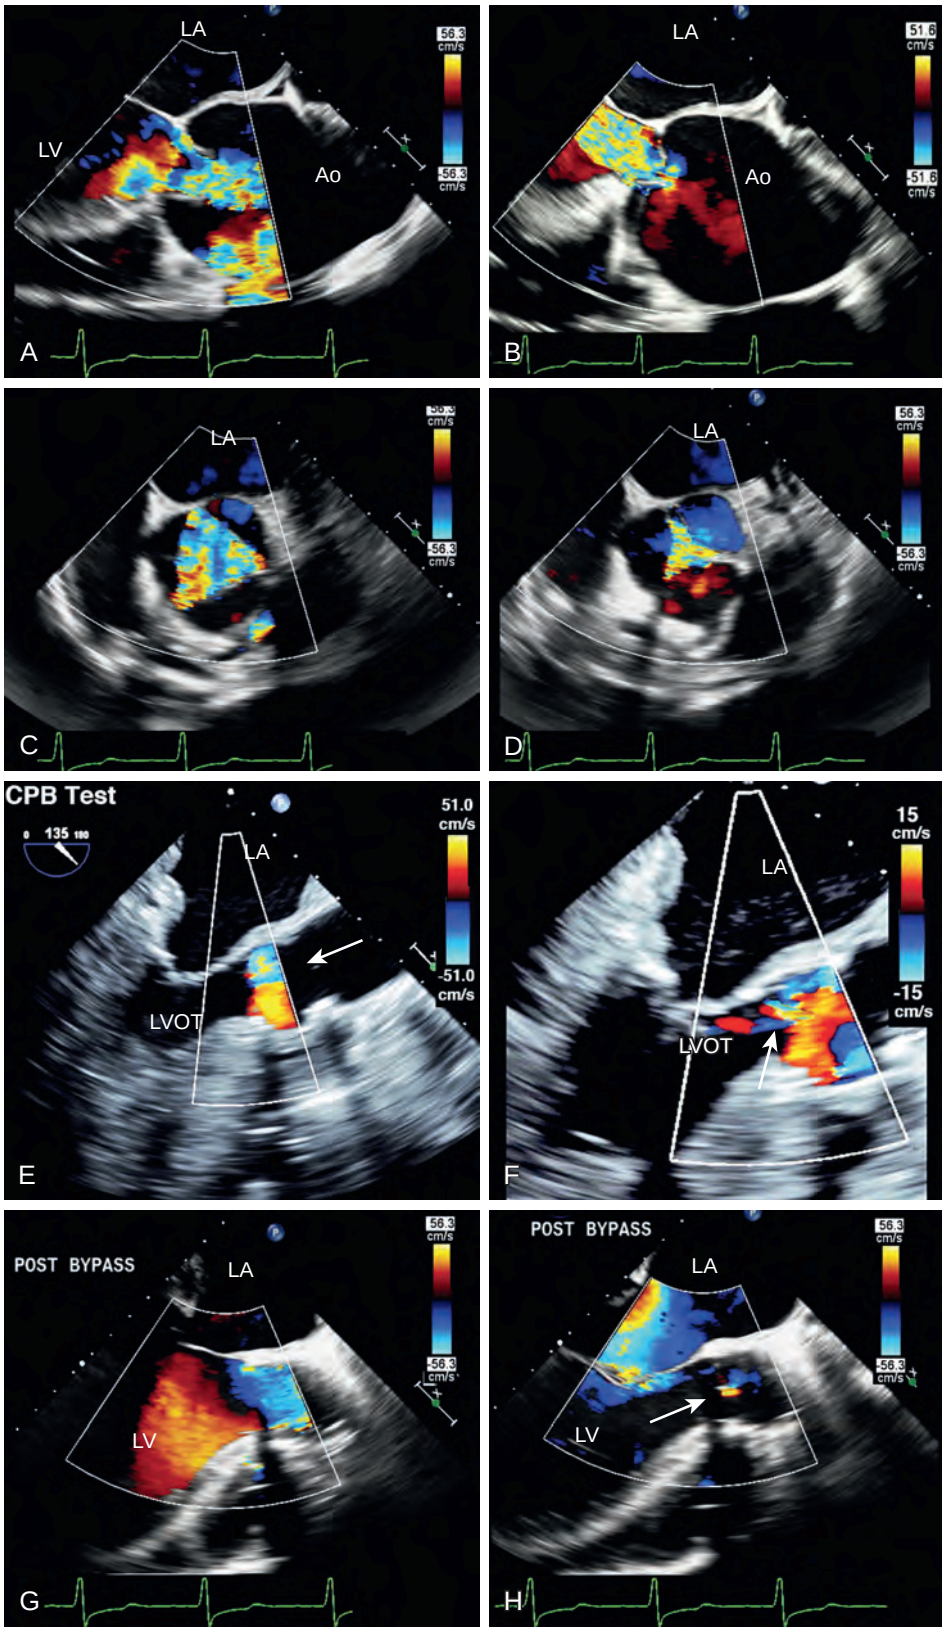

Fig. 15.60 Aortic insufficiency (AI) and repair. (A–D) Prerepair color Doppler images from (A and B) long- and (C and D) short-axis windows depicting severe central AI. Images on the *left* are obtained during systole and those on the *right* are obtained during diastole. (E) and (F) were obtained during cardiopulmonary bypass, after repair of the aortic valve. Color Doppler imaging was used and the color scale was adjusted from 51 to 15 cm/s to increase the sensitivity of detecting residual AI. This is accomplished by infusing cardioplegia into the proximal aortic root under 80 mm Hg of pressure measured from the cardiopulmonary bypass *(CPB)* machine. (G) and (H) were obtained during a stable period after separation from CPB, during (G) systole and (H) diastole and shows trace AI. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle.

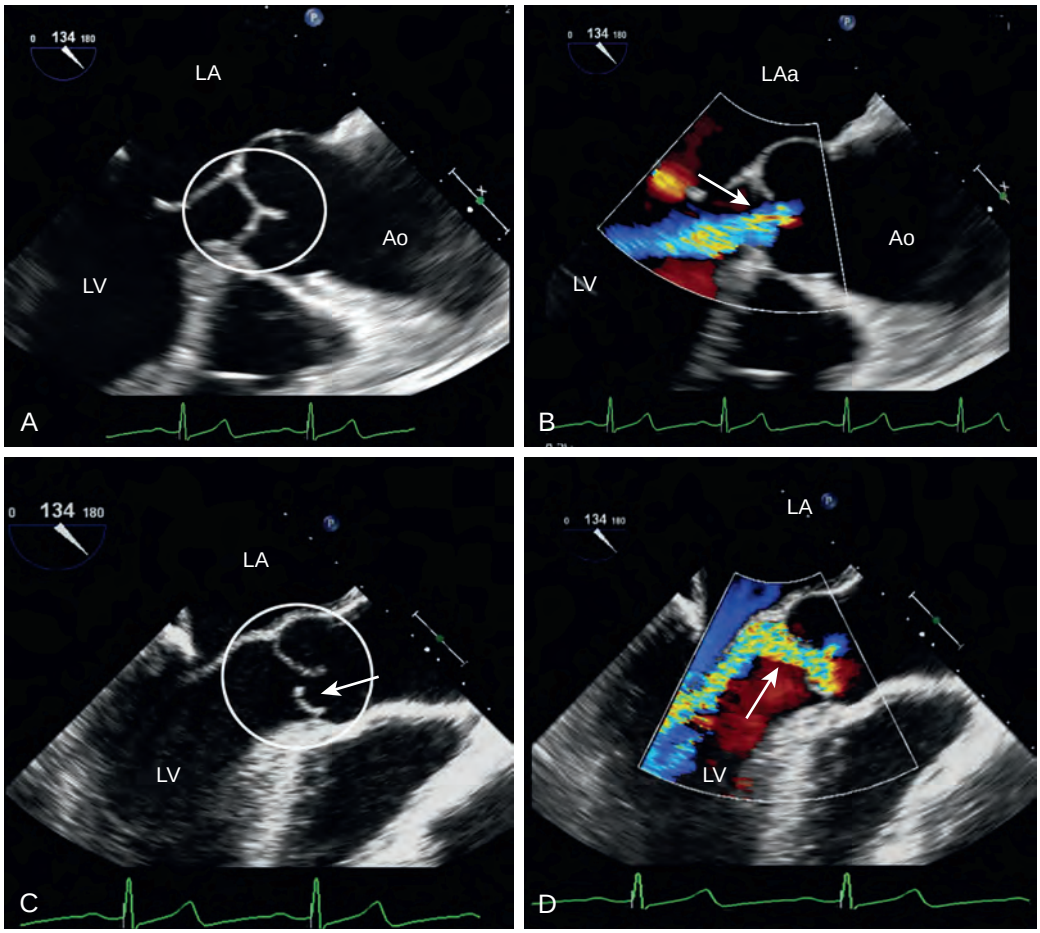

Fig. 15.61 Aortic insufficiency (AI) jet direction. The AI jet may be centrally or eccentrically directed. (A) Centrally directed AI, which might be consistent with equally dysfunctional leaflets. (B) Eccentrically directed insufficiency denoting unequal leaflet dysfunction. (C) and (D) The right coronary cusp prolapses (*circle* in C) and the AI jet (*arrow* in D) is directed away from it. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle.

Type II dysfunction reflects excess leaflet mobility (Figs. 15.61 and 15.62). Excess mobility is noted by either prolapse or flail of one of more leaflets, while fenestrations are noted by multiple areas in which the integrity of the leaflets is decreased. These causes may reflect fibroelastic deficiency of the leaflet. *Type III dysfunction* also reflects restricting leaflet motion or endocarditis (Fig. 15.63). Repair should be considered for type I and type II dysfunctions.

Imaging of the native and prosthetic AVs are similar. The examination assesses function and pathology including leaflet number, thickness, mobility, and the presence of masses, the latter of which may represent endocarditis, suture materials, or fractured calcium deposits. Any evidence of instability and/or hypolucency within the aortic wall or between the prosthesis and the surrounding tissues/annulus would suggest dehiscence and/or infection/abscess (Figs. 15.64 and 15.65).[21,22] Finally, imaging of the surrounding tissues will point to secondary causes of AI such as root abscess or aortic dissection (see Fig. 15.64). Imaging from multiple planes helps to overcome effects of imaging artifacts and increases the confidence in the diagnosis.[21,22]

After valve surgery, the examination should differentiate between valve repair and replacement, and for the latter, whether or not a mechanical or bioprosthetic valve was placed (Fig. 15.66). The stented and stentless bioprosthetic valves can be differentiated by the presence of both the stent and the supportive struts with the stent (Fig. 15.67). Periprosthetic thickening results from edema or hematoma, which begins to resolve in the early postoperative period.[92] For patients with stentless or repaired valves, this may result in a smaller EOA in the immediate postoperative period followed by a significant increase in EOA over the first 3–6 months with resolution of the perivalvular swelling (see Fig. 15.67).[92] Leaflet mobility, thickness, and integrity, as well as the stability of the valve within the annular area should all be checked.

The Doppler examination allows both qualitative and quantitative evaluations including presence, direction, and width of normal and abnormal blood flow in and around the prosthetic valve.[54,93] Visualization of the three levels of the regurgitant jet is useful to better define the anatomy and severity of AI.[70] While qualitative imaging includes both transesophageal (TE) and gastric windows, most of the quantitative assessment is best achieved from the stomach where blood flow and the Doppler beam can be best aligned to allow measurement of the maximum flow velocities (Figs. 15.66 and 15.68).[17,20–22]

Aortic Regurgitation

AI/AR results from either primary aortic leaflet/valve abnormalities or secondarily from ascending aortic pathology.[21,22,85,87,92,93] Trace or mild AI may be seen in the absence of significant pathology, however, this occurs in the minority or cases (<20%). Similar to the MV, regurgitant lesions can be grouped based on leaflet pathology and mobility (normal, excessive, and restricted). Primary valve pathologies

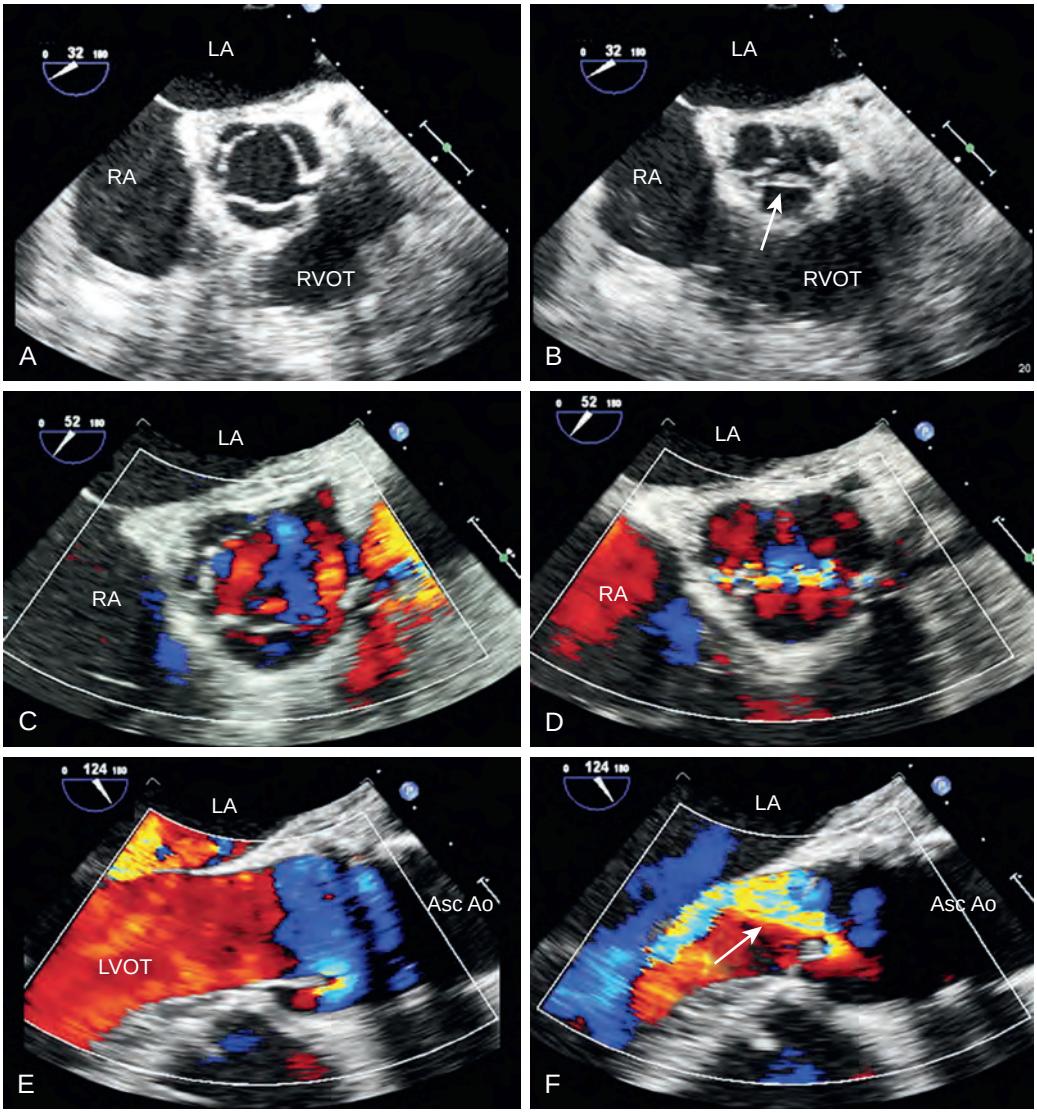

Fig. 15.62 Aortic valve (AV) leaflet fenestrations. AV in (A–D) short- and (E and F) long-axis views during systole *(left column)* and diastole *(right column)*. (B) Right coronary cusp *(arrow)* appears redundant. In the figure immediately below (D) AV insufficiency is seen at the same level where the valve appears redundant (E). (F) shows an eccentric aortic insufficiency jet which appears to be directed away from the right coronary cusp. *Asc Ao,* Ascending aorta; *LA,* left atrium; *LVOT,* left ventricular outflow tract; *RA,* right atrium; *RVOT,* right ventricular outflow tract.

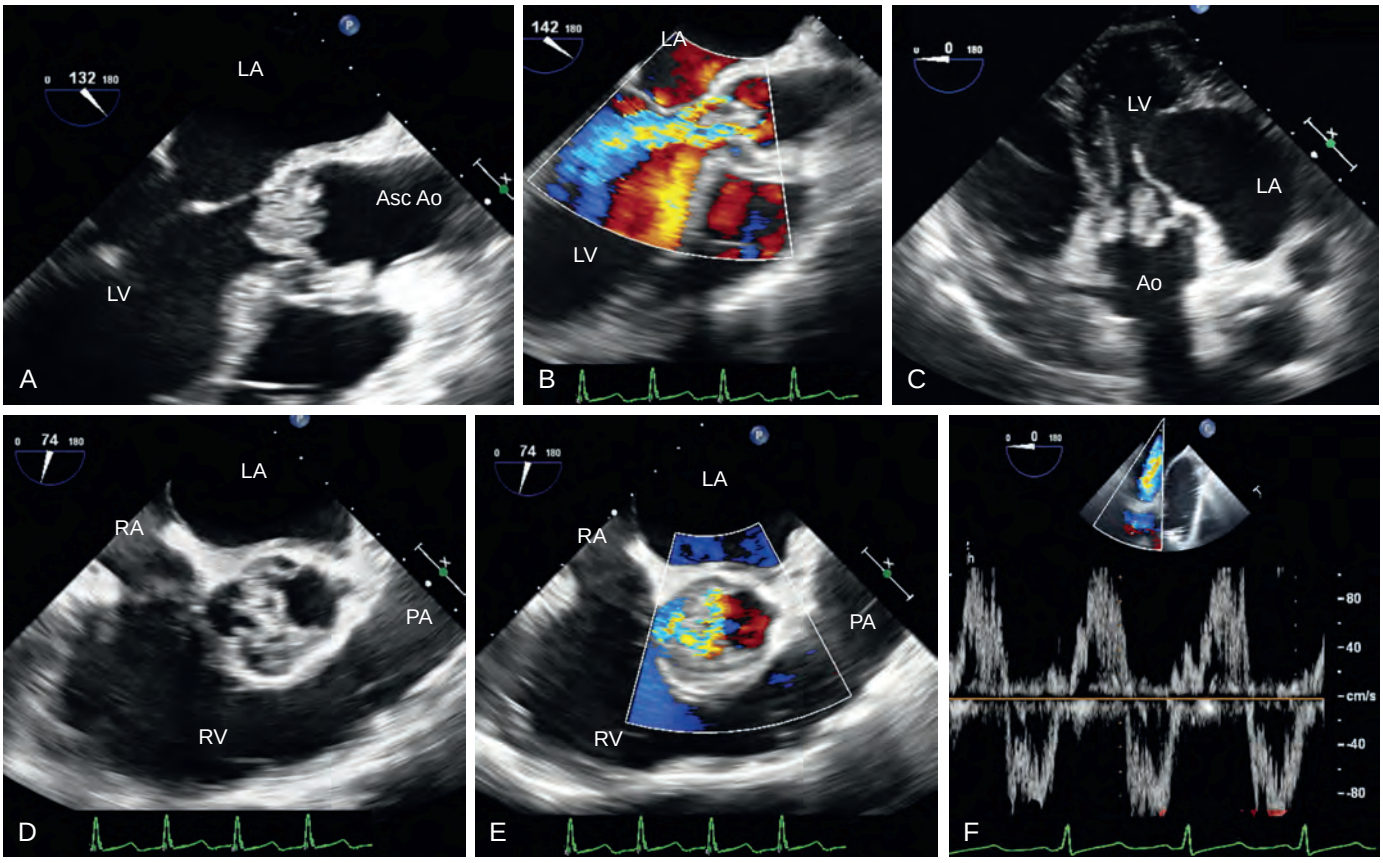

Fig. 15.63 Aortic insufficiency caused by endocarditis. Endocarditis of the aortic valve (AV) can manifest with a range of leaflet/annular/aortic disease and insufficiency. (A) and (B) Significant leaflet involvement and severe insufficiency. (C) Transgastric imaging showing significant involvement of the AV. (A–C) show thickened, irregular, and flail AV leaflets, which are associated with large mobile masses. (D) and (E) AV in short-axis view with and without color Doppler, showing severe insufficiency. (F) Pulsed-wave Doppler of the ascending aorta showing diastolic flow reversal consistent with severe dysfunction. *Asc Ao,* Ascending aorta; *LA,* left atrium; *LV,* left ventricle; *PA,* Pulmonary artery; *RA,* right atrium; *RV,* right ventricle.

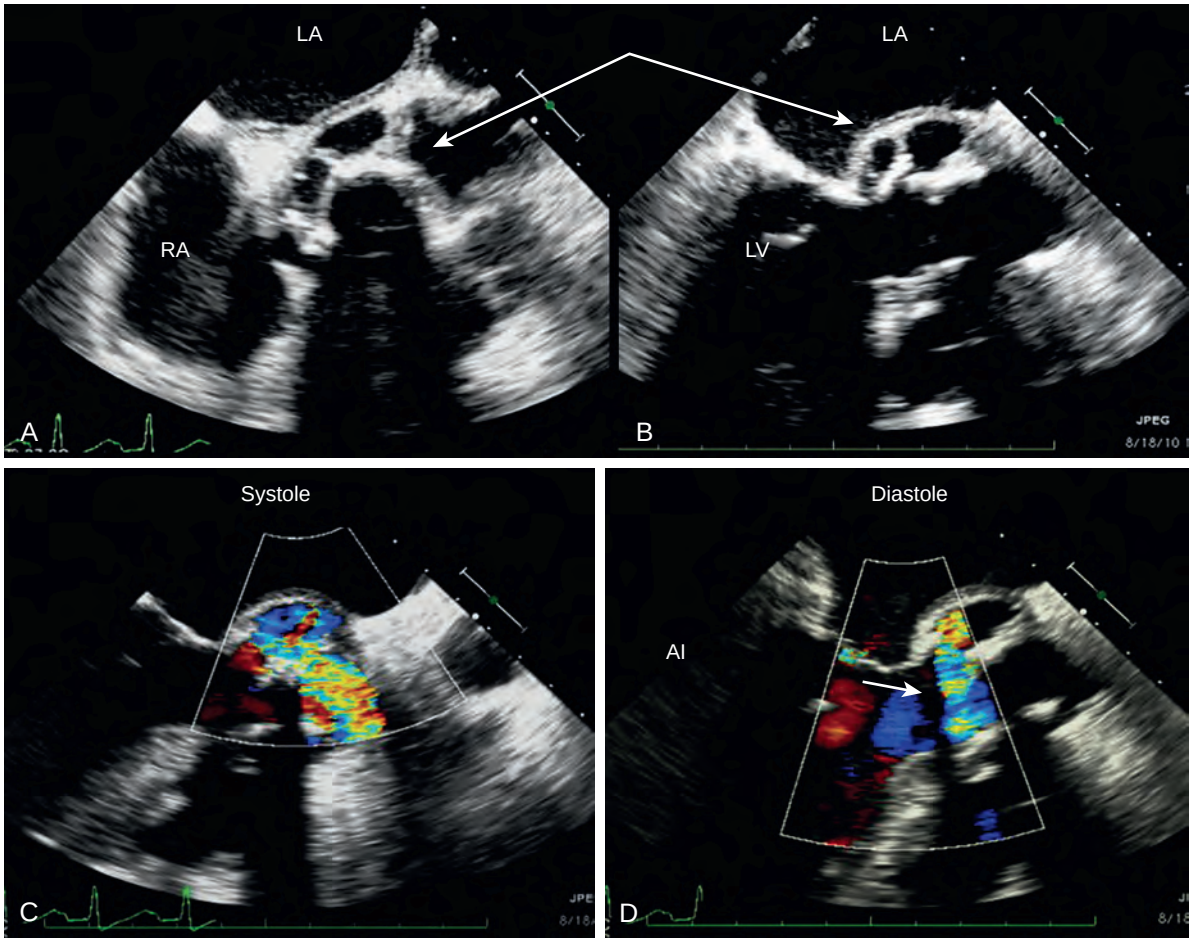

Fig. 15.64 Periaortic abscess. Periprosthetic aortic abscess highlighted by an echolucent space surrounding a previously placed bioprosthetic valve. (A) and (B) Valve in short and long axes. (C) and (D) Color Doppler imaging in the long-axis window during systole and diastole, the latter demonstrating aortic insufficiency *(AI)*. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

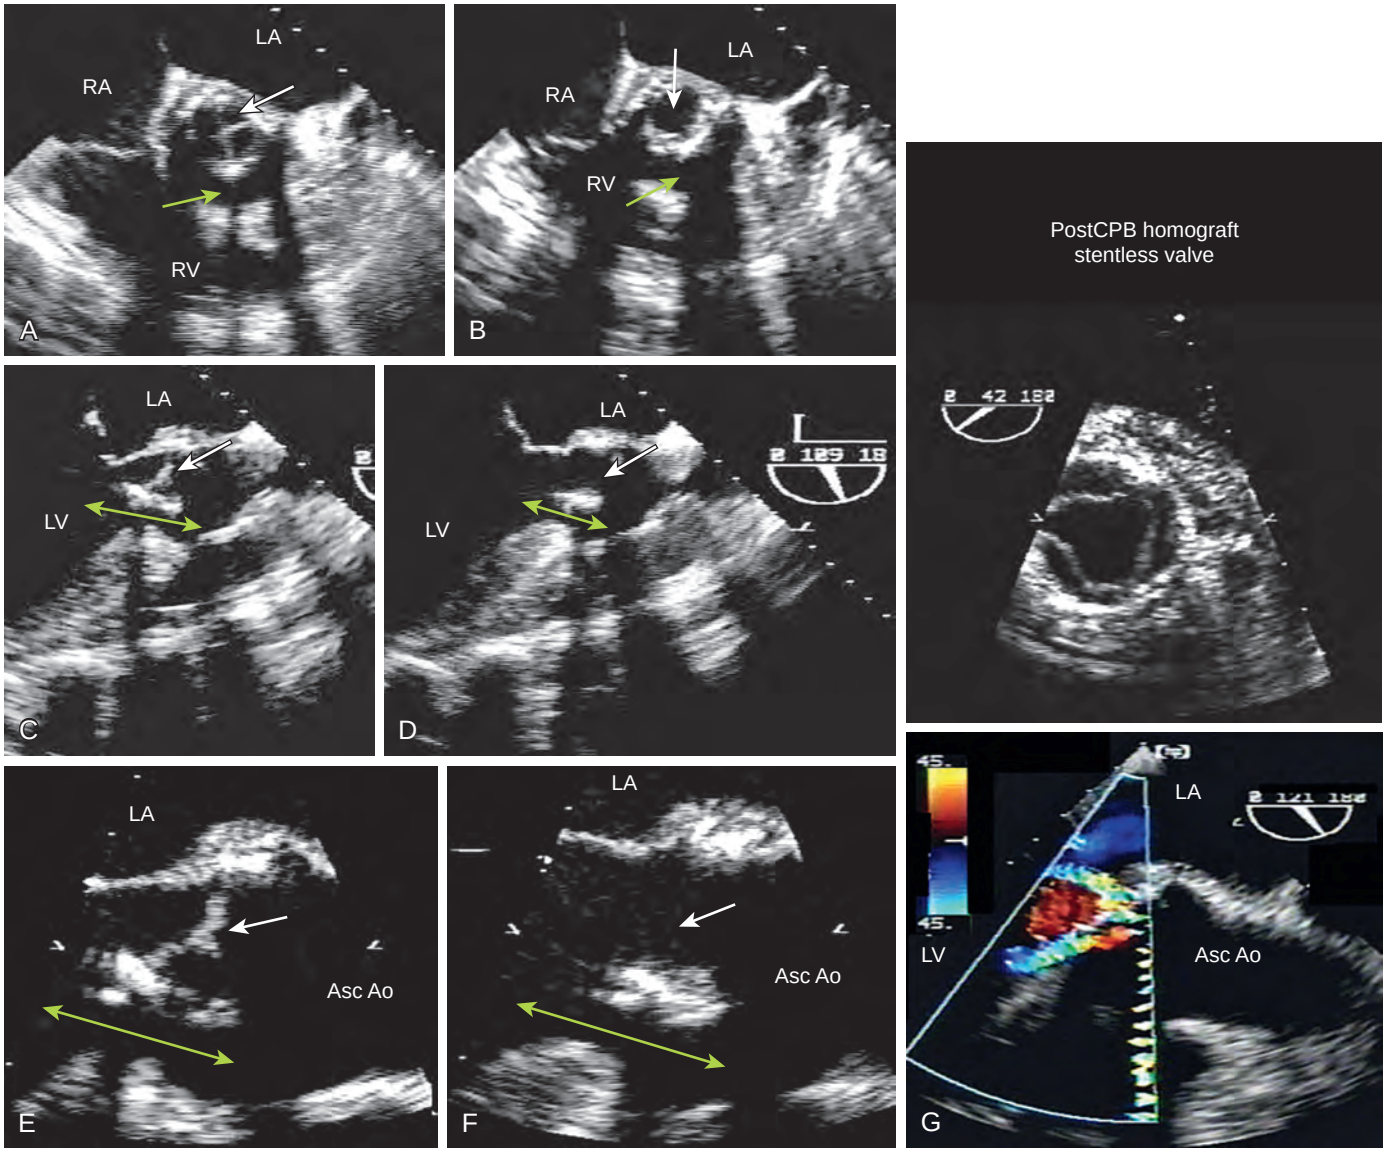

Fig. 15.65 Aortic bioprosthesis dehiscence. Multiple images of a normally functioning bioprosthetic valve that has separated from the anterior part of the native annulus (ie, dehiscence). (A), (C), and (E) were obtained during diastole and (B), (D), and (F) during systole. The *yellow arrows* point to the site of dehiscence. (G) Complicated eccentric regurgitant color Doppler profile. *Top right,* Postbypass *(PostCPB)* homograft that replaced the previous bioprosthetic valve. *Asc Ao,* Ascending aorta; *LA,* left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

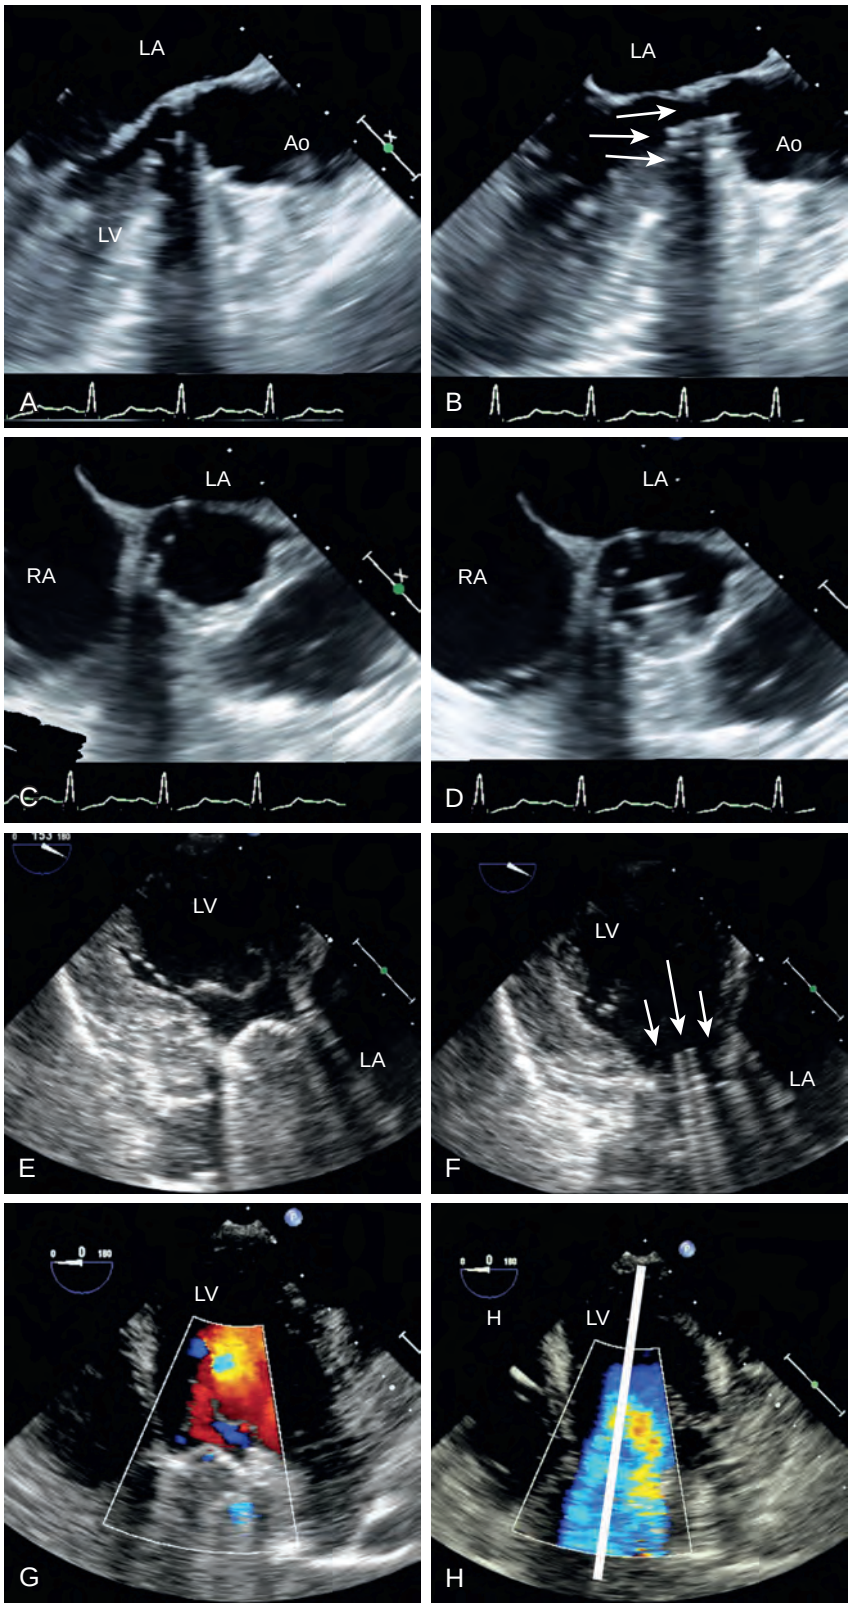

Fig. 15.66 Aortic valve replacement: mechanical valve. Normally functioning bileaflet mechanical valve in the aortic position. Left-sided figures were obtained during diastole and right-sided figures during systole. (A–D) Midesophageal long (A and B) and short (C and D) two-dimensional views of the valve. Normal leaflet mobility is noted by seeing the edges of each leaflet during ventricular systole as seen in (B) and (D). (E–H) Transgastric imaging complements transesophageal imaging. Color Doppler imaging shows (G) insignificant insufficiency and (H) normal Doppler flow during systole. *Ao*, Aorta; *LA*, left atrium; *LV*, left ventricle; *RA*, right atrium.

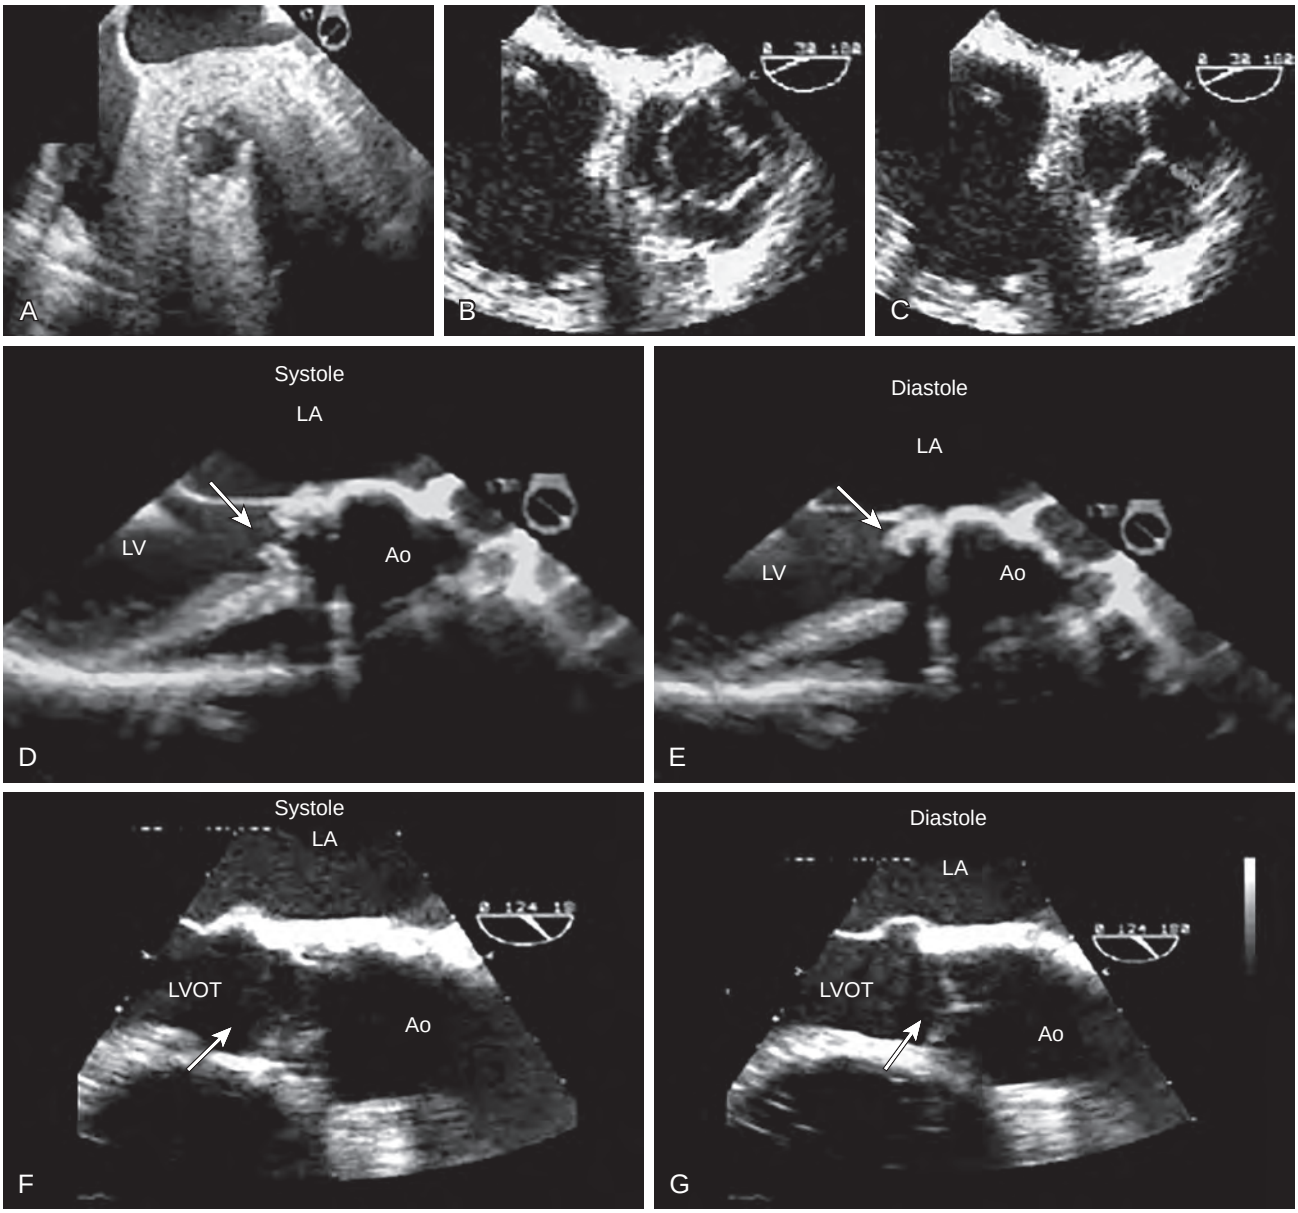

Fig. 15.67 Before and after imaging of a stentless valve in the aortic position. (A–C) Short-axis views of a patient who underwent stentless aortic valve replacement. The period immediately after bypass showed (A) perivalvular thickening caused by either edema or hematoma, which (B and C), within 48 hours was nearly completely resolved. (D–G) Second case, showing long-axis views of a stentless aortic valve. (D) and (E) are immediately after bypass showing the cloth edges of the stentless valve *(white arrows)* in the outflow tract. These were associated with high systolic gradients and systolic obstruction. (F) and (G) At follow-up, 6 months later, showing the cloth edges to have flattened into the LVOT tissues and associated with a reduction in transvalvular pressures and an increase in the calculated effective orifice area. The valvular hemodynamics of the stentless valve is known to improve between 24 hours and 6 months after placement. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle; *LVOT,* left ventricular outflow tract.

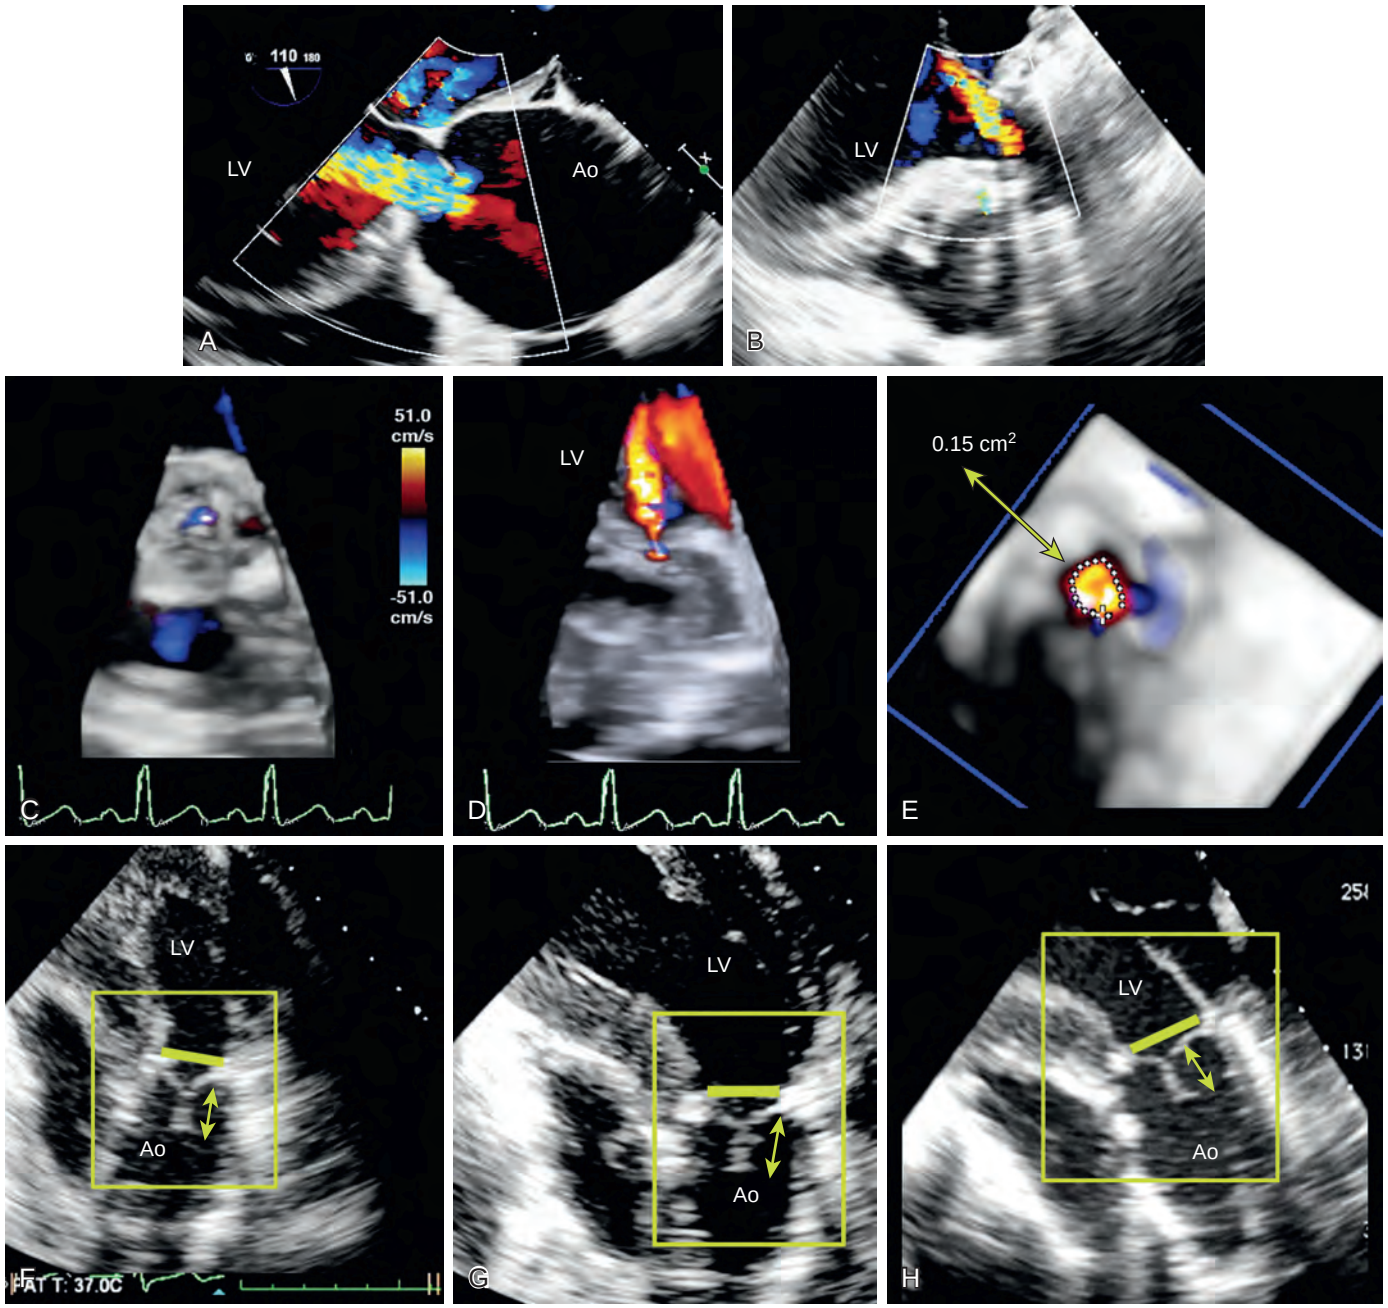

Fig. 15.68 Aortic insufficiency (AI) and repair. These images demonstrate the benefits of performing a comprehensive echocardiographic exam using different ultrasound modalities and both transesophageal and gastric windows. (A) Prerepair and (B) postrepair midesophageal long-axis color Doppler views show significant AI. Postrepair image shows a significant color Doppler profile but the valve is not well seen. (C) Midesophageal and (D) and (E) transgastric windows, three-dimensional volumetric color data sets allow visualizations of the regurgitant jet below, at, and above the valve. (D) Narrow jet of insufficiency at the valvular level, which expands due to entrainment. Editing the data set allows planimetry of the regurgitant jet, which measures 0.15 cm^2 in area consistent with mild AI. (F–H) Transgastric two-dimensional images allowing visualization of the coaptation level (ie, no residual prolapse; *solid line*) and coaptation length *(arrows-line). Ao,* Aorta; *LV,* left ventricle.

include bicuspid AV, quadricuspid AV, myxomatous degeneration (fibroelastic disease), fenestrations, endocarditis, calcification (often associated with AS), radiation therapy, rheumatic disease, and trauma (Figs. 15.61–15.63, 15.69, and Table 15.6). The AV also can be involved in association with a subvalvular membrane or a VSD (Fig. 15.70). Leaflets may prolapse or flail, or display fenestrations, masses, or calcification. Secondary causes include aortic root pathology such as dilation, dissection, and infection in which the aortic leaflets may be involved or appear normal (see Figs. 15.60, 15.64). Determining the cause of AI is important to determine the best mode of therapy and whether or not the valve can be repaired or requires replacement.

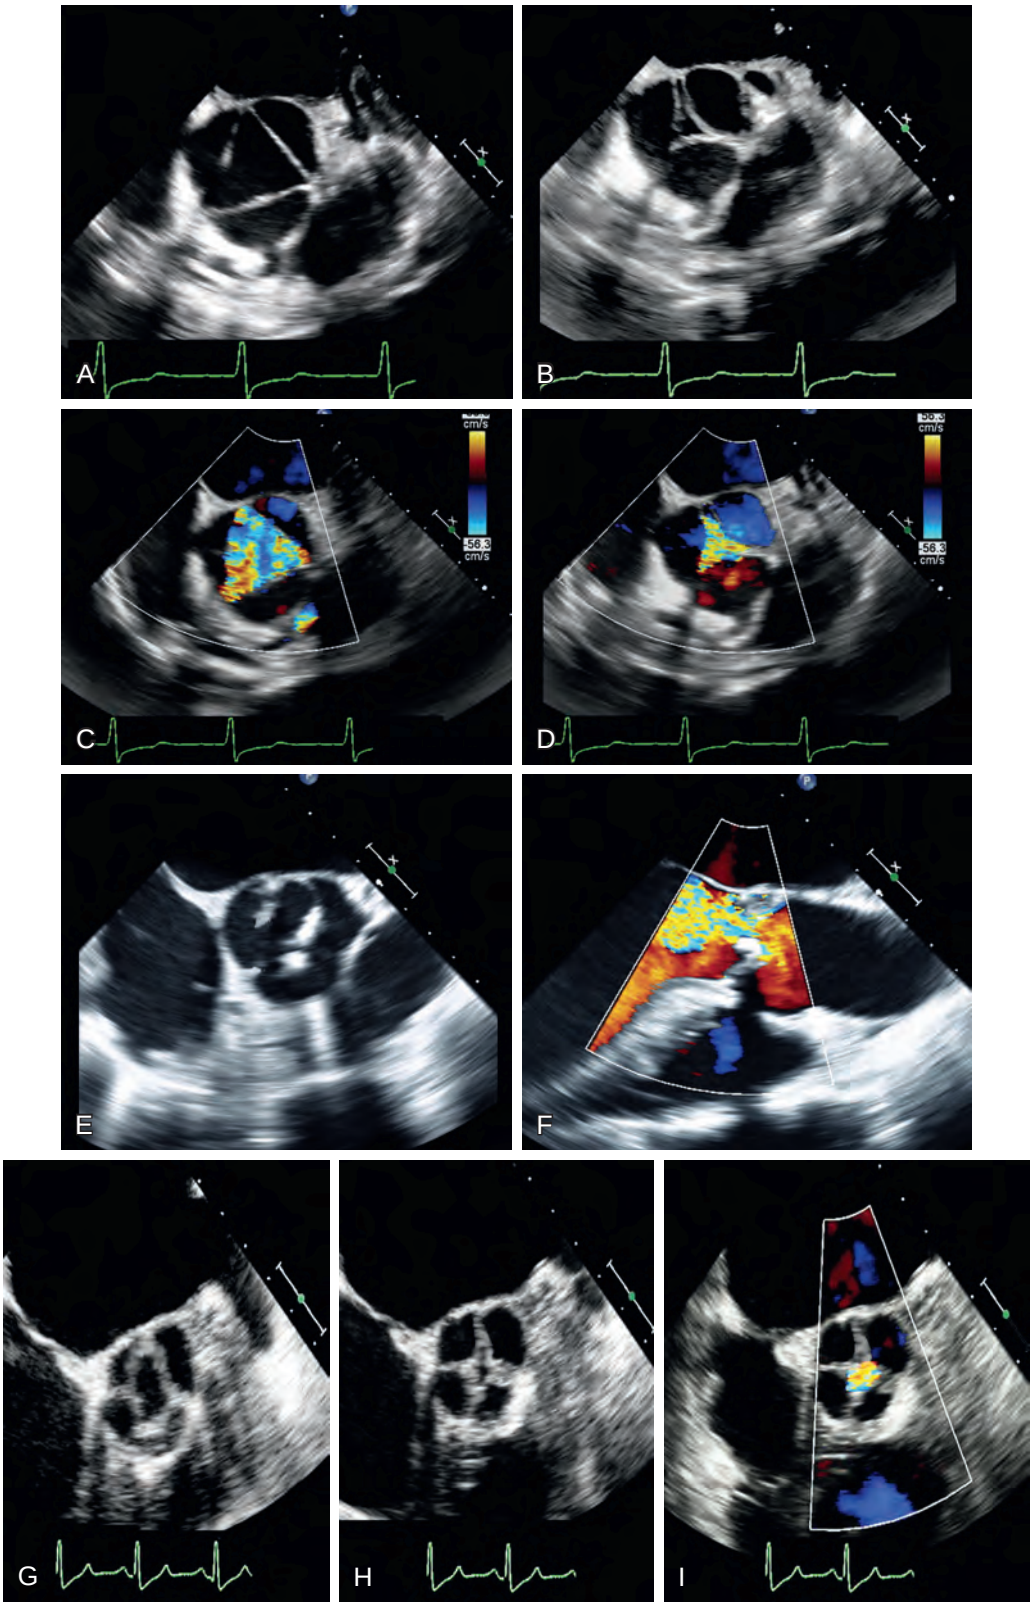

Fig. 15.69 Aortic valve (AV): bicuspid, trileaflet, quadricuspid. (A) and (B) Trileaflet valve associated with a dilated aorta. (C) The same valve during ventricular systole. (D) Centrally directed aortic insufficiency (AI) jet. (E) and (F) Bicuspid valve with AI. Bicuspid valves may manifest with either primary stenosis, regurgitation, or a mixed dysfunction. Associated disorders may include aortic root dilation, aortic coarctation, and/or mitral valve degenerative disease. (G–I) Quadricuspid AV during systole *(left),* and diastole *(middle and right).* The color Doppler analysis shows mild to moderate AV insufficiency. AV insufficiency is the predominant finding/dysfunction for quadricuspid valves. Of note, unicuspid valves (not shown) manifest primarily with stenosis.

TABLE 15.6 Aortic Valve Regurgitation: Degrees of Severity

	Mild	*Moderate*	*Severe*
Angiographic grade	1+	2 +	3–4+
Jet density/appearance	Faint/incomplete	—	Dense/complete
Color Doppler jet width/LVOT width	<0.25	0.25–0.65	>0.65
Doppler vena contracta (cm)	<0.3	0.3–0.6	>0.6
Pressure half time (ms)	>450	250–450	<250
Pulsed-wave Doppler ascending/descending aorta	—	—	Reversal
Regurgitant volume (mL/beat)	<30	30–60	>60
Regurgitant fraction (%)	<30	30–60	>60
Regurgitant orifice area (cm^2)	<0.3	—	>0.3
Secondary findings	LAE, LVE, LVSD, PHTN		

LAE, Left atrial enlargement; *LVE,* left ventricular enlargement; *LVOT,* left ventricular outflow tract; *LVSD,* left ventricular systolic dysfunction; *PHTN,* pulmonary hypertension.

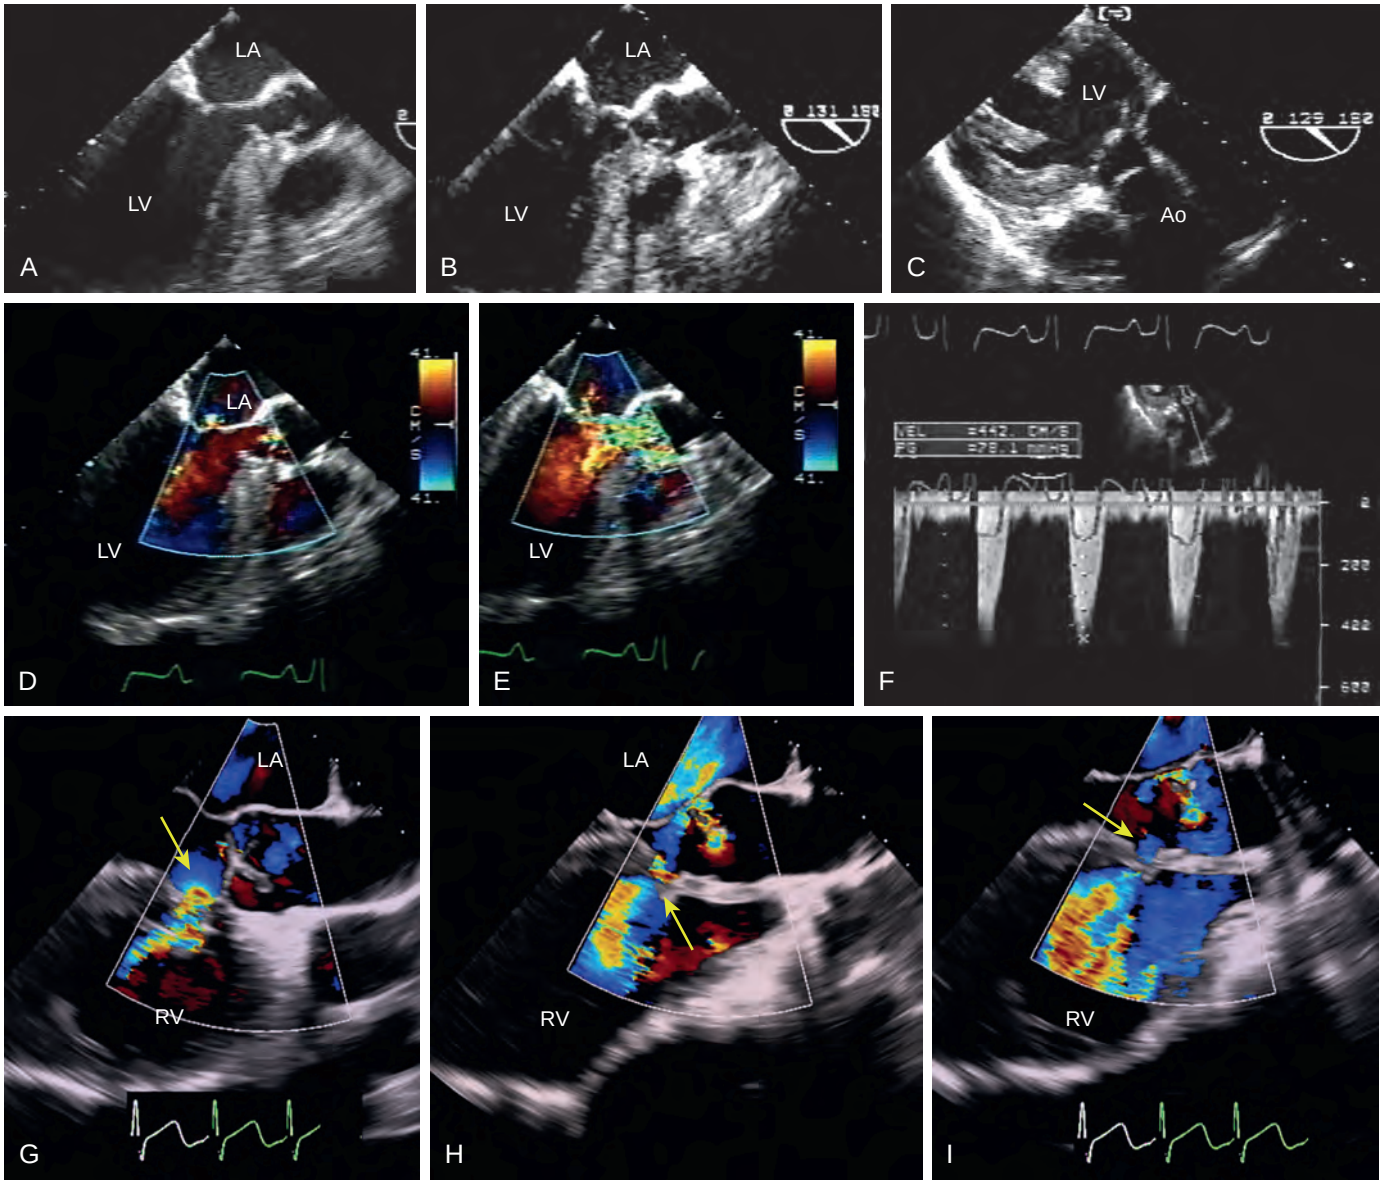

Fig. 15.70 Subaortic valve membrane and ventricular septal defect (VSD). (A) Subaortic valve membrane during systole with evidence of good systolic excursion of the aortic valve (AV) leaflets. (B) Subaortic valve membrane during systole. (C) Transgastric image showing the subaortic valve membrane appearing parallel to the close AV. (D) Color Doppler image showing mild AV insufficiency. (E) Turbulent outflow consistent with a fixed outflow obstruction. Interrogation with continuous-wave Doppler across the left ventricular outflow tract records a gradient greater than 70 mm Hg. Given the normal excursion of the aortic leaflets, the elevated gradient is due to subvalvular obstruction. (G) VSD *(yellow arrow).* (H) and (I) VSD and coexistent (or associated) AV insufficiency. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle.

Aortic Valve Regurgitation of the Prosthetic or Repaired Valve

Prosthetic valves are associated with a "normal" signature or expected regurgitant jets and should be differentiated from "abnormal" flows. Normal or nonproblematic regurgitant jets are less than 3 mm in width and do not extend far from the valve.[21,22,87,92,93] Bioprosthetic valves typically display a central regurgitant jet, while mechanical leaflets display a variety of regurgitant jets depending on the valve type. Imaging parallel to the valve leaflets will allow better visualization of the normal two regurgitant jets directed centrally. A single-leaflet valve (or tilting disk valve) has one larger and one smaller jet, while the ball-in-cage valve will have a surrounding series of small jets. Abnormal paravalvular regurgitant jets are greater than 3 mm in width and/or are eccentrically directed away from the middle.[56] Smaller jets may also be considered abnormal, but in the absence of obvious pathology (mobile materials; valve instability) these do not tend to progress over time.[54] Abnormal flows can result from a number of causes. Prosthetic valve incompetence is similar to that of native valves with some additional etiologies. These include endocarditis, leaflet deterioration or degeneration, restricted leaflet mobility, or valvular dehiscence/abscess. As with other prosthetic valves, the defect may occur within the aortic prosthesis or around it (paravalvular).

Repair of the AV generally is applied to regurgitant valves.[54,85,87,93] Although the goal is to eliminate regurgitation, mild or less AI is acceptable (see Fig. 15.60).[85,87,92] The location and direction of the regurgitant jet depends on the pre repair pathology and the repair technique. The repair can be assessed before separating from cardiopulmonary bypass by filling up the proximal aorta and generating pressure on the valve (see Fig. 15.60). Either by noting spontaneous echo contrast, or with the color gains adjusted lower, it is possible to assess residual regurgitation. Long-term function (return of AI or need for reoperation) is determined by the coaptation level (no residual prolapse), coaptation length (>6 mm), and severity of residual AI (see Figs. 15.60 and 15.68).[85,87,92]

Hemodynamics and pathophysiologic cardiac changes associated with AI depend on the acuity. Acute AI due to aortic dissection, endocarditis, or trauma causes an acute volume load to the left ventricle causing increased ventricular pressures, myocardial stress, and oxygen consumption. Since the left ventricle has not had time to compensate, the increase in LV end-diastolic volume is relatively less compared to the increase in LV end-diastolic pressure. This is transmitted backward to the left atrium and the pulmonary vasculature, causing pulmonary edema. In order to maintain forward flow, LV contractility and heart rate must increase.

Cardiovascular changes with chronic AI result from a prolonged increase in ventricular volume and pressure overload, ultimately causing myocardial stretch/dilation, and increased myocardial oxygen consumption ($M\dot{V}O_2$). Initially, concentric (or eccentric) hypertrophy occurs and contractility is preserved. With continued progression there is a greater amount of ventricular dilation compared to hypertrophy. The ventricular walls start to thin and LV pressures do not initially increase. The AI causes impairment of isovolumic relaxation and results in a large pulse pressure with a low systemic diastolic blood pressure. Myocardial ischemia occurs due to increases in $M\dot{V}O_2$ (secondary to ventricular stretch and increased LV pressure), as well as lower systemic diastolic blood pressures reducing coronary perfusion. The various changes ultimately result in a reduced LVEF, and increased left heart and pulmonary pressures, the latter two associated with clinical decompensation.

Assessing regurgitant flow of the AV is similar for both native and prosthetic valve disease (see Table 15.6). It is necessary to know what is expected for native valves and acceptable prosthetic valves. For example, a single-leaflet valve (or tilting disk valve) will have a regurgitant jet directed away from the sewing ring from the edge of the major orifice. Homografts should NOT have any regurgitant jets; however, they may be seen depending on the native valve function prior to excision and preparation. 2D imaging identifies the number and mobility and integrity of the leaflets as well as the stability of the valve to determine the integrity of the surrounding tissues. A valve that appears to rock or one that has an echolucent space within the aortic wall, or in between the prosthesis and surrounding tissues, might suggest infection and/or dehiscence.

Assessing AI severity begins with CFD to identify the regurgitant jet, direction, and make an initial qualitative assessment.[20] Although the color Doppler jet area has been described, it is less accurate to quantify AI severity. There are indirect and direct methods that are more accurate to quantify AI severity.[69,94] The former includes assessment of the VC (narrowest jet width just beyond or downstream to the AR orifice), and the ratio of the proximal jet width to the width of the LVOT (see Fig. 14.76). The limitations to the VC and jet width ratio occurs when either the LVOT cannot be seen clearly due to imaging artifact from prosthetic materials, or when the AI jet is either eccentric and/or complex.[62,70] The PHT or DT is used to assess the pressure changes across the regurgitant orifice as a reflection of the ROA.[95,96] A small PHT (<450 ms) reflects significant (more than mild) AI (Fig. 15.71). However, the PHT is affected by net chamber compliance. For a given severity of AI, PHT is shortened with increasing LV end-diastolic pressure, vasodilator therapy, and in patients with a dilated

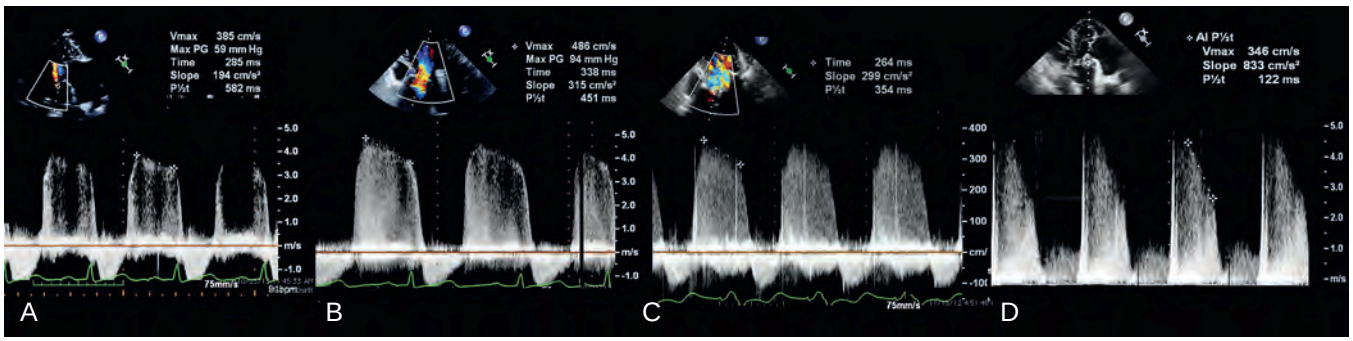

Fig. 15.71 Pressure half time (PHT): aortic insufficiency (AI). (A–D) From *left* to *right* the Doppler profiles show reduction in PHTs from 582 ms to 122 ms, which is consistent with increasing severity of AI. The limitation of the PHT assessment is the impact on net compliance, which in turn is affected by a host of variables including acuity of AI, coexistence of aortic valve stenosis, and a history of hypertension. Although supportive of different degrees of AI, the PHT assessment should not be used as the sole determinant of AI severity. Qualitatively, the Doppler profile in (A) is not as dense or complete as the others, reflecting the regurgitant volume. The more cells that pass through, the more dense the flow profile will be.

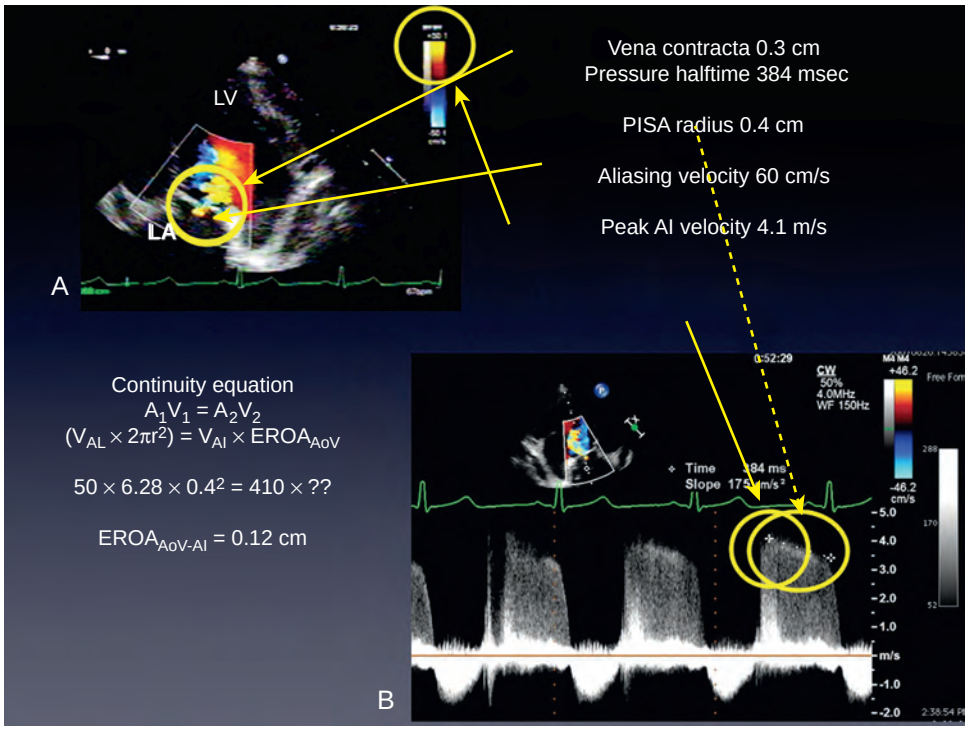

Fig. 15.72 Use of the flow convergence method to assess the severity of aortic insufficiency (AI). In this case the effective regurgitant orifice area *(EROA)* is 0.12 cm^2 and consistent with mild AI. This is also consistent with a vena contracta of 0.3 cm. The pressure half time of 384 ms would suggest moderate AI, but this measure is significantly affected by changes in net chamber compliance between the aorta *(Ao)* and left ventricle *(LV)*. *LA,* left atrium; *PISA,* proximal isovelocity surface area.

compliant aorta, or lengthened in chronic AI.[20,96] Thus, this parameter serves only as a complementary finding for the assessment of AI severity.

The PISA method has been utilized to measure ROA and regurgitant volume (Fig. 15.72).[70]

$$CSA_{AI} \times V_{PeakAIVel} = (2pr_{PISA}{}^2 \times V_{NL})$$
$$CSA_{AI} = (2pr^2 \times V_{NL}) / V_{PeakAIVel}$$

If the EOA were multiplied by the TVI (continuous-wave Doppler), the result would be the volume flowing across the orifice each cardiac cycle. For a regurgitant valve, this would be the regurgitant volume:

$$\text{Regurgitant volume}_{AI} = EOA_{AI} \times TVI_{AI}$$

Other Doppler methods include documentation of diastolic flow reversal (severe AI) in the ascending or descending aorta, the former being more sensitive, while the latter is more specific. The continuity equation may be used to determine the regurgitant volume as the difference between the SV across the PA and the AV.

$$SV_{PA} = SV_{AV} - \text{Regurgitant volume}_{AI}$$

When feasible, either with 2D or 3D imaging, the ROA can be obtained by planimetry.

Quantifying the severity of regurgitant flow[20–22,85] is similar for native and prosthetic AVs (see Table 15.6). For prosthetic valves, regurgitant jet widths less than 3 mm are either consistent with normal regurgitant flows or suggest that such a small abnormal flow is not likely to progress. Findings consistent with significant abnormal (more than moderate) prosthetic AR include dense or complete regurgitant jets, VC greater than 0.3 cm, regurgitant jet width/LVOT diameter ratio higher than 25%, PHT less than 400 ms, ROA greater than 0.3 cm^2, regurgitant volume greater than 30 mL/beat, and a regurgitant fraction greater than 30%. Severe AR may be defined as a VC greater than 0.6 cm and an ROA greater than 0.6 cm^2. Diastolic flow reversal in the aorta is consistent with more than moderate AR. The flow convergence method has been applied to determining AR, but is less studied. Mild, moderate, and severe AR are defined as ROA of less than 15 mm^2, 15.30 mm^2, and greater than 30 mm^2, respectively. These ROAs are associated with regurgitant volumes of less than 30, 30 to 60, and greater than 60 mL/beat. For chronic AR, secondary changes in cardiac geometry and function support the presence of significant (moderate or greater) AR, including ventricular dilation, contractile dysfunction, LA enlargement, and pulmonary hypertension.

Surgical Indications

With the goal of preventing long-term dysfunction, surgical treatment of AI should be performed[24–26] (Fig. 15.73). Indications include symptomatic patients with severe AI. Surgery is also indicated for asymptomatic patients with severe AI and LV systolic dysfunction defined as an LVEF less than 50%, and/or a dilated left ventricle described as an LV systolic diameter larger than 50 mm, LV end-diastolic diameter greater than 70 mm, and/or LV end-diastolic volume index greater than 110 mL/m^2.[97] Surgery is also recommended for asymptomatic severe AI in patients undergoing other cardiac surgical and/or ascending aortic procedures.[24–26]

Aortic Stenosis

Changes in the native AV architecture occur with age and commonly include thickening found in more than 20% of patients older than 65 years and up to a 4% incidence of AS found in patients older than 85 years. The vast majority of fixed native AS is due to elderly (or senile) calcific trileaflet AS.[17] This is followed by bicuspid AS and rheumatic AS (see Figs. 14.64 and 14.65; Video 14.52; Table 15.7). Other less common outflow obstructions include unicuspid valve, supravalvular stenosis (eg, Williams syndrome), and subvalvular obstruction, for example, membrane (see Fig. 15.70). Hypertrophic obstructive cardiomyopathy is a dynamic form of obstruction that should be delineated

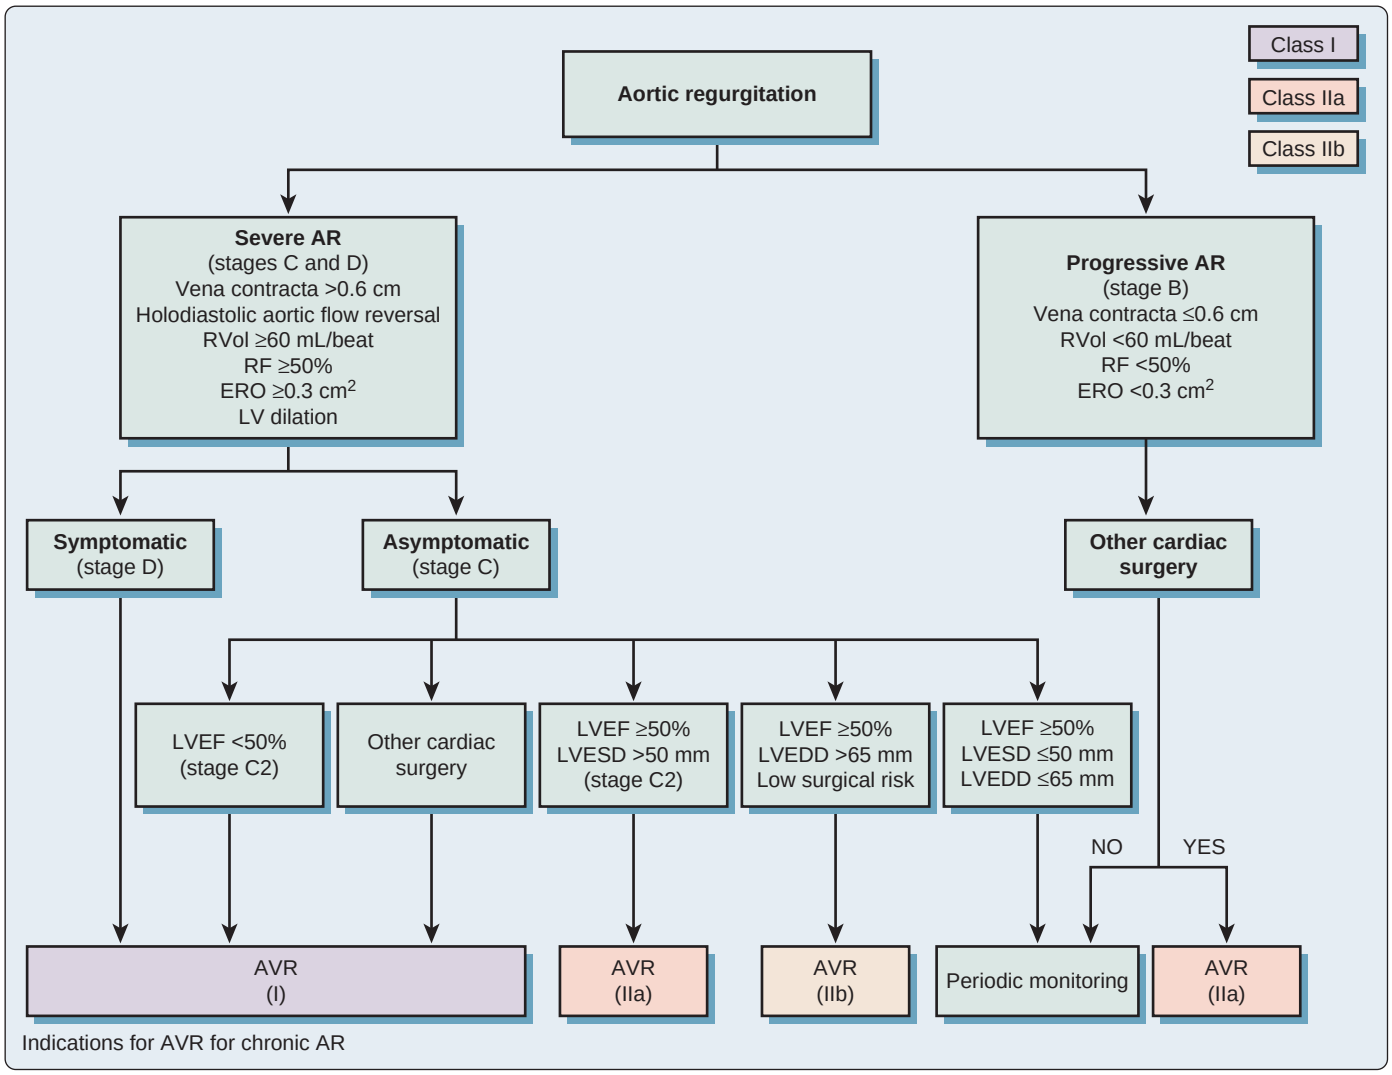

Fig. 15.73 Decision algorithm for aortic insufficiency (AI). The decision algorithm was taken as a consensus by an expert panel and based on outcome data and interpretation. Decisions are classified as class I, class IIa, class IIb, the former being supported by sufficient evidence such that intervention should be performed, while the latter two are supported by evidence that suggests that the benefits of intervention outweigh the risks and that intervention is reasonable based on multiple (IIa) or isolated trials or nonrandomized data (IIb). Treatment for AI usually includes percutaneous intervention. The decision is based on a number of considerations including severity, presentation (symptoms), changes in cardiopulmonary function, repairability, and timing (ie, whether or not another primary cardiac procedure was being performed). *AR,* Aortic regurgitation; *AVR,* aortic valve replacement; *ERO,* effective regurgitant orifice; *LV,* left ventricle; *LVEF,* left ventricular ejection fraction; *LVEDD,* left ventricular end-diastolic diameter; *LVESD,* left ventricular end-systolic diameter; *RF,* regurgitant fraction; *RVol,* regurgitant volume. *(Reprinted with permission from Nishimura RA, Otto CM, Bonow RO, et al. 2014 AHA/ACC guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines.* J Am Coll Cardiol. *2014;63:e57–e185.)*

TABLE 15.7 Aortic Valve Stenosis: Degrees of Severity

	Mild	*Moderate*	*Severe*
Jet velocity (m/s)	<3.0	3.0–4.0	>4.0
Acceleration time (ms)	<100		>100
Mean pressure gradient (mm Hg)	<25	25–40	>40
AV area (cm^2)	>1.5	1.0–1.5	<1.0
AV area index (cm^2/m^2)	>0.85	0.85–0.65	<0.65

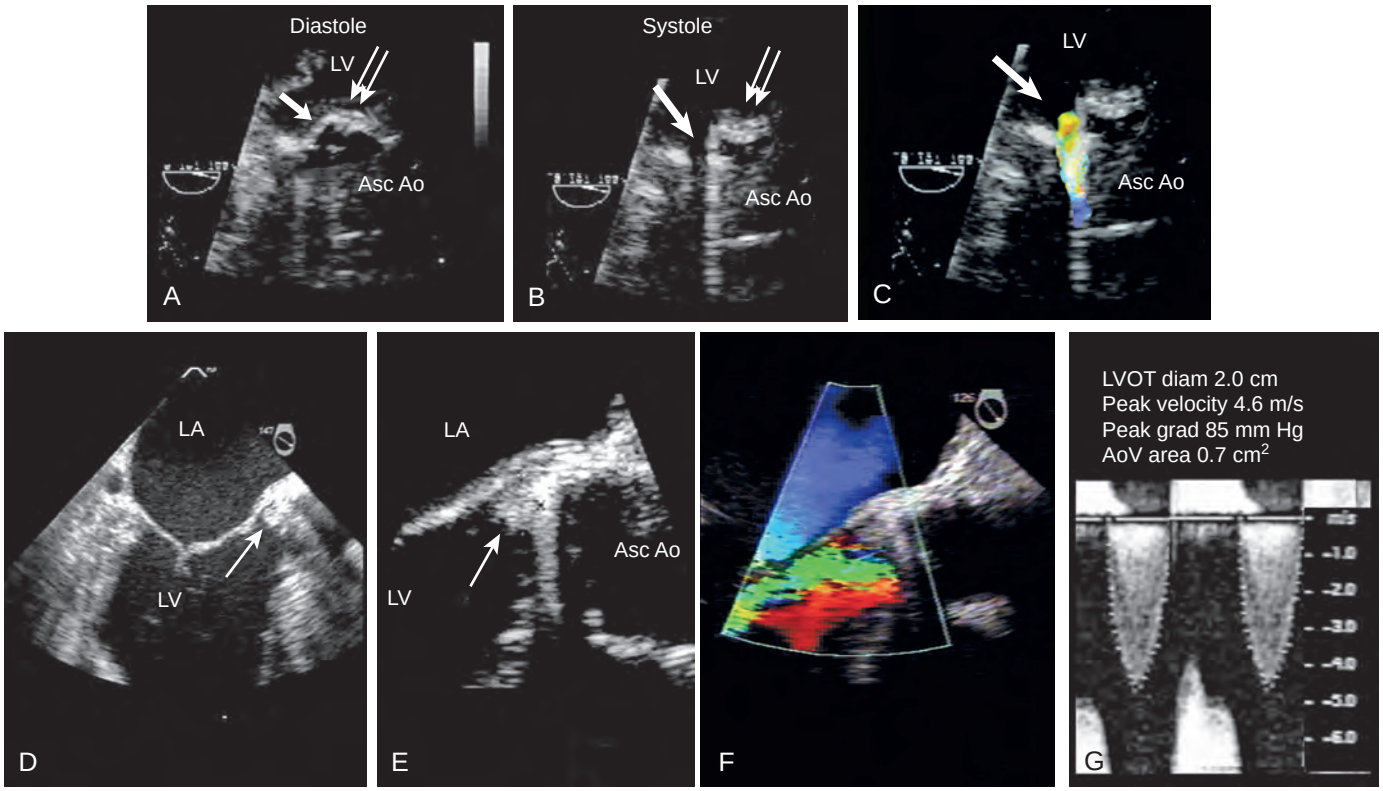

Fig. 15.74 Prosthetic valve stenosis. Two causes of prosthetic valve stenosis include a stuck mechanical leaflet (A-C), and an obstructing mass (D-G) due to thrombus or pannus. The *arrows* in (A) and (B) point to the mechanical leaflets. The transgastric images are obtained during diastole (A) and systole (B). During diastole (A) the *single and double arrows* point to the closed leaflets. During systole (B) the *single arrow* points to the open leaflet while the double arrows point to a persistently closed leaflet, which is confirmed with color Doppler (C) showing flow through the one orifice *(arrow)*. (D)–(G) Echo dense mass obstructing the aortic valve orifice in a patient after aortic valve replacement with a mechanical valve. These masses (*arrows* in D and E) were likely clot given history of recent discontinued coumadin. (F) Color and (G) continuous-wave Doppler imaging show mixed dysfunction of insufficiency and stenosis. *Asc Ao,* Ascending aorta; *AoV,* aortic valve; *LA,* left atrium; *LV,* left ventricle; *LVOT,* left ventricular outflow tract.

from fixed forms of obstruction (see Chapter 24). There is also coexistence of obstruction at different levels.[98]

Trileaflet calcific AS is characterized by calcium collection at the leaflet tips. Rheumatic stenosis is considered with commissural fusion and thickening of the trileaflet valve with a central appearing triangular orifice. Rheumatic AV disease most often occurs in conjunction with MV disease. Bicuspid AS results from fusion of the commissures with or without calcification. The most common configuration of a bicuspid AV is fusion of the right and left commissures with or without a raphe seen. Fusion of the left and noncoronary cusps is least common. A subvalvular membrane may be a simple protrusion of tissue or a circumferential narrowing of the subvalvular space. Supravalvular stenosis appears as an hourglass-shaped deformity in the supravalvular space with or without irregularities of the coronary arteries. Delineating where the obstruction occurs is extremely important to therapy decision making.

Prosthetic Valve Aortic Stenosis

Mild prosthetic AS is not uncommon with the majority of prosthetic valves placed.[21,22] Prosthetic valve areas are less than a normal native AV in the same annular space. Although AVA data vary among different prosthetic valves, in general, a 19-, 21-, or 23-mm prosthetic AV yields an EOA of approximately 1.1, 1.3, and 1.5 cm^2, respectively (see Table 15.3).[88,90,91] Abnormal prosthetic valve stenosis is suspected based on symptoms of heart failure and fatigue, as well as recorded high gradients and/or lower than expected AVA. Causes of prosthetic AS include restricted leaflet motion or mass obstruction (Fig. 15.74).[21,22] Causes of an elevated gradient in the presence of a normally functioning valve include subvalvular obstruction (hypertrophic obstructive cardiomyopathy or a subvalve membrane), supravalvular obstruction, and PPM. Distinguishing flow profiles can identify and differentiate between dynamic outflow tract obstruction, valvular stenosis, and MR (Fig. 15.75).[20,98]

Differences between gradients measured during echocardiography and cardiac catheterization result from pressure recovery phenomena or different techniques to measure peak gradients. The former is the result of energy conversion downstream from the AV, which results in a lower gradient during cardiac catheterization. Doppler echocardiography yields an instantaneous peak gradient while a lower peak-to-peak gradient is measured during invasive catheterization. Regardless, mean gradients remain similar.

Outflow obstruction causes an increase in outflow resistance and an increase in LV stress and pressure. To compensate (ie, maintain forward flow), left ventricular hypertrophy develops and the ventricular contractility increases to overcome the resistance. Although the left ventricular hypertrophy is an important compensation, it also results in diastolic dysfunction. With progression of left ventricular hypertrophy and diastolic dysfunction, hemodynamics become more dependent on a regular heart rate with atrial contraction, diastolic filling time, and maintaining ventricular preload. Over time, increased wall stress, left ventricular hypertrophy, diastolic dysfunction, and increased $M\dot{V}O_2$ with reduced coronary flow reserve result in ischemia, contractile

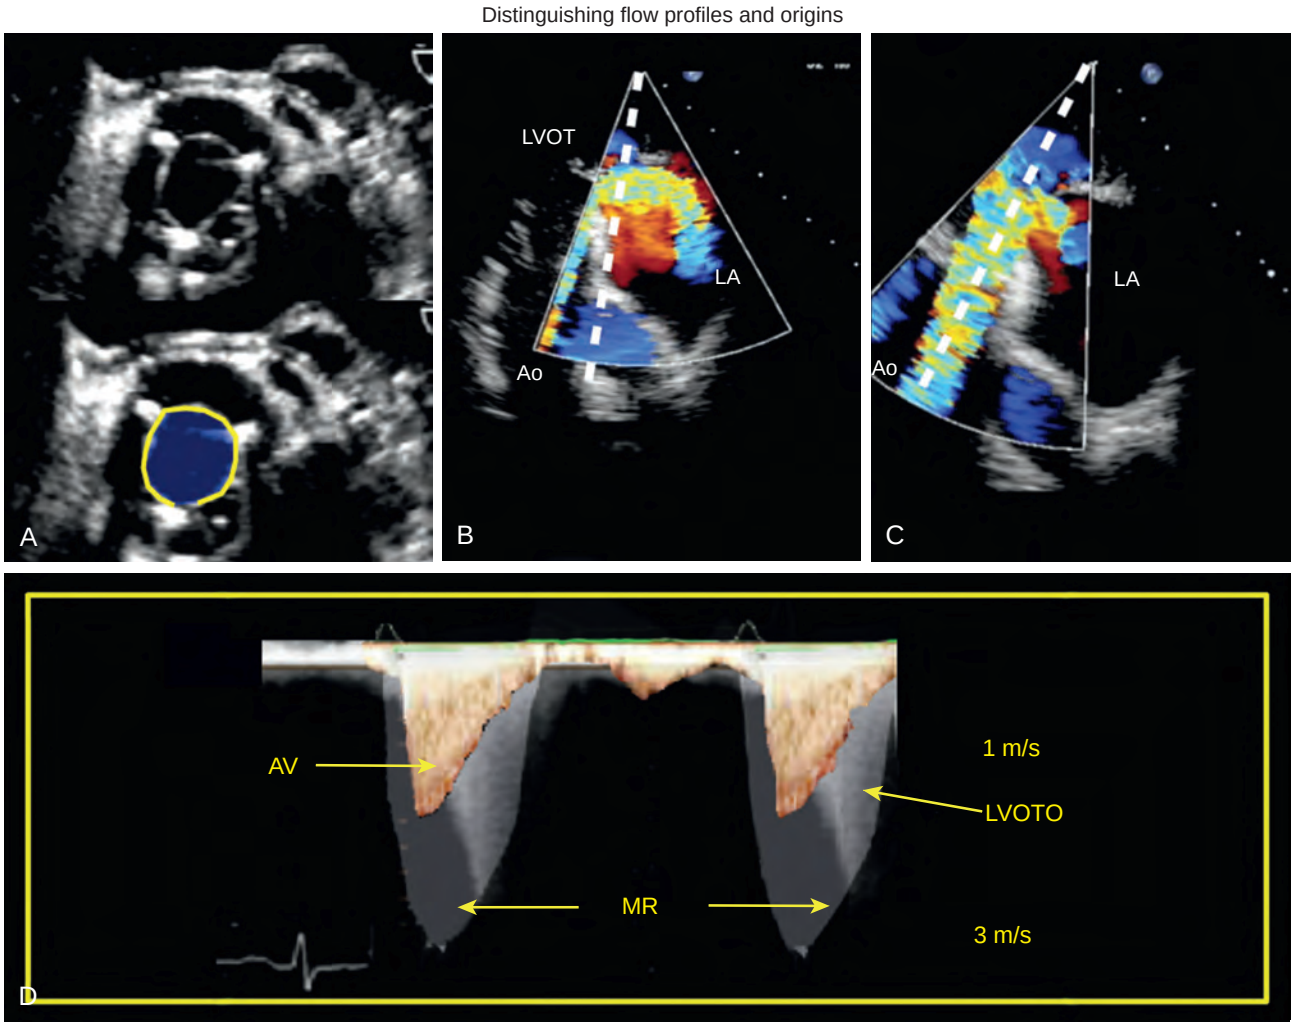

Fig. 15.75 Flow profiles. (A) Short-axis view of a normally functioning bioprosthetic valve immediately after aortic valve replacement. (B) and (C) The period after bypass is complicated by dynamic outflow tract obstruction and mitral regurgitation *(MR)*. (D) Three different Doppler flow profiles recorded during Doppler interrogation from transgastric windows. The valvular profile *(AV)* is lower velocity (approximately 1.5 m/s), early peaking (acceleration time < 80 ms). Left ventricular outflow tract obstruction *(LVOTO)* is a higher velocity late peaking profile. These are distinct from the holosystolic MR profile. *Ao,* Aorta; *LA,* left atrium.

dysfunction, reduced CO, and myocardial fibrosis. Hemodynamic and clinical decompensation occur and regression of left ventricular hypertrophy is less likely to occur despite relief of the obstruction. This is complicated by secondary changes such as increased atrial size and dysfunction with arrhythmias, pulmonary hypertension, and pulmonary edema. Atrial arrhythmias contribute toward further clinical deterioration, and pulmonary vascular changes increase the severity of right-sided heart dysfunction.

Assessing forward flow across the native and prosthetic AV defines valvular hemodynamics and severity of dysfunction[17,21,22] (see Table 15.7). Severity assessment is similar to that of the native AV. Depending on the type of valve, forward blood flow projects in different ways. While bioprosthetic valves have a single forward flow, mechanical valves will have two (single-leaflet) or three (bileaflet) forward projecting jets. Knowledge of expected normal flows helps differentiate them from abnormal valvular flows.

The evaluation includes both qualitative and quantitative assessments, in which the former identifies turbulent or high velocity flows and where to direct the Doppler beams for further quantitative analyses. Although Doppler imaging from ME windows could add to the qualitative assessment, quantitative analysis primarily involves TG imaging in which the ultrasound beam is aligned with transvalvular flow. While stenosis is most commonly a valvular problem, obstruction to ventricular outflow may occur below (subvalvular membrane or hypertrophic obstructive cardiomyopathy) or above the valve (supravalvular stenosis). The coexistence of AI increases flows and, therefore, velocities and gradient.

Qualitatively, AS can be considered based on the presence of turbulence during CFD (exceed Nyquist limit) and/or on the shape of the transvalvular TVI profile[17,21,22] (see Figs. 14-67 and 14-68; Video 14.53) A normal contour of the AV flow velocity profile is an early peaking and triangular shape (see Fig. 15.75). With increasing narrowing or stenosis, the contour peaks later and the shape becomes more round. Along with this change in shape is a respective change in the acceleration time from a relatively short period to the peak velocity (<80 ms) to a more prolonged acceleration phase (>100 ms) consistent with AS.[17,21,22] The profile for AS should be distinguished from those of subvalvular LVOT obstruction and MR, all of which occur in systole (Fig. 15.76).

American Society of Echocardiography level 1 recommendations for assessing AS include measurement of transvalvular jet velocity, calculation of the mean transvalvular gradient, and assessment of the AVA.[17,21,22,88,89] The former two are reflections of AS, and affected by

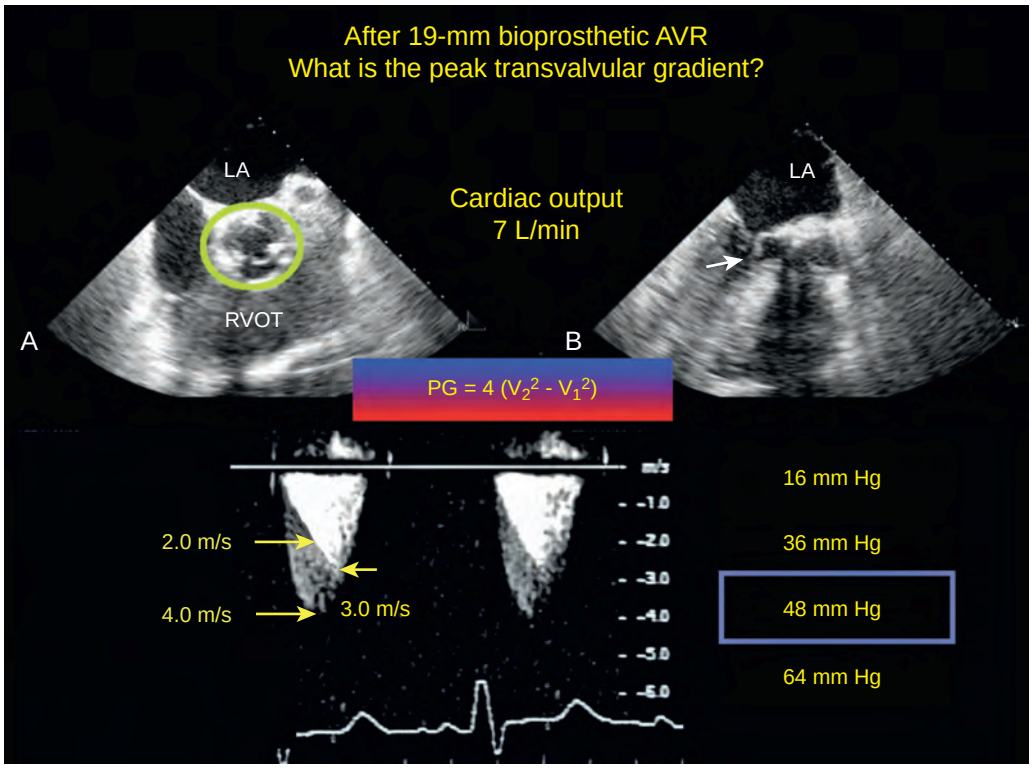

Fig. 15.76 Normal aortic valve *(AV)* and left ventricular outflow tract *(LVOT)*. Short- and long-axis views of the AV during systole. (A) Normally functioning 19-mm bioprosthetic aortic valve. (B) Narrowed LVOT. The continuous-wave Doppler profile shows two distinct flow profiles. The higher peaking profile is generated from the AV while the inner envelope is late peaking and due to dynamic LVOT obstruction. This presents a dilemma when assessing transvalvular gradient, since the subvalvular velocity is high enough it cannot be omitted from the Bernoulli equation. Although the peak velocity is 4 m/s (gradient 64 mm Hg), when considering the subvalvular flows, the more accurate gradient across the valve is closer to 48 mm Hg. *Ao*, aorta; *AVR*, aortic valve replacement; *LA*, left atrium; *PG*, pressure gradient; *RVOT*, right ventricular outflow tract.

chamber pressures and flows.[88,89] The latter can be directly measured, when feasible, using planimetry, or calculated using the continuity equation.

Outcome data and treatment algorithms are based on transvalvular jet velocities and valve area.[99] For velocities less than 3 m/s, AV replacement (AVR) is not recommended and may be of little benefit regarding hemodynamics. A velocity greater than 4 m/s is considered severe and AVR is recommended. For intermediate velocities, other considerations are included in the decision algorithm such as the AVA and amount of AI present. Although simple and reproducible, the evaluator should consider that the jet velocity is dependent on blood flow or CO, as well as the ability to align the ultrasound beam with blood flow.

Peak and mean gradients are calculated from velocities using the Bernoulli equation. Caution must be considered when the subvalvular (LVOT) velocity is elevated (>1.4 m/s) and should be included in the gradient measure. As many as 10% to 15% of AS cases may be associated with subvalvular outflow narrowing or obstruction (see Fig. 15.76). While a mean gradient less than 40 mm Hg does not suggest severe AS, it does not rule it out either. Measuring the AVA by planimetry or calculating it by using the continuity equation may define more accurately the severity of AS by providing an anatomic area or EOA, respectively.[17,21,22] Planimetry is more commonly performed from the ME AV short-axis window. Accurate planimetry may not be possible owing to degree of calcification, imaging artifacts, and the inability to visualize the inner edges of the AV in a planar fashion.[17,88] The continuity equation (conservation of mass) allows calculation of the AVA from Doppler data and a measurement of the LVOT diameter (subvalvular). Clinical data show that peak velocities (V_{LVOT} and V_{AV}) can be substituted for the TVI of the respective sites.[88,89]

The valve area should be considered in the context of each individual case. An AVA of 1.0 has a different impact on a patient with a BSA of 1.5 as compared to one with a BSA of 2.0; indexing the AVA according to the patient size or BSA adds perspective. An indexed AVA (AVAi) less than 0.6 cm^2/m^2 is consistent with severe AS, and an AVAi greater than 0.85 cm^2/m^2 is consistent with mild AS.[29]

A potential source of error in the calculation of AVA by continuity equation is the need to measure the diameter of the LVOT, which is assumed to be circular, which, alone, is a potential error. Two-dimensional measurements have a 5% to 10% error. When the LVOT diameter is halved (radius) and then squared, the total error may be as great 15.20%. An AVA of less than 1.0 cm^2 is considered severe AS.

A simplified dimensionless index (velocity ratio [VR]) that is not affected by the error of 2D measurements or geometric assumptions compares either the TVIs or peak velocities of the LVOT to that across the AV.[17,22,88,89,91]

$$VR = TVI_{LVOT}/TVI_{AV} \text{ or } V_{LVOT}/V_{AV}$$

A value less than 0.25 is consistent with severe AS. This ratio is essentially an abbreviated version of the continuity equation, without the 2D (or 3D) measurements. For the great majority of patients, the LVOT diameter is less than 2.2 cm. If inserted into the continuity equation, a VR of 0.25 would yield an AVA less than 1.0 cm^2. A VR of 0.2 would be consistent with severe AS even for an LVOT diameter as large as 2.5 cm.

Parameters consistent with abnormal (more than mild) prosthetic AV obstruction are similar to that of the native AV and include transvalvular jet velocities greater than 3 m/s, mean gradients greater than 25 mm Hg, and an acceleration time greater than 100 ms.[21,22] Since gradients are affected by hemodynamics, valve function should be more accurately quantified by calculation of the AVA. For all assessments, hemodynamic data should be recorded to help define the meaning of Doppler data.

To avoid error associated with calculating the AVA, a DVI or VR is useful to categorize prosthetic valve opening as normal or not. A VR less than 0.35 is consistent with prosthetic valve stenosis and should prompt further evaluation. The corollary, however, is not as clear. While a VR greater than 0.35 for smaller prosthetic valves (19 and 21 mm) suggests normal opening, larger valves are associated with higher VR (>0.40).[21,22]

Indexing the AVA according to the patient's BSA yields information specific for each patient. Perhaps more clinically relevant is an indexed EOA or AVA (AVA/BSA; cm^2/m^2) of a prosthetic AV. The patient's size or physical needs are considered when determining the size of prosthesis to place. PPM describes the mismatch between the area of the prosthetic valve selection (AVA) and the patient's size (BSA).

$$AVAcm^2/BSAm^2$$

PPM has been categorized as mild, moderate, and severe for EOAi equal to 0.85 to 1.00 cm^2/m^2, 0.65 to 0.85 cm^2/m^2, and less than 0.65 cm^2/m^2, respectively.[29] Outcome data suggest improved short- and long-term outcomes are improved with a properly sized valve. Greater clinically significant outcomes are seen with severe PPM (ie, <0.65 cm^2/m^2). PPM may also have less clinical impact on older adults (older than 75 years) and/or smaller patients (BSA < 1.75 m^2).

Miscellaneous Issues

Analyses should be performed at a time when patient hemodynamics (CO/SV) are optimized, or, at least known. This is especially important for the condition known as low gradient AV stenosis.

$$AVA\ (EOA) < 1.0\ cm^2$$

$$\text{Mean pressure gradient} < 30–40\ \text{mm Hg}$$

Low gradient AV stenosis may be seen in patients with reduced LVEF (<40%) or CO, arrhythmias, and significant MR.[100] In these conditions, reduced flow across the AV is associated with a lower gradient. For such cases, calculation of AVA is necessary. If the AVA is less than 1.0 cm^2, a stress echocardiogram (either exercise or dobutamine) should be considered to differentiate between true AS and pseudo-AV stenosis, the latter being the result of reduced opening forces. Hemodynamic goals of the test include an increase in the heart rate of either 10 to 20 beats/minute, an increase of more than 100 beats/minute, and/or an increase in SV or ejection fraction of 15% to 20%. True AS is characterized by a rise in the mean gradient greater than 40 mm Hg with a persistent AVA less than 1.0 cm^2. An increase in the AVA greater than 1.0 cm^2 supports pseudo-AV stenosis. An absence of a hemodynamic response to stress (ie, no change in LVEF) suggests a lack of contractile reserve, which is associated with increased morbidity and mortality with surgery.

Other conditions that affect the echocardiographic-derived gradient include poor alignment of the ultrasound beam with blood flow, which may underestimate the true flow velocity and subsequently calculated gradient. The presence of AI and/or a high flow state will increase jet velocity and overestimate the severity of AV obstruction. Erroneous measurement of the mitral regurgitant jet will cause overestimation of the true transaortic valve velocity. The former is a holosystolic jet compared to a decrescendo-crescendo flow profile (see Fig. 15.75). Finally, sequential narrowings (subvalvular or supravalvular stenoses or obstructions) affect detection of the true gradient across the AV (see Fig. 15.76).

Differences in pressure gradient between that obtained during cardiac catheterization and echocardiography can occur as a result of poor alignment between the ultrasound beam and blood flow, causing an underestimation during Doppler echocardiography. The peak gradient during echocardiography is an instantaneous peak gradient and is larger than that measured during catheterization, which is the gradient between the peak transvalvular pressure and the peak LV pressure. During catheterization the two peaks occur at different times. A third cause is a phenomenon called *pressure recovery*. When flow crosses the stenotic AV, potential energy is converted to kinetic energy and a high pressure gradient is recorded.[17,21,101,102] However, downstream from the stenotic valve, energy is lost to turbulence and viscous forces. Energy may be converted back to potential energy, causing a rise in pressure or pressure recovery. The amount of pressure recovery is related to the differences in the cross-sectional area (CSA) of the ascending aorta.

$$PR = 4v^2 \times 2EOA/AoA \times (1 - EOA/AoA)$$

Pressure recovery is related to the ratio of the EOA/AoA or the EOA of the AV and the CSA of the ascending aorta. Pressure recovery is most significant for patients with an ascending aortic diameter less than 3.0 cm.

Surgical or Procedural Intervention

Surgical or transcutaneous AVR is indicated for severe AS with symptoms[8–10,24–26] (Fig. 15.77). Surgical AVR also should be considered for asymptomatic patients with severe AS undergoing other cardiac or aortic procedures, or in the presence of LV systolic dysfunction (LVEF <50%) without another cause, an abnormal exercise/stress test result, and/or those who might be suitable candidates for TAVR. AVR can be considered for moderate AS in patients undergoing other cardiac surgical procedures. Other considerations might include asymptomatic patients with very severe AS (peak velocity >5.5 m/s), or low gradient (mean <40 mm Hg) AS if reserve function is documented and it is believed that the AS is true and contributing toward the low flow state.

Tricuspid Valve

Normal Anatomic and Functional Features

The normal TV area is 4 to 6 cm^2 and the normal annular diameter is less than 28 mm. The TV has three unequal-sized leaflets (septal, anterior, posterior). Like the mitral annulus, the TV annulus is a 3D saddle-shaped ellipsoid structure that changes its shape and area during the cardiac cycle.[103,104]

The septal leaflet is attached to the medial or septal wall, which is in continuity with the fibrous trigone of the heart. The posterior leaflet is the smallest of the three leaflets. The anterior leaflet is the largest of the three. The leaflets are attached via chordae to three respective papillary muscles and each papillary muscle gives off chords to at least two leaflets. Congenital variations include two to nine papillary muscles and as many as six leaflets.

In the presence of RV enlargement or failure, tricuspid annular enlargement occurs and the annulus becomes more planar. The septal area is attached to the fibrous trigone and stays relatively stable. Annular dilation tends to occur anteriorly and laterally away from the fibrous skeleton and is associated with the development of TR.

Prosthetic or Repaired Tricuspid Valve

The importance of TV function and its impact on right-sided heart function and patient outcome is increasingly appreciated.[105–109] As a result, TV surgery has increased either alone or in association with surgical procedures on the left side of the heart. The majority of TV surgeries are treating TR, and more than 80% are repaired. However, valve replacement is performed with primary valve disorders (endocarditis, rheumatic valvitis, carcinoid syndrome, traumatic rupture) or for patients in whom recurrent regurgitation is suspected after repair.[110,111]

The TV should be assessed for disease, function, and indications for surgery.[24,25] Severe TV dysfunction is an indication for surgery. Moderate TV dysfunction should receive consideration for surgery

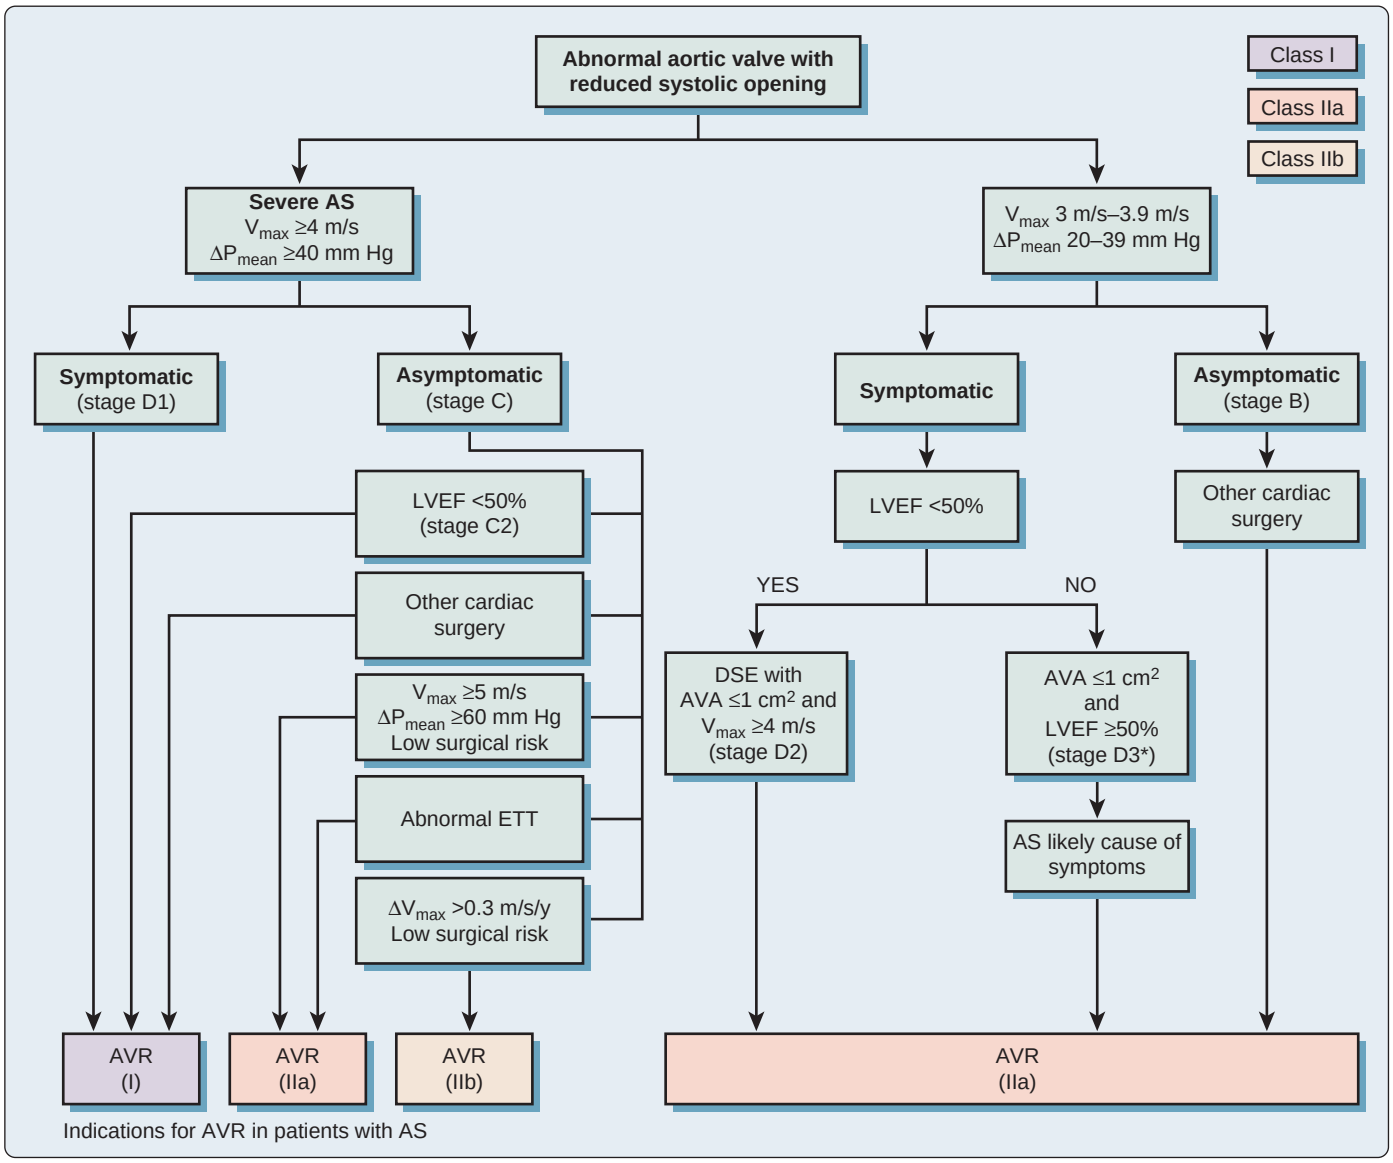

Fig. 15.77 Decision algorithm for AS. The decision algorithm was taken as a consensus by an expert panel and based on outcome data and interpretation. Decisions are classified as class I, class IIa, class IIb, the former being supported by sufficient evidence such that intervention should be performed, while the latter two are supported by evidence that suggests that benefits of intervention outweigh the risks and that intervention is reasonable based on multiple (IIa) or isolated trials or nonrandomized data (IIb). Treatment for AS usually includes percutaneous intervention. The decision is based on a number of considerations including severity, presentation (symptoms), changes in cardiopulmonary function, and timing (ie, whether other cardiac surgical procedures are scheduled). *AS,* aortic stenosis; *AVA,* ; *AVR,* aortic valve replacement; *DSV,* ; *ETT,* ; *LVEF,* left ventricular ejection fraction. *(Reprinted with permission from Nishimura RA, Otto CM, Bonow RO, et al. 2014 AHA/ACC guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology/ American Heart Association Task Force on Practice Guidelines.* J Am Coll Cardiol. *2014;63:e57–e185.)*

when patients are undergoing surgical procedures for the left side of the heart. Primary TV leaflet pathology increases the likelihood that valve replacement may be necessary. Valve repair for regurgitant valves is a first consideration; however, if recurrent dysfunction is predicted and/or primary leaflet pathology is not repairable, then replacement is considered. The value of echocardiography cannot be overstated.

For assessing post-TV repair or replacement, it is important to know the details of the surgical procedure, including what kind of valve was placed or how the valve was repaired. Previous knowledge of normal echocardiographic findings for specific valves and/or successfully repaired valves help delineate what is normal and what is not. Details include whether or not a bioprosthetic or mechanical valve was placed and what kind of valve and how many leaflets are present. For valve repairs, annulus type (flat vs saddle shaped, full vs partial), leaflet resection or repair, or augmentation helps practitioners understand what is seen during imaging. TV repair mainly consists of annular reduction with a prosthetic annuloplasty ring or suture (DeVega procedure). Similar to a repair for MR, more severe functional impairment at baseline increases the likelihood for repair failure; thus, replacement may be necessary. For all echocardiographic assessments,

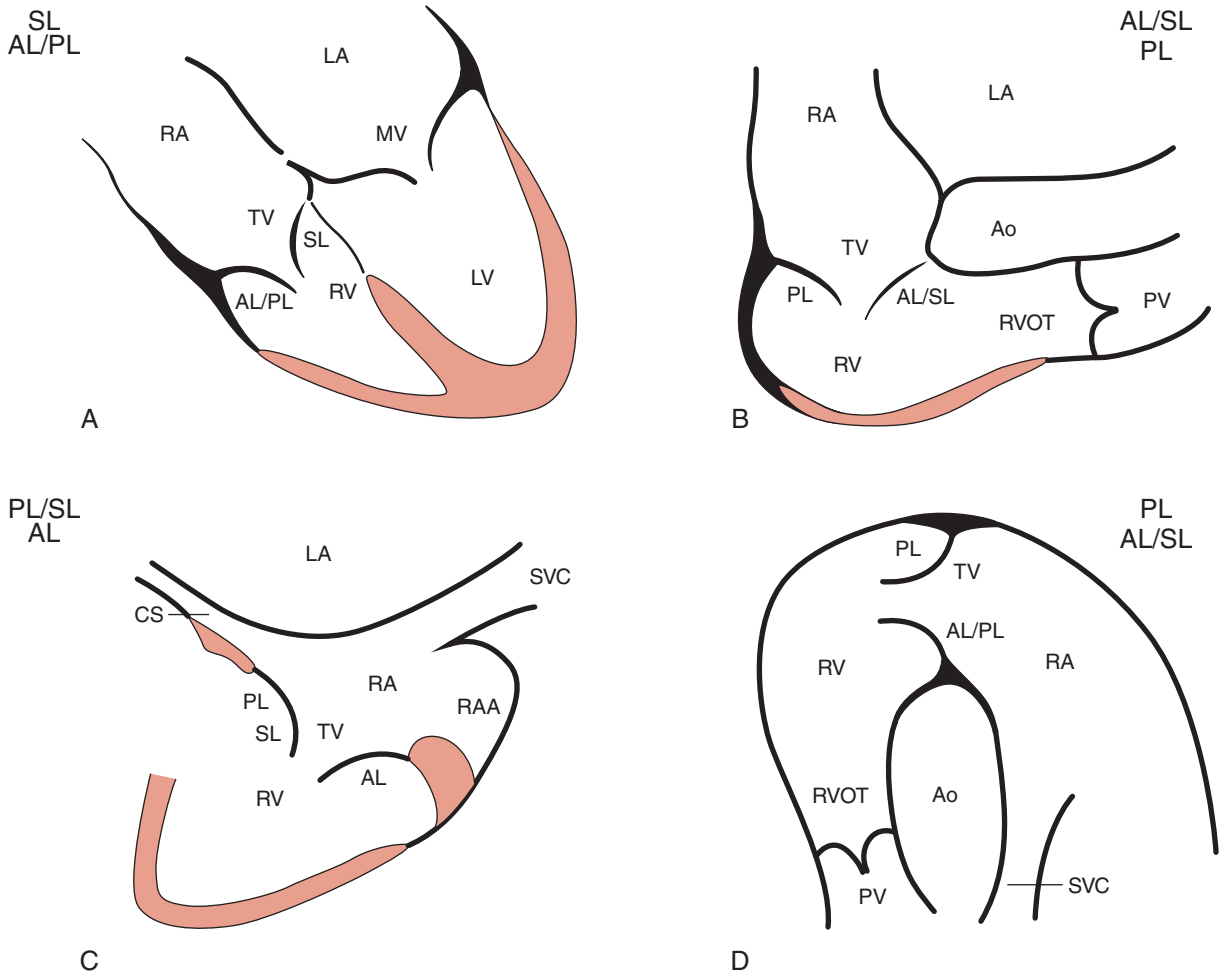

Fig. 15.78 Tricuspid valve *(TV)* imaging windows. The schematics represent the typical echocardiographic windows used to visualize the TV allowing color Doppler assessment (better facilitated from midesophageal windows) and annular measurements, which may be more accurate from the transgastric windows. (A–C) are obtained from midesophageal windows (four-chamber, right ventricular inflow/outflow, and coronary sinus view) while (D) is obtained from a transgastric window with the transducer rotated between 110 and 140 degrees. Depending on the rotation of the transesophageal echocardiography probe, the image may display anterior *(AL)*, septal *(SL)*, or posterior *(PL)* leaflet. *Ao*, Aorta; *LA*, left atrium; *LV*, left ventricle; *MV*, mitral valve; *RA*, right atrium; *RAA*, right atrial appendage; *RV*, right ventricle; *RVOT*, right ventricular outflow tract; *SVC*, superior vena cava.

recording of the patient's hemodynamic status improves the perspective at the time of evaluation.

The Echocardiographic Examination

The 2D examination involves visualization of the TV and its surrounding tissues[112] (Fig. 15.78). The assessment should evaluate leaflet mobility, thickness, integrity, masses, and stability within the annular tissues.[17,18,20] Extraneous mobile structures or materials before and after surgery may represent endocarditis, rupture or tears of the subvalvular apparatus, or suture or retained native tissues after valve surgery. Rocking or unstable annular motion or an echolucent space might suggest abscess or dehiscence of a prosthesis. The greater the amount of leaflet disease there is, the more likely valve replacement will be necessary.

A part of the 2D exam is to determine whether or not the regurgitant TV should and could be repaired, or whether or not valve replacement is warranted. Determining whether or not TR progresses or regresses involves a number of variables. The greater the amount of TV leaflet disease, the less likely that TR will improve and that repair will be feasible.[105,110,111] TR that results from either annular dilation and/or leaflet tethering can be repaired. The long-term success of the repair can be determined by assessing the geometry of the TV apparatus (see Fig. 14-92). Progression of TR is likely with a TV annular diameter larger than 2 cm/m^2, especially if the change in annular diameter during the cardiac cycle is less than 20%.[18–20] These are reflective of significant long-standing regurgitation and less reversibility of annular changes.[113] Similar to the MV, leaflet geometry or tethering can be used to predict successful repair. Tethering heights greater than 0.8 cm and/or tethering areas greater than 1.6 cm^2 reflect significant geometric changes, are associated with severe TR, and are less likely to be successfully repaired with regard to long-term event-free survival[110,114,115] (Figs. 15.79 and 15.80).

Previous data suggest that the TV annulus should be measured from TG and not TE windows.[112] Since the TV annulus is complex, multiple views and measurements yield a more complete assessment, and the largest annular diameter should be measured. More recent 3D data confirm that the annulus dilates anteriorly and that the annulus may be either elliptical or circular, the latter reflecting long-standing and severe TR (Figs. 15.81 and 15.82). Although the 3D data highlight the complexity of the TV annulus, outcome data up until now have been based on 2D imaging during which the largest diameter should be sought.

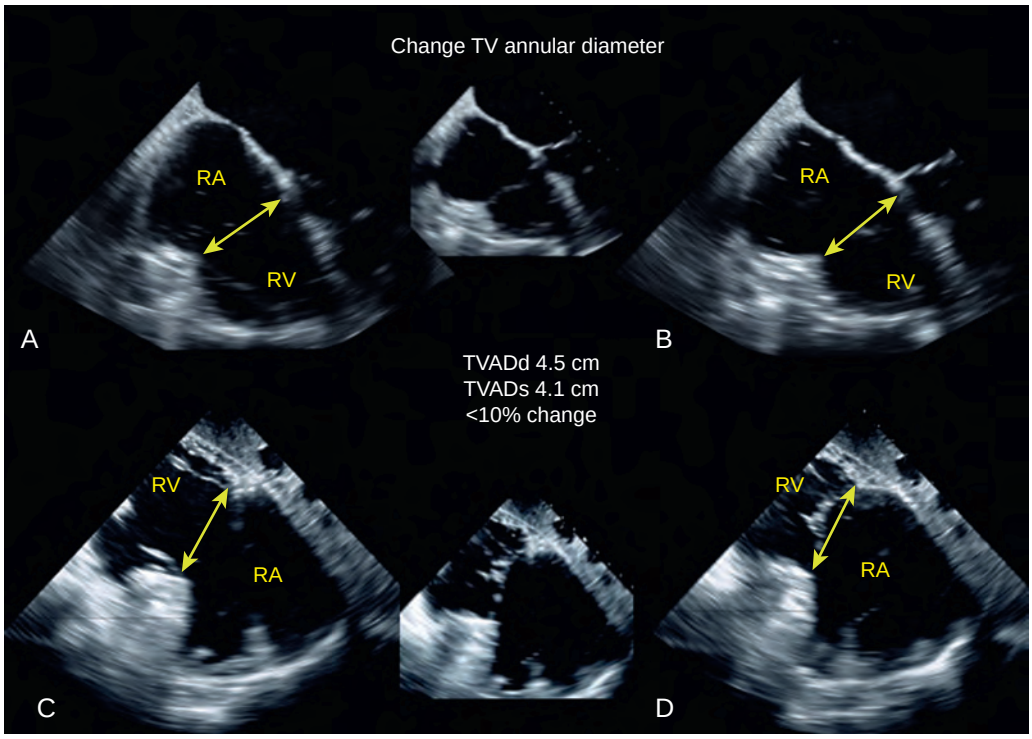

Fig. 15.79 Assessment of tricuspid annular changes. Using two echocardiographic windows, the change in tricuspid valve annular diameter *(TVAD)* is assessed during the cardiac cycle to help determine reversibility of tricuspid regurgitation (TR) in helping to determine whether or not a repair should be considered. (A) and (B) Midesophageal four-chamber views. (C) and (D) Transgastric views. A change less than 10% supports performing tricuspid valve surgery if TR is present. *RA,* Right atrium; *RV,* right ventricle.

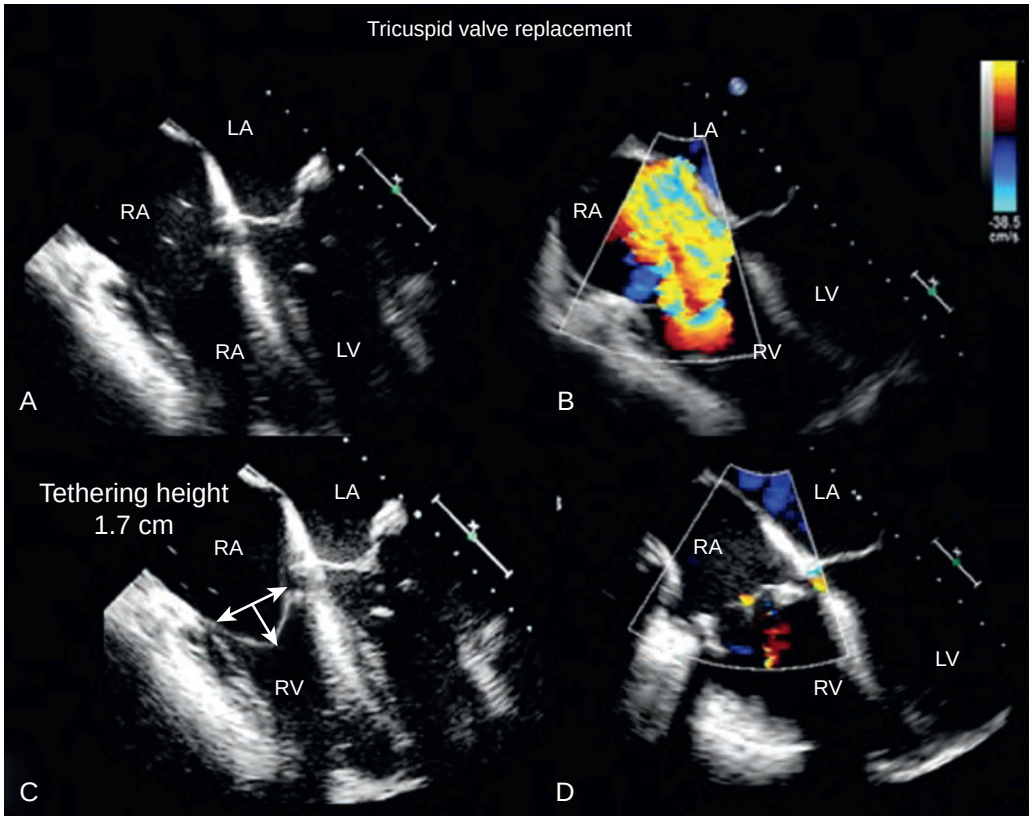

Fig. 15.80 Severe functional tricuspid regurgitation (TR) and tethering. (A) and (B) From the midesophageal four-chamber view, a case of severe functional TR is shown. (C) The annular dimensions and tenting height are measured to assess the severity of tricuspid valve dysfunction. (D) Similar to mitral valve tethering, significant tricuspid valve tethering suggests ventricular remodeling. For the tricuspid valve when the tenting height is greater than 1.0 cm, ventricular changes may be severe enough such that a tricuspid repair may not adequately eliminate regurgitation. For such cases, valve replacement should be considered. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

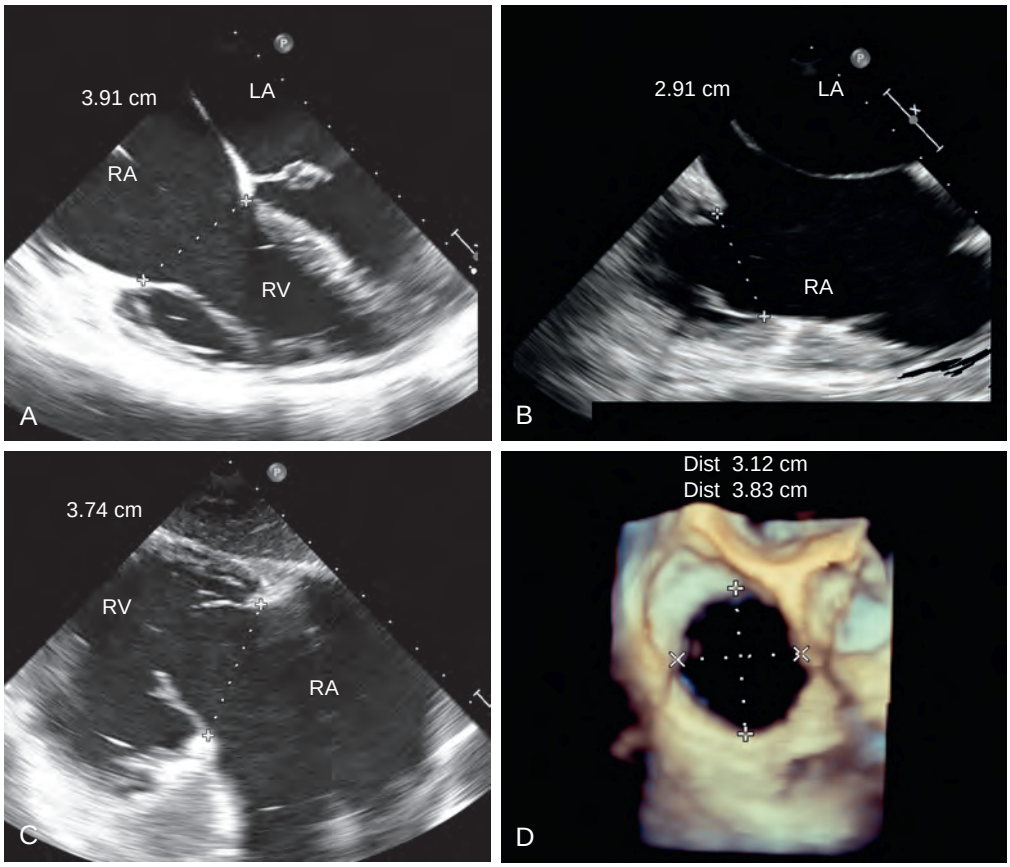

Fig. 15.81 Annular diameter assessment with two- (2D) and three-dimensional (3D) imaging. The introduction of 3D imaging demonstrates that the shape of the tricuspid valve (TV) annulus is not easily predicted. (A–C) Significant variability of the 2D annular diameters likely represents variations of the imaging plane and rotation of the transesophageal echocardiography probe. (D) The 3D image is able to identify these variabilities and perhaps yield a more accurate assessment of TV annular dimensions. However, to this date, tricuspid regurgitation outcomes are still based on 2D imaging. *LA,* Left atrium; *RA,* right atrium; *RV,* right ventricle.

The Doppler examination includes color (CFD), pulsed-wave, and continuous-wave techniques. The former allows both qualitative and quantitative evaluations, including occurrence, direction, and width of normal and abnormal blood flows in and around the prosthetic valve. The normal transvalvular velocity is less than 0.7 m/s. CFD highlights areas of turbulence, suggesting high velocity flows. Quantitative analyses can be performed from both conventional and CFD imaging of blood across the TV. Additional quantitative Doppler assessment includes tricuspid peak velocities, pulmonary valve insufficiency (PI), and calculation of the RV and PA pressures using the Bernoulli equation.

Prosthetic valve function and appearance are assessed by echocardiography. Images are similar to those of the same valves in other cardiac positions. Assessment includes multiple windows to determine function, assess for disease, and help determine the need for further surgery (Fig. 15.83).

Tricuspid Regurgitation

Normal mild TR is found in up to 75% of patients without clear disease or reason and is considered normal (Fig. 15.84).[116] Pathologic TR either results from a primary valvular disorder or is secondary to either primary RV dysfunction or pulmonary hypertension and increased afterload. Similar to other valvular regurgitations, TR can be described by leaflet mobility (ie, normal, excessive, and restrictive) (Table 15.8).

TR, regardless of it origin, causes a volume overload state that contributes to the progression of right-sided heart failure and greater TR. Patients present for fatigue, atrial fibrillation, and/or signs and symptoms reflecting right-sided heart failure (ascites, hepatomegaly, peripheral edema, jugular venous distention). The echocardiographic examination identifies the presence and origin of TR and assesses the severity of TR. Depending on the echocardiographic findings, the surgeon may decide to repair the valve or replace it. Valve replacement may be preferred if significant tethering of the TV leaflets or primary TV disease is noted and not thought to be adequately managed with a repair (ie, annular reduction alone).

The more common primary causes of TR include rheumatic valvitis (restrictive), myxomatous degeneration (excessive), and endocarditis (excessive).[105] Excess mobility may also result from trauma. Secondary causes account for the majority of TR cases, and the leaflets appear normal with either normal or restricted mobility. Secondary TR is associated with right-sided heart dysfunction, dilation, and annular changes, the latter including dilation, flattening, and development of a circular shape (from an ellipsoid).[113] Depending on the severity of dysfunction, the leaflets may appear restricted or tethered, reflecting either papillary muscle dysfunction or RV remodeling. Other causes of TR include radiation or the presence of catheters or wires passing between the TV leaflets preventing their closure.

The echocardiographic examination helps to determine the diagnosis, severity of dysfunction, and whether or not surgery is indicated. It also determines whether there is excessive mobility, as with myxomatous/degenerative changes, endocarditis, or trauma, or restricted/tethering changes seen with functional TR, or, in the presence of short and thickened leaflets (ie, rheumatic valvitis, radiation,

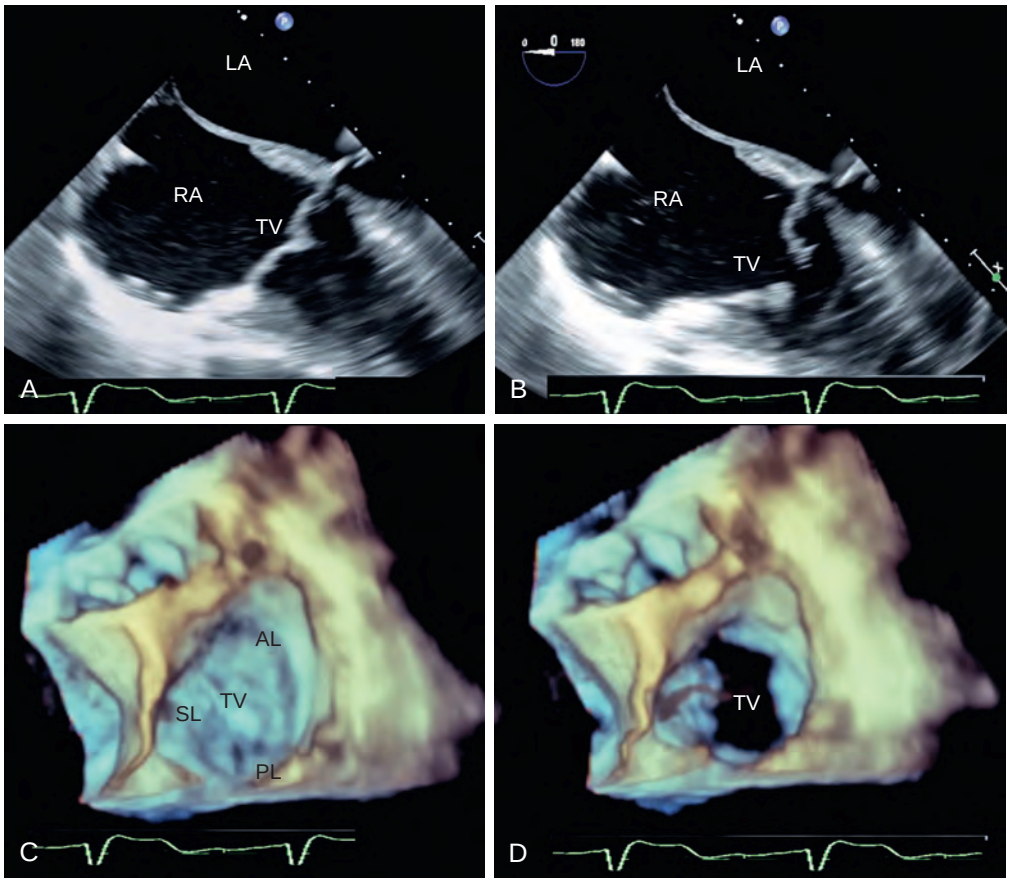

Fig. 15.82 (A) and (B) Two-dimensional and (C) and (D) three-dimensional (3D) images of the tricuspid valve *(TV)* annulus and leaflets during the cardiac cycle. Although the potential for 3D assessment of the TV leaflets is possible, it is our experience that it is not consistent, perhaps owing to the thinness of the leaflets. *AL,* Anterior leaflet; *LA,* left atrium; *PL,* posterior leaflet; *RA,* right atrium; *SL,* septal leaflet.

TABLE 15.8 Tricuspid Regurgitation: Degrees of Severity

	Mild	*Moderate*	*Severe*
Angiographic grade	1	2	3
Color Doppler jet area (cm^2)	<5	5–8	>8
Vena contracta width (cm)	—	<0.7	>0.7
Caval size (cm) with or without respiratory variation	≤1.5 with 50% variation	1.5–2.0 Variable respiratory effects	>2.0 without variation
Cava and/or hepatic vein flow	Systolic predominance	Systolic blunting	Systolic blunting or reversal
Regurgitant orifice area (cm^2)	—	—	>0.4
Regurgitant volume (mL)	—	—	>45
PISA radius (mm; with NL 15–40 cm/s)	<5 mm = mild >9 mm = severe		
Secondary findings	IVC/SVC dilation, PHTN, RAE, RVE		

IVC/SVC, Inferior vena cava/superior vena cava; *NL,* Nyquist limit; *PHTN,* pulmonary hypertension; *PISA,* proximal isovelocity surface area; *RAE,* right atrial enlargement; *RVE,* right ventricular enlargement.

carcinoid) (Figs. 15.85–15.87). The presence of normal-appearing leaflets with or without normal mobility points to TR from secondary RV dysfunction and/or pulmonary hypertension.

The echocardiographic findings guide the choice of surgical procedure. Most cases of TR can be repaired (>80%), especially for annular dilation (>2 cm/m^2) with normally appearing and mobile leaflets. However, TR in the presence of significant leaflet pathology and/or restriction suggested by tethering with a tenting height greater than 1.0 cm or tenting area greater than 1.6 cm^2 are less likely to improve with repair and may even progress more (see Figs. 15.79, 15.80, 15.87). The actual goal of reduction annuloplasty may vary from returning the annulus to normal (<3.0 cm) or a 25% reduction from the preoperative baseline (Fig. 15.88).

Prosthetic valve (or repaired valve) regurgitation is assessed in similar fashion to the native TV. Regurgitation is caused by either excessive or restricted leaflet mobility. In the case of prosthetic valves, paravalvular leak can occur. Diagnoses include endocarditis, leaflet deterioration, restricted or stuck leaflet, and/or dehiscence/abscess.

Assessing regurgitant flow of the native and prosthetic TV is similar (see Table 15.8). Analysis of Doppler imaging helps the practitioner detect, describe, and quantify TR. Imaging includes both TE and TG

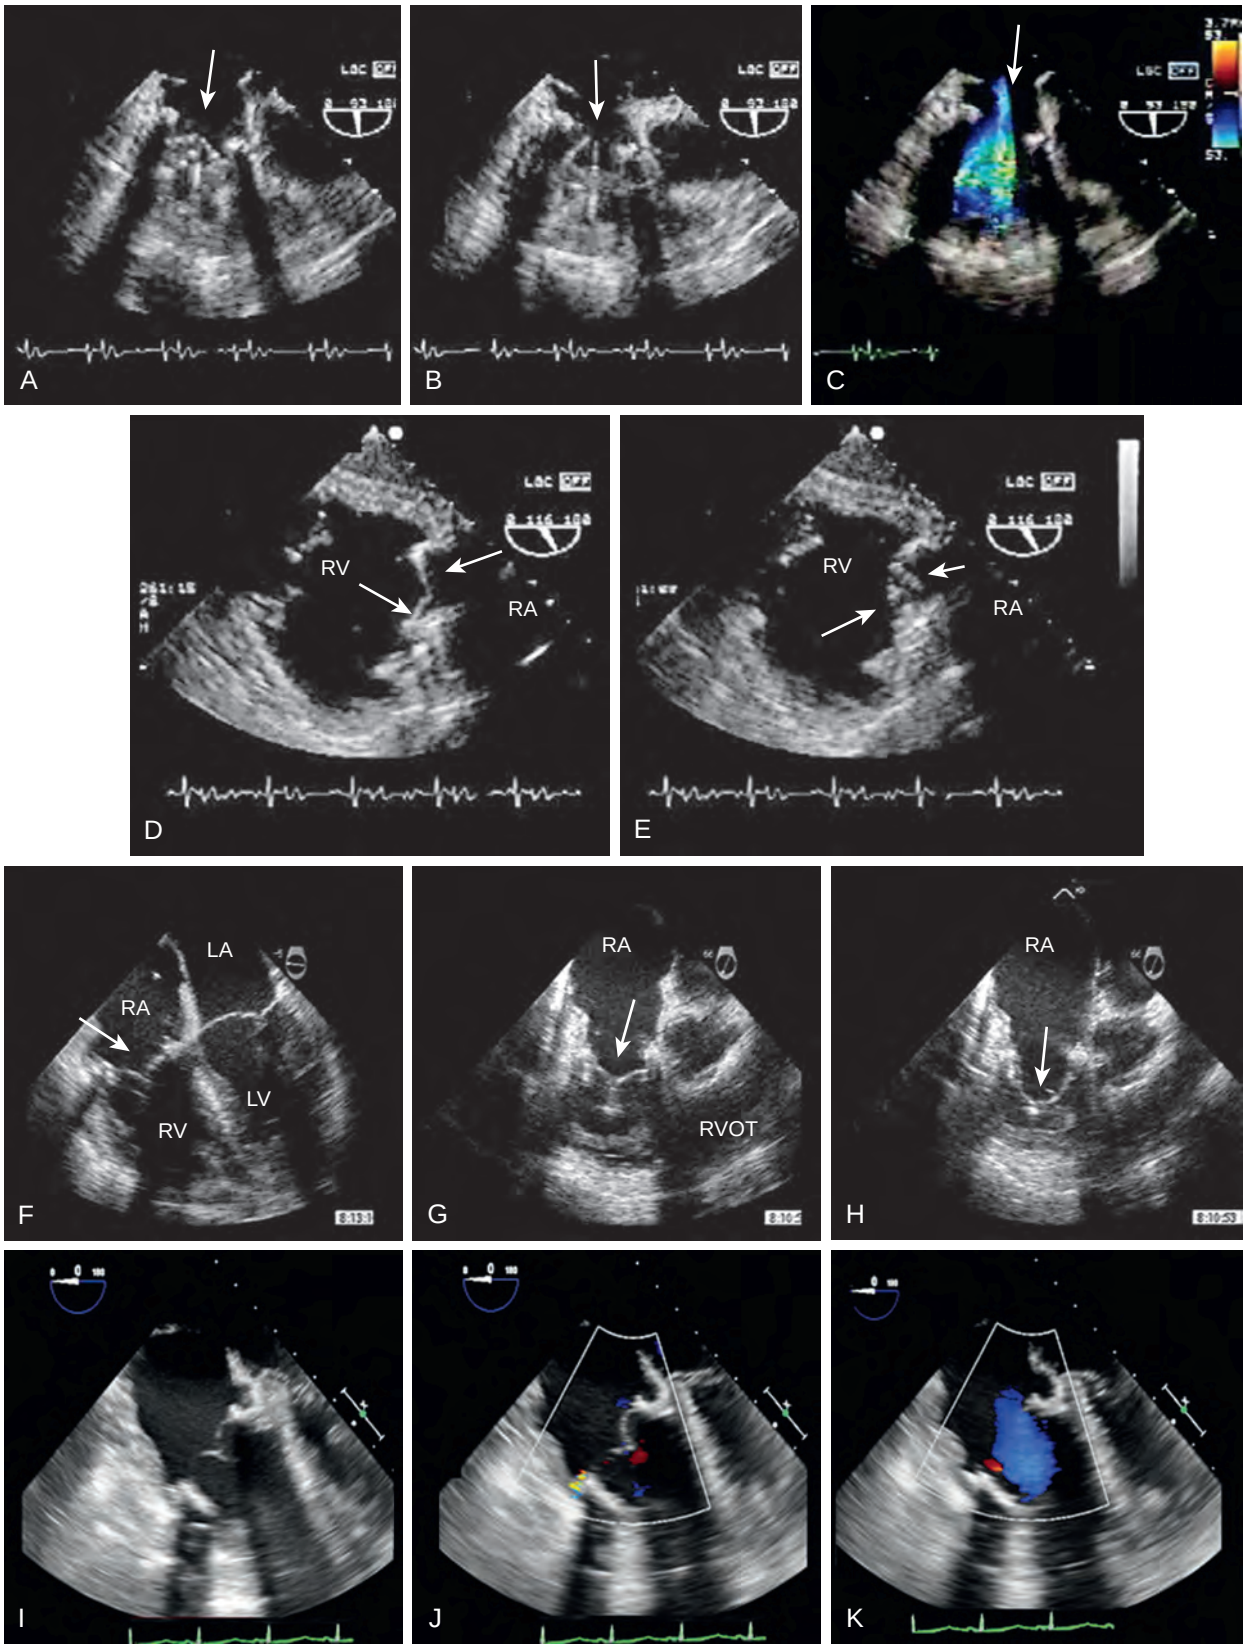

Fig. 15.83 Normal prosthetic valves in the tricuspid position. Normal functioning (A–E) mechanical and (F–K) bioprosthetic valves in the tricuspid position during both two-dimensional and color Doppler imaging. As can be seen, depending on surgical placement and valve rotation, imaging may include a variety of transducer angles and probe positions. *LA,* Left atrium; *LV,* left ventricle; *MV,* mitral valve; *RA,* right atrium; *RV,* right ventricle; *RVOT,* right ventricular outflow tract.

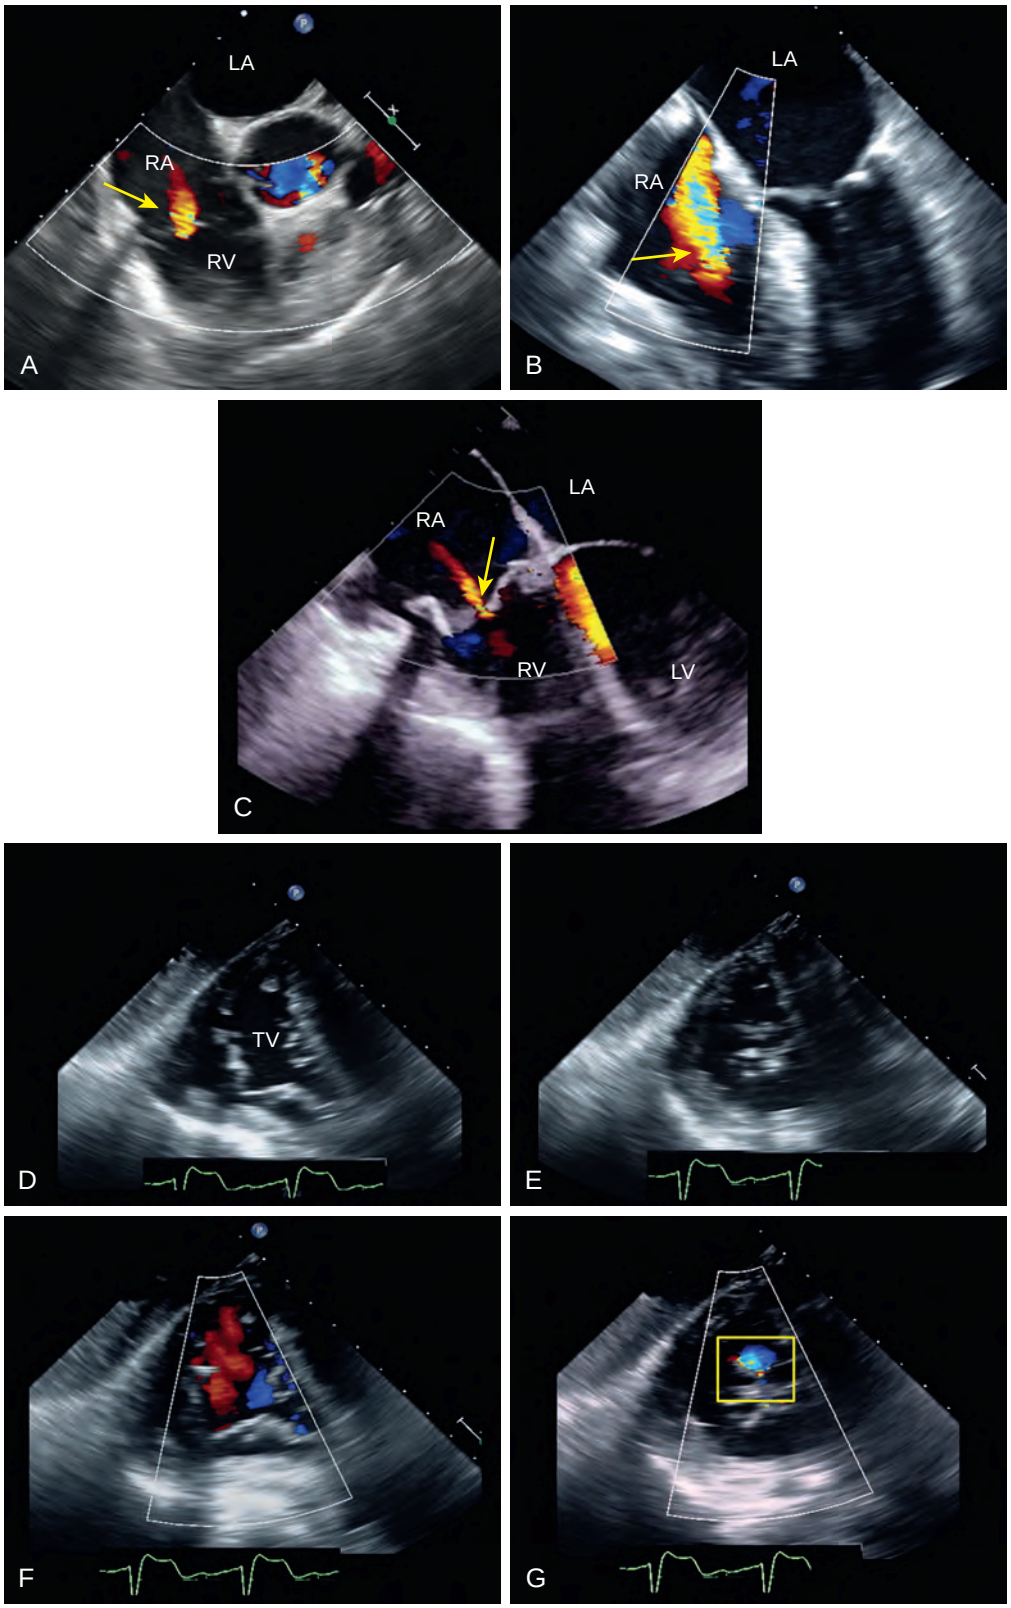

Fig. 15.84 Tricuspid jet width. Views are generated by four different patients. (A) Mild and (B) severe tricuspid regurgitation based on the measured vena contracta. (C) Normal functioning bioprosthetic valve with a small central regurgitant jet *(arrow)*. (D–G) Tricuspid valve *(TV)* and regurgitant jet can be assessed from transgastric images of the TV in a short-axis view. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

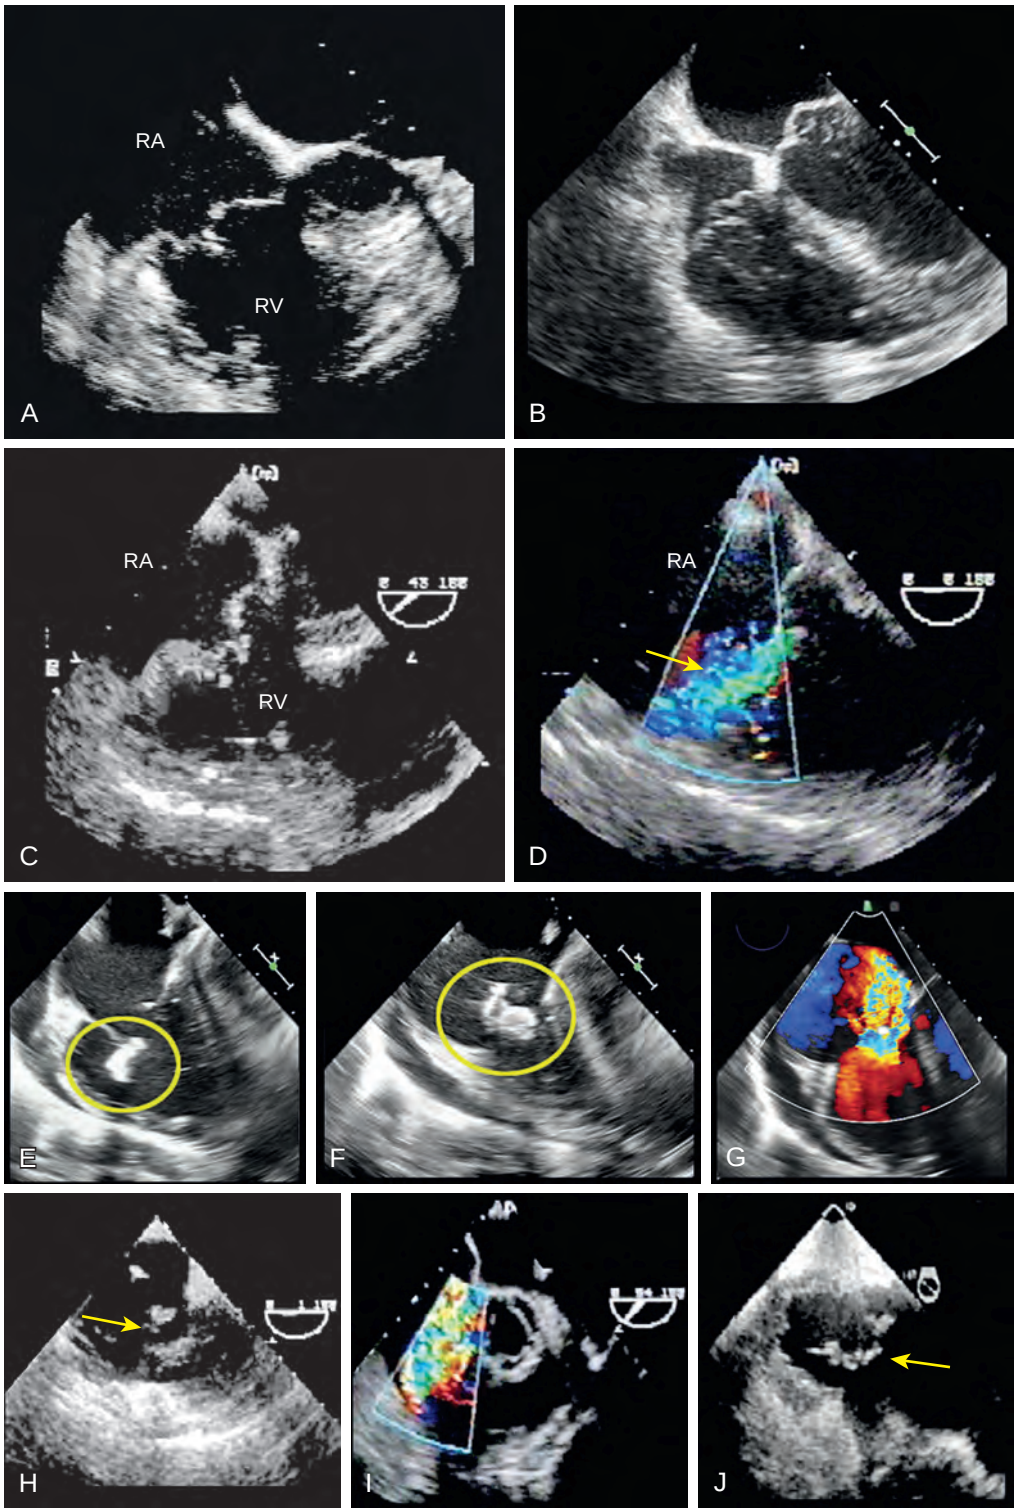

Fig. 15.85 Excessive tricuspid valve leaflet motion. Images are from four different patients. (A) and (B) Myxomatous changes in the tricuspid leaflets. (C) and (D) Severe eccentric tricuspid regurgitation (TR) directed away from the prolapsing septal leaflet *(arrow)*. (E–G) Endocarditis with severe TR *(circles)*. (H–J) Trauma victim with rupture of the anterior leaflet causing severe TR *(arrows)*. *RA,* Right atrium; *RV,* right ventricle.

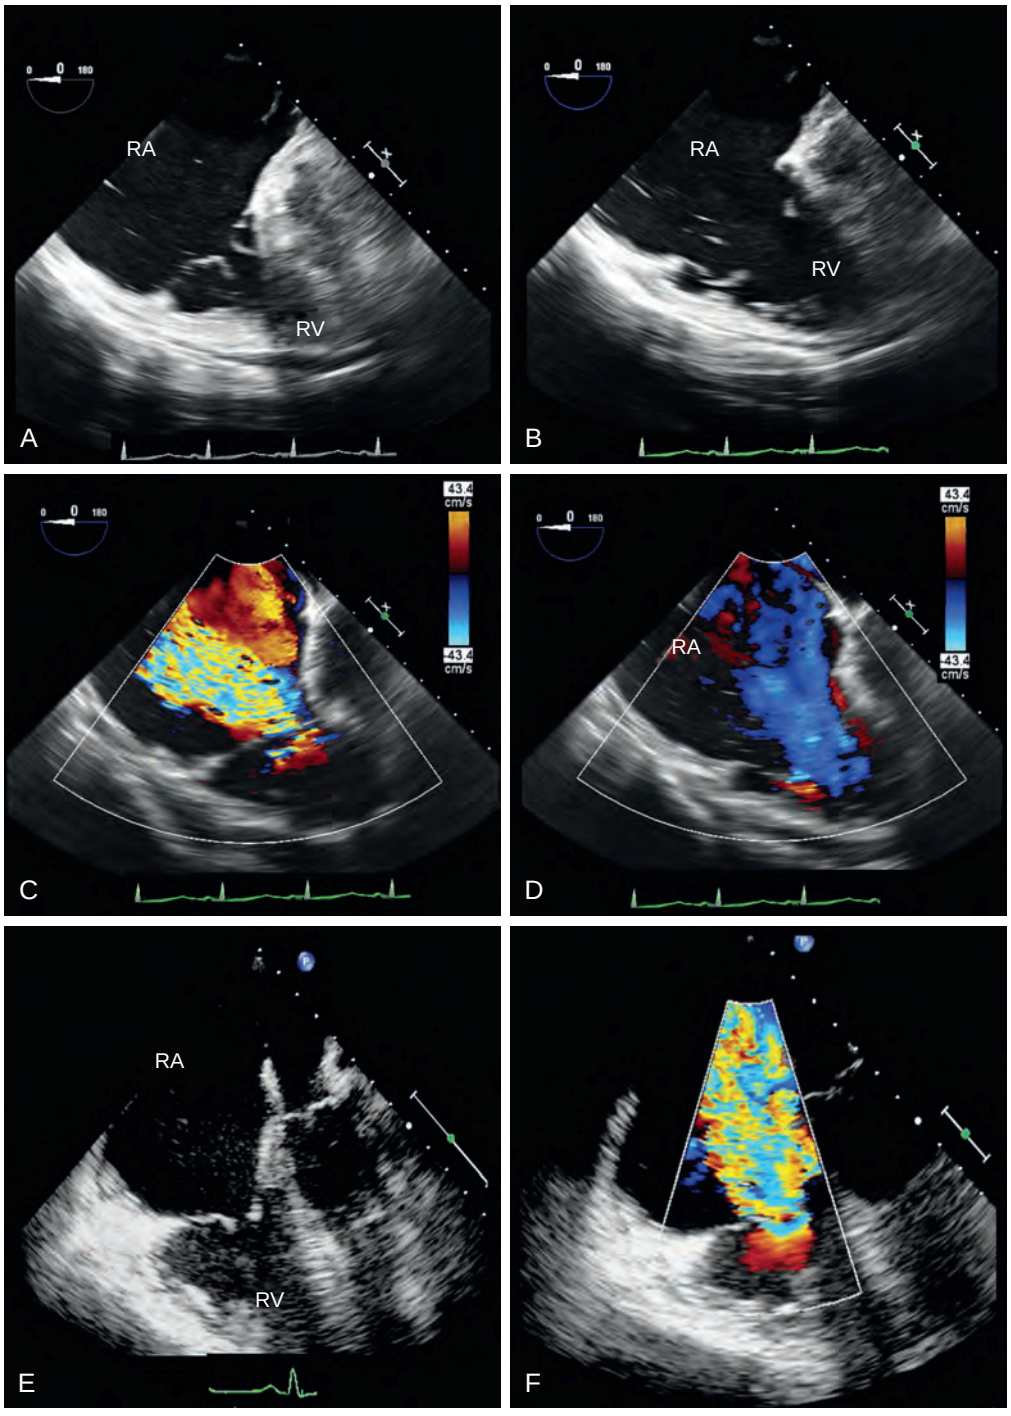

Fig. 15.86 Restricted tricuspid valve (TV) leaflet. Contrasting Fig. 15.85, these images were obtained from two different cases of restricted tricuspid leaflet causing severe tricuspid regurgitation (TR). (A–D) Images from a patient with rheumatic disease (confirmed by pathologic examination) during (A and C) systole and (B and D) diastole with two-dimensional and color Doppler imaging. (C) Severe TR. (E) and (F) Carcinoid involvement (confirmed by pathologic analysis) of the TV. In both cases severe TR was present and both patients underwent valve replacement. *RA*, Right atrium; *RV*, right ventricle.

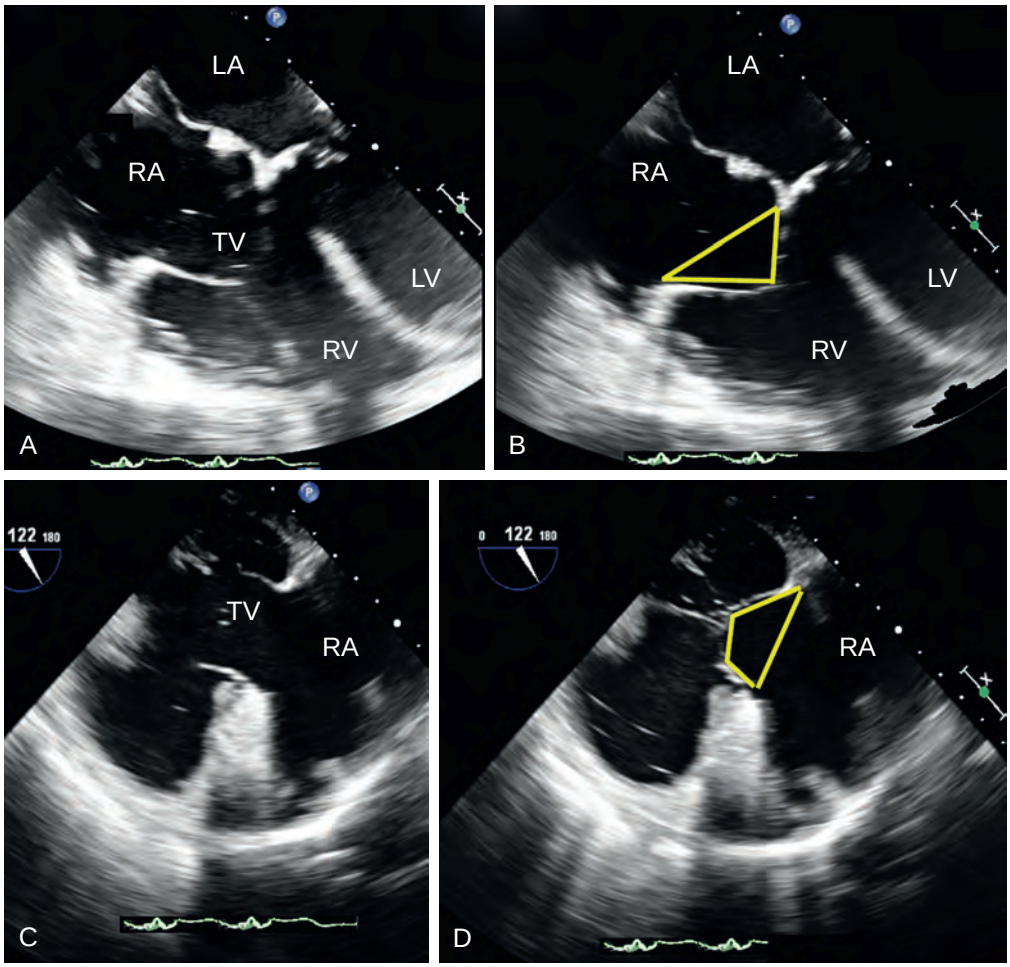

Fig. 15.87 Tricuspid leaflet tethering. (A–D) This patient has severe functional tricuspid regurgitation and significant tethering of the tricuspid valve leaflets resulting from right ventricular dilation and remodeling. The tenting height measured from both (B) midesophageal and (D) transgastric windows was greater than 1.0 cm. Valve replacement was performed. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

windows to assess the presence, severity, and cause of regurgitant flows. Approximately 70% to 80% of patients have mild TR without structural abnormality and, in the absence of disease, may be considered normal.[116] Normal or acceptable regurgitant jets are typically less than 3 mm in width.[69] For prosthetic valves, any paravalvular regurgitant jet is abnormal; however, if the jet is less than 3 mm in width, it is likely to either remain stable or decline on follow-up. Regurgitant jets greater than 3 mm signify greater than mild TR in severity.

Assessing severity of regurgitant flow is similar for native, postrepair, and prosthetic valves (see Table 15.8). Parameters associated with abnormal and more than mild TR include caval diameter greater than 1.5 cm with some amount (<50%) of variation during the respiratory cycle.[105] Specific assessments of the TR jet are not as well studied compared to the MV. Qualitatively, a dense and complete appearance during continuous-wave Doppler is consistent with significant TR. Although the color Doppler jet area is not specific for all levels of severity, a value greater than 8 cm^2 is consistent with severe TR.[18–20,69] A VC greater than 0.3 cm (>3 mm) is abnormal.[69] A VC greater than 7 mm is consistent with severe TR. Although it might be assumed that a VC between 0.3 cm and 0.7 cm suggests moderate TR, the literature reports relatively lower specificity and sensitivity.[69] The presence of flow convergence is considered abnormal. Quantifying effective regurgitant orifice area (EROA), regurgitant volume, and regurgitant fraction are not well studied. However, with the Nyquist limit set between 15 and 40 cm/s, a PISA radius greater than 9 mm is consistent with severe TR, while less than 5 mm is consistent with mild TR.[18–20,69] An EROA greater than 40 mm^2 and a regurgitant volume greater than 45 mL are consistent with severe TR. The value of at least identifying, and perhaps quantifying, flow convergence has been shown for eccentric TR jets, with which the jet area underestimates severity and measures of VC may be difficult.[117]

Additional data that allude to either the cause or the presence of significant TR include RV and right atrial (RA) dysfunction, and increased PA pressures.[118] RA and RV dilation and dysfunction may result in TR via annular dilation and/or leaflet tethering, but also, with continued regurgitation are secondarily affected. If the majority of TR is functional and secondary, then the presence of pulmonary hypertension may allude to the causative factor and may also be a target of medical therapy. Systolic flow reversal in the venae cavae or hepatic veins is consistent with moderate or worse TR. A dilated vena cava that changes little during the cardiac cycle is consistent with a volume and/or pressure overload state found with TV dysfunction.

Surgical Indications[24–26] (Fig. 15.89)

Surgery is indicated for symptomatic patients (right heart failure) with severe TR. Surgery is also indicated for severe TR (with or without symptoms) when the patient is undergoing other cardiac surgical procedures. Surgery should be considered with mild/moderate/or severe

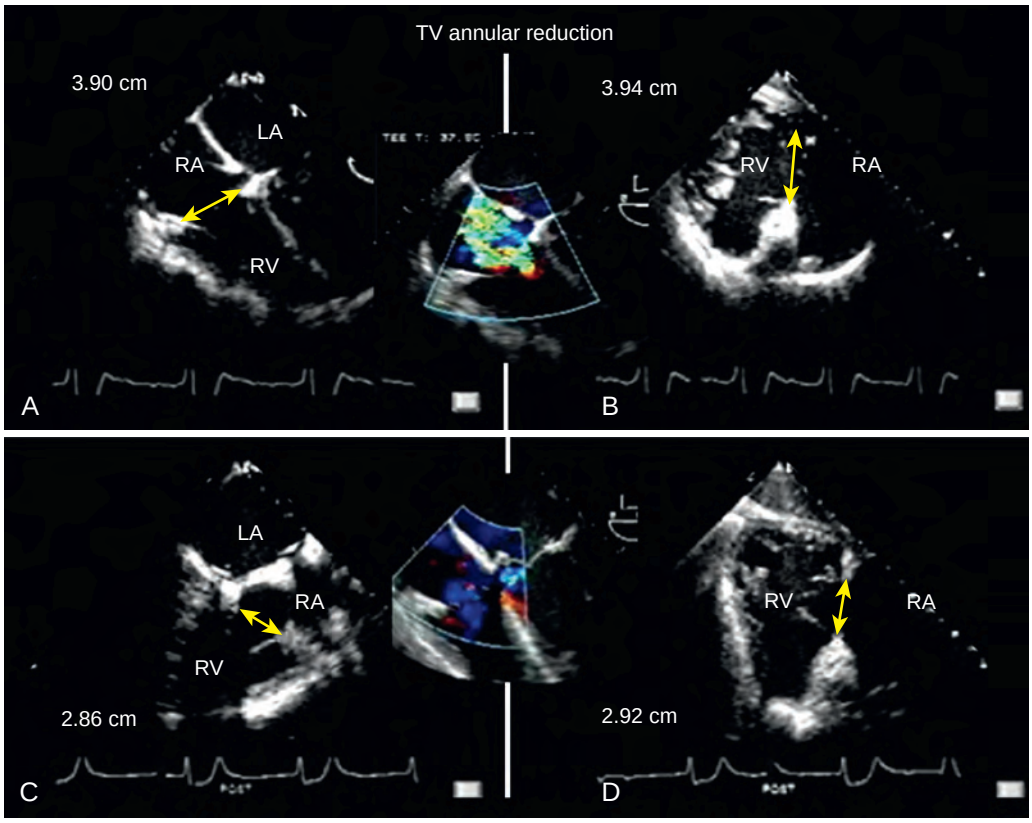

Fig. 15.88 Tricuspid annular reduction. (A) and (B) Dilated annulus with severe regurgitation (before repair). (C) and (D) Significant reduction in annular diameter and regurgitation (immediately after repair). *LA,* Left atrium; *RA,* right atrium; *RV,* right ventricle; *TV,* tricuspid valve.

TABLE 15.9 Tricuspid Stenosis: Degrees of Severity

	Mild	*Moderate*	*Severe*
Peak jet velocity (m/s)	≤1.5	—	>1.7
Mean pressure gradient (mm Hg)	<5–6	—	>7
Pressure half time (ms)	<200	≥200	>230
Tricuspid valve area (cm^2)	—	—	<1.0
Vena cava (cm) with or without respiratory variation	≤1.5 with variation	—	2.0 without variation
Secondary findings	IVC/SVC dilation, RAE, right-to-left septal bowing		

IVC/SVC, Inferior and superior vena cava; *RAE,* right atrial enlargement.

TR in the presence of a dilated TV annulus (>40 mm or >20 mm/m^2) who are scheduled for other cardiac surgical procedures.

Tricuspid Stenosis

Tricuspid valve stenosis (TS) is uncommon. Causes include rheumatic valvitis, obstructing tumors or masses, congenital pathology, and infiltrative processes, each of which may also be associated with regurgitation.[105] The most common cause of TS is rheumatic valve disease, but infrequently it occurs in the absence of other rheumatic valvular involvement such as MS/MR (Table 15.9).

Assessment of the stenotic TV demonstrates leaflet findings including restricted mobility, thickening, calcification, masses, and/or diastolic doming (Fig. 15.90). Secondary findings of TV dysfunction include a dilated right atrium and enlarged cavae. Assessments of the RA and RV function and size may indicate the clinical impact of TV dysfunction. As is the case with the MV, valvitis results in leaflet and chordal thickening. Other causes of obstruction are suspected based on both history and echocardiographic findings. Causes of prosthetic valve stenosis depend on the type of valve and are similar to causes of prosthetic valve stenosis at the other cardiac sites. These include deterioration or thickening of tissue valves, restricted or stuck tissue or mechanical leaflets, the presence of clot, or obstructing masses or wires (Fig. 15.91).

Forward flow obstruction results in a very dilated right atrium and vena cava. The risk of atrial fibrillation is high. Although the right ventricle is not necessarily dilated or dysfunctional, the clinical picture is one of right-sided heart failure.[105]

Assessing forward flow across the TV and determining whether or not it is normal depends on whether the valve is native, repaired, or prosthetic (see Table 15.9). Depending on the type of prosthesis, forward blood flow projects in different ways. Similar to bioprosthetic and prosthetic valves in other positions, normal signature flows have been described with bioprosthetic valves having a single forward flow and mechanical valves having two (single-leaflet) or three (bileaflet) forward projecting jets.[119–121] The evaluation of forward flow consists of both qualitative and quantitative assessments, the latter consisting of transvalvular velocities, pressure gradients, and calculation of prosthetic valve area.

A normal transvalvular velocity is significantly lower than the MV. Forward flow velocity is normally less than 0.7 m/s.[105] The mean gradient is typically less than 2 mm Hg. Data for TS report mean gradients between 2 and 10 mm Hg with an average of 5 mm Hg.[23,122–124] A problem with assessing TS with transvalvular velocity and gradients is the dependence on RA function, which, with continued TS, declines such that pressure generation may be compromised. Nevertheless, obstruction is considered when flow velocity exceeds 1 to 2 m/s. The evaluation consists of both qualitative (color Doppler) and quantitative assessments (pulsed-wave and continuous-wave Doppler), the latter consisting of transvalvular flow velocities and pressure gradients.

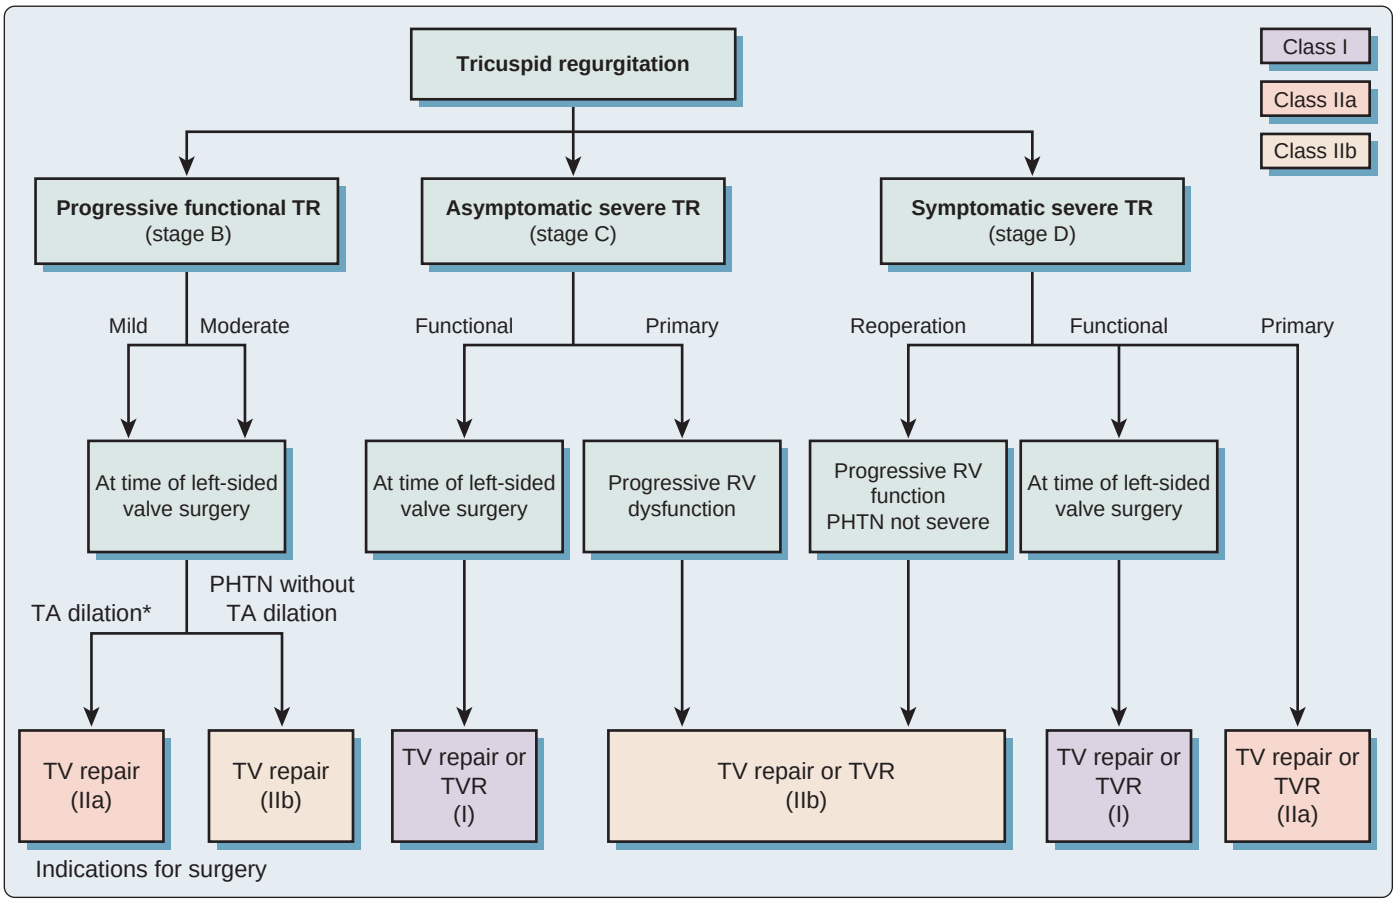

Fig. 15.89 Decision algorithm for intervention of the tricuspid valve *(TV)*. The decision algorithm was taken as a consensus by an expert panel and based on outcome data and interpretation. Decisions are classified as class I, class IIa, class IIb, the former being supported by sufficient evidence such that intervention should be performed, while the latter two are supported by evidence that suggests that the benefits of intervention outweigh the risks and that intervention is reasonable based on multiple (IIa) or isolated trials or nonrandomized data (IIb). Intervention for tricuspid regurgitation is based on a number of considerations including cause, presentation (symptoms), changes in cardiopulmonary function, repairability, and timing (ie, whether other cardiac surgical procedures are scheduled). *PHTN,* Pulmonary hypertension; *RV,* right ventricle; *TA,* tricuspid annular; *TR,* tricuspid regurgitation; *TVR,* tricuspid valve replacement. *(Reprinted with permission from Nishimura RA, Otto CM, Bonow RO, et al. 2014 AHA/ACC guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines.* J Am Coll Cardiol. *2014;63:e57–e185.)*

Doppler assessment is performed primarily from the TE windows as the Doppler ultrasound beam is more easily aligned with transtricuspid flow. Given the limitations of the Doppler data and the lack of validation, specificity, and sensitivity for different measures, additional analyses of the TV, right heart function, and caval/hepatic flows and diameters might allude to dysfunction and subsequent diagnosis.

Doppler data that are consistent with abnormal forward flow or obstruction include a peak jet velocity greater than 1.5 m/s and a mean gradient greater than 5 mm Hg. Similar application of the PHT for MVs has not been validated for the TV.[17] However, a PHT greater than 190 to 200 ms has been described and is consistent with nonobstructing flow.[24,122] Assessment and calculation of valve area can be performed using the continuity equation or planimetry; the latter may not be feasible because of the difficulty in visualizing the leaflet edges. The continuity equation can be performed assuming that a reference site (PA or LVOT) or method can be assessed or employed to measure an SV, which, when divided by the TV flow profile or TVI, would yield a valve area.[124]

$$\text{TV Area} = \text{SV}/\text{TVI}_{\text{TV}}$$

Other Doppler findings consistent with severe TS are a transvalvular TVI greater than 60 cm and a valve area less than 1.0 cm^2. The presence of moderate or greater TR may cause underestimation of the valve area (overestimate severity) using the continuity equation by elevating the TVI. Normally, the venae cavae are less than 1.5 cm in diameter, which changes more than 50% during spontaneous respiration. A dilated vena cava with less respiratory change would suggest elevated right-sided heart pressures/volumes and dysfunction, which can be caused by TS.

Surgical Indications

Surgery or balloon commissuroplasty is indicated for severe and symptomatic TV stenosis or for severe TS in the presence of right-sided heart failure.[24–26]

Pulmonary Valve

Normal Anatomic and Functional Features

The PV is a three-leaflet valve that is similar in structure to the AV, except that the leaflets tend to be thinner and function in a lower

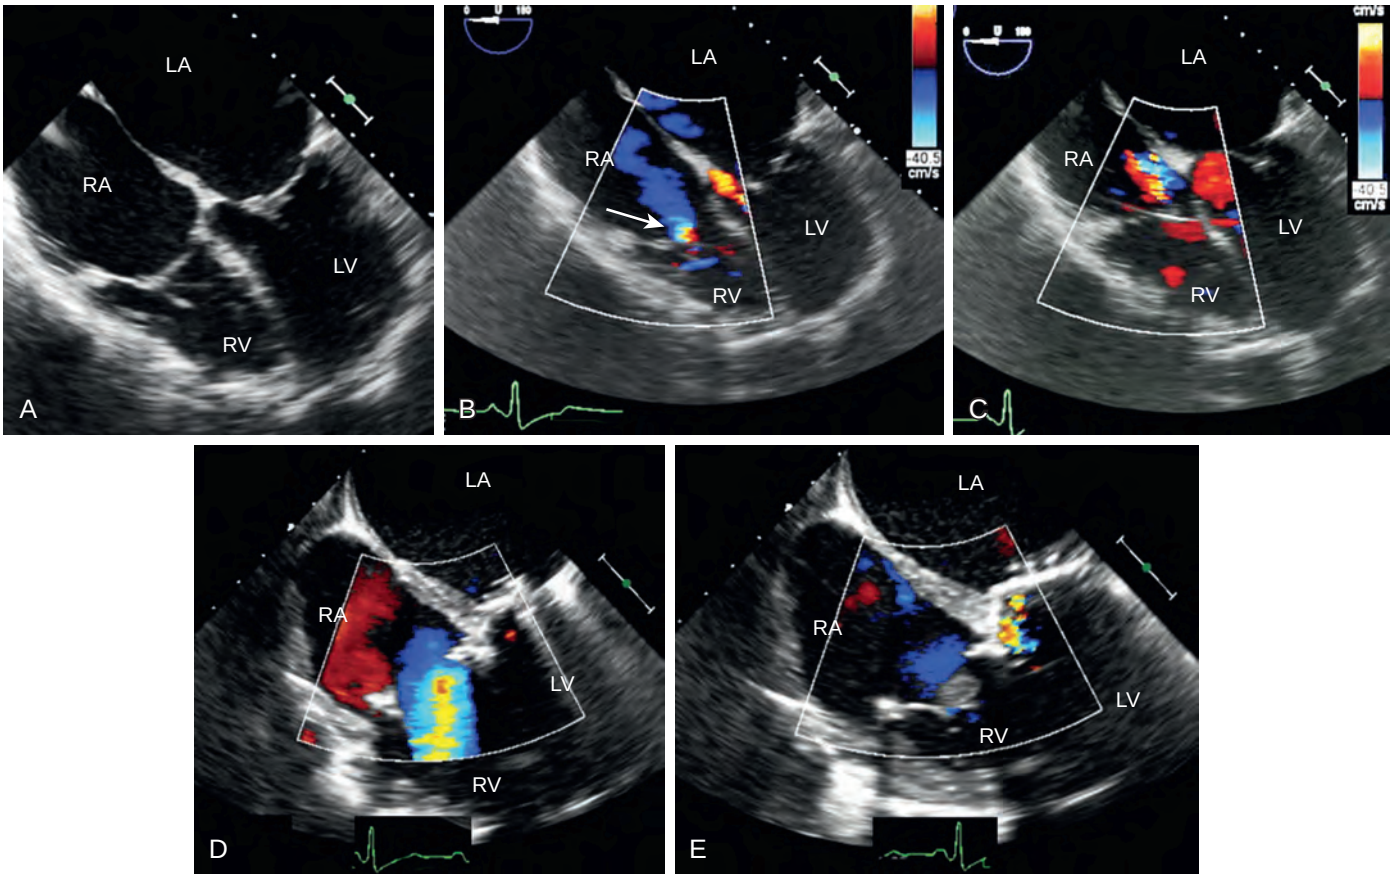

Fig. 15.90 Rheumatic tricuspid valve stenosis. The top panel of images were obtained prior to valve replacement and demonstrate the (A) classic doming of the tricuspid valve (TV) leaflets. The valve also shows fusion of the leaflet tips complicated by (B) tricuspid stenosis and (C) regurgitation. Of interest is the lack of demonstrative turbulent forward flow across the TV. Since flow velocities dictate color Doppler appearance, the lack of turbulent flow may not negate the presence of abnormal flows. The *arrow* in (B) points to a flow convergence area during diastole, which suggests the presence of obstruction or relative narrowing at the valvular level. This patient also had mitral stenosis and had undergone mitral and TV replacements. (D) and (E) Valve replacement with a bioprosthetic valve. *LA,* left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

pressure system.[18] Similar to the LVOT, the RV outflow tract (RVOT) includes subvalvular, valvular, and supravalvular tissues. The PV lies in the middle of the RVOT. At the ventricular-arterial juncture, the PV is supported by the wall of the circular PA. Surrounding the three-leaflet structure are three smaller sinuses followed by the STJ.

It is important to know what type of valve prosthesis was implanted and to have knowledge of the characteristic 2D and CFD images.[21,22] For all echocardiographic assessments, recording of the patient's hemodynamic status improves the perspective at the time of evaluation. The majority of valves are either stented or stentless (xenografts) bioprosthetic valves. Placement of the prosthetic valve may occur at the annular level or more distal to allow a larger sized valve to be placed. Percutaneous valve replacement has become more popular and may continue to replace surgical placement. Quantitative data regarding prosthetic valve function in the pulmonic position are lacking. Determination of what is normal and abnormal is similar to that of normal native valve function.

Echocardiographic Examination

The 2D and CFD examinations of the PV are accomplished from a number of TE and TG echocardiographic windows. Imaging from multiple sites and angles helps to construct a 3D impression of the prosthetic valve and flows. With regard to Doppler quantitative assessment, both TE and TG windows variably enable alignment between the ultrasound beam and blood flow[125] (Figs. 15.92 through 15.94).

The 2D examination involves visualization of the PV and its surrounding tissues from TE and TG windows. The assessment should evaluate leaflet presence, motion, integrity, masses, and the surrounding tissues. The stability of the valve and whether or not the prosthesis is rocking should be determined. Instability might suggest prosthetic dehiscence and/or infection of the surrounding supportive tissues.

Imaging of the supravalvular and subvalvular areas also should be done to assess for RVOT/subvalvular narrowing, and for PA pathology (see Fig. 15.94). Because of its anterior location, and potential for artifact, the prosthetic PV may be difficult to image using TEE. Epicardial imaging may prove to be the best modality for intraoperative evaluation. Secondary evidence of PV dysfunction includes right-sided heart failure and dilation, elevated RV pressures, and/or significant TR.

The Doppler examination includes CFD, pulsed-wave, and continuous-wave Doppler. The former allows both qualitative and quantitative evaluations including occurrence, direction, and width of normal and abnormal blood flows. Qualitative and quantitative imaging includes both TE and TG windows (Figs. 15.94 and 15.95). It is important to view the PV from multiple windows to increase the chance of aligning the ultrasound beam with the direction of blood flow. Since right heart flows have lower velocity than the left heart

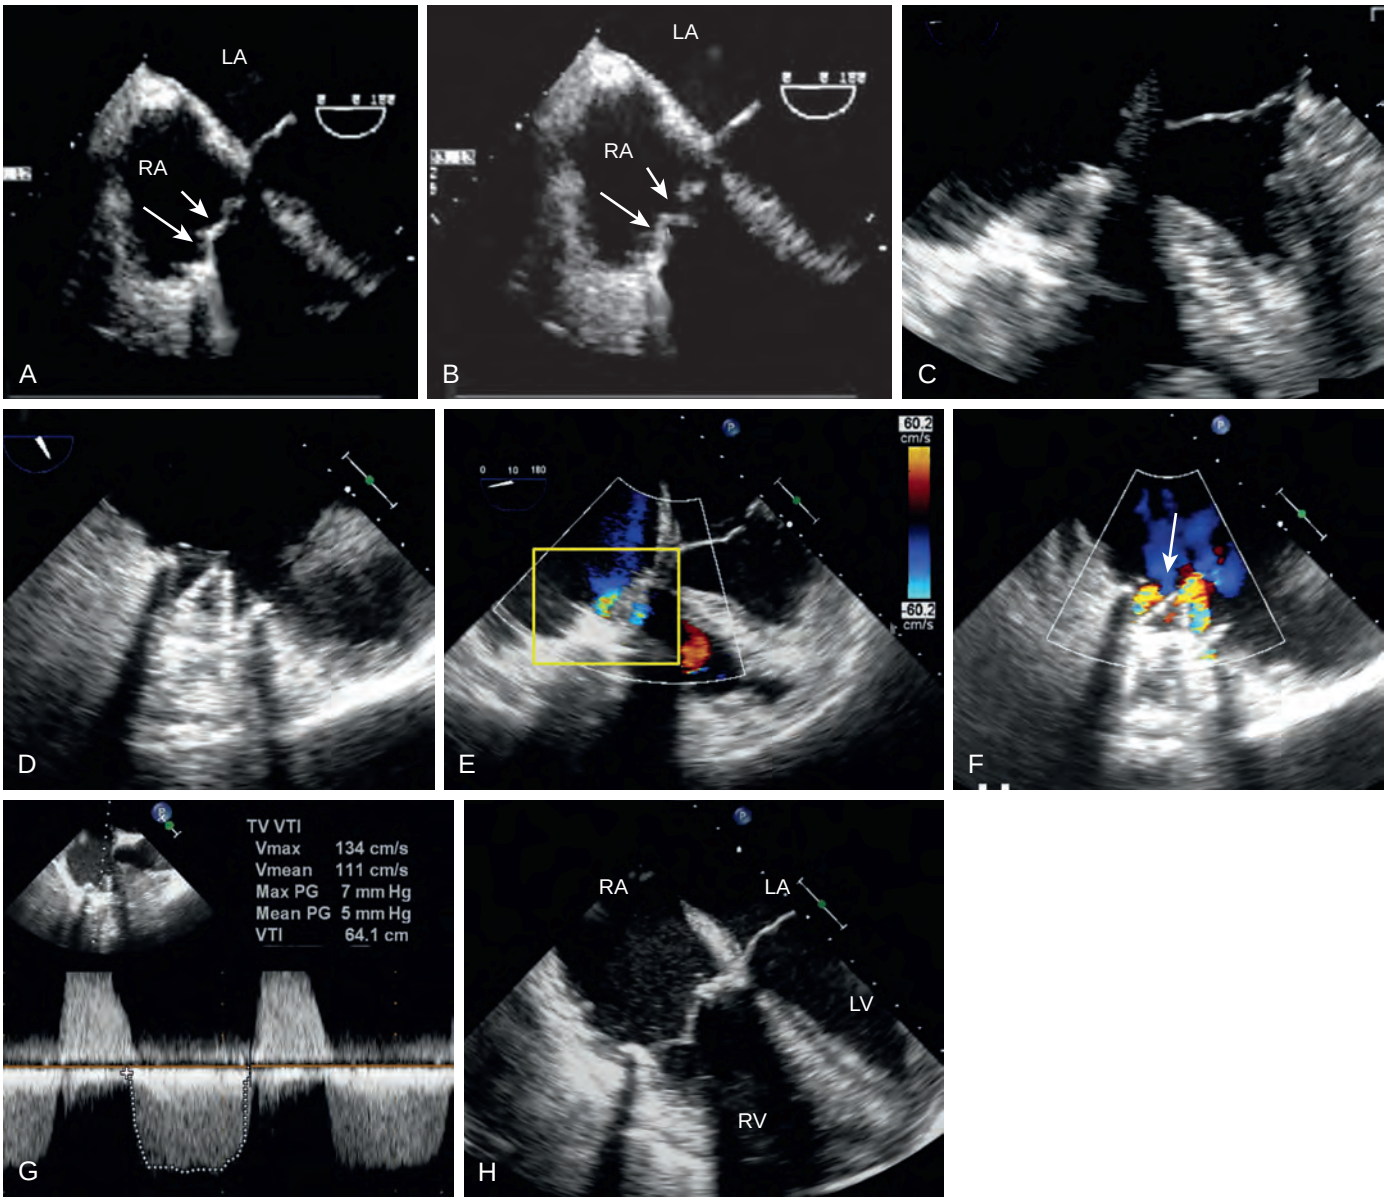

Fig. 15.91 Stuck mechanical valve leaflet in the tricuspid position. Two cases (A/B and C–H) are shown in which one of the mechanical leaflets of a bileaflet mechanical valve is stuck in a closed position (*arrows* in [A] and [B]). (E) and (F) Color Doppler imaging is unrewarding due to imaging artifact *(box* and *arrow);* however, (G) continuous-wave Doppler shows a profile consistent with tricuspid valve stenosis with a mean gradient of 5 mm Hg. In both cases, (H) valve replacement with a bioprosthetic valve was performed. *LA,* left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

counterparts, it may be necessary to reduce the color scale to highlight turbulent jets and identify potentially abnormal flows.

Pulmonary Valve Insufficiency

PI is found in up to 75% of patients in the absence of any abnormality and is considered normal[18] (see Fig. 15.95). These jets are centrally directed. Abnormal PI has greater proximal jet width, VC greater than 3 mm, and/or eccentrically directed flow (Table 15.10). Mild-to-moderate PI can be seen in patients with moderate-to-severe pulmonary hypertension (ie, functional PI). Otherwise, severe PI is caused by a primary valvular abnormality including bicuspid or quadricuspid valves, leaflet prolapse, hypoplasia, postrepair after tetralogy of Fallot, carcinoid syndrome, endocarditis, or rheumatic valvitis[18,105] (Figs. 15.96 and 15.97).

Prosthetic valve regurgitation results from valve deterioration, infection, dehiscence, or leaflet restriction. In assessing regurgitant flows of prosthetic valves in the pulmonary position, the presence of normal or expected regurgitant jets should be differentiated from abnormal jets. The presence of central trace/mild PI in the absence of disease is a normal finding for bioprosthetic valves, while mechanical valves have two to three washing jets that are known. Findings consistent with abnormal regurgitant jets include jets greater than 3 mm, larger regurgitant jet/RVOT diameter ratio (>25%), an eccentric jet, and/or reversal of diastolic flow in the PA.[21,22]

Two-dimensional imaging of the PV elucidates valvular anatomy, leaflet number, leaflet mobility, and thickening. However, compared to the AV, the PV leaflets are thinner and more difficult to visualize with TTE or TEE. Multiple windows and angles help to obtain the best image of the PV.

PI is sought during CFD interrogation of the RVOT. Its severity is determined by the appearance of the continuous-wave flow profile, the ratio of the proximal jet width to the RVOT diameter, and the PHT.

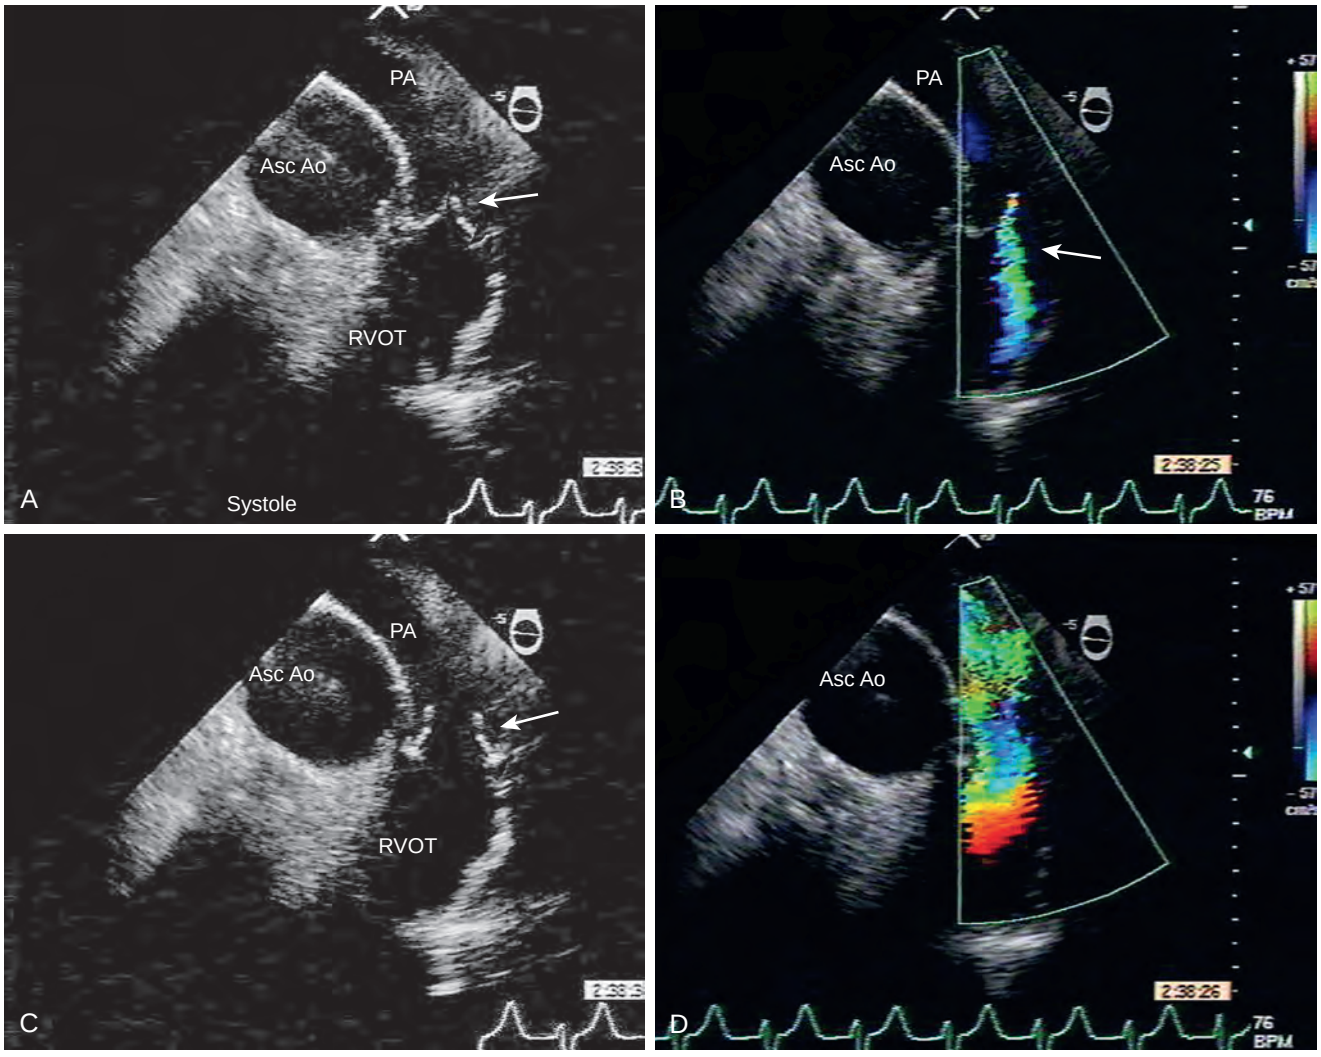

Fig. 15.92 Pulmonary valve replacement: bioprosthetic valve. (A–D) Imaging from the upper esophageal windows of the main pulmonary artery *(PA)* and a cross-section of the ascending aorta *(Asc Ao)*. Color Doppler imaging shows (B) the expected centrally directed regurgitant jet and (D) normal forward flows of a bioprosthetic valve. *RVOT*, right ventricular outflow tract.

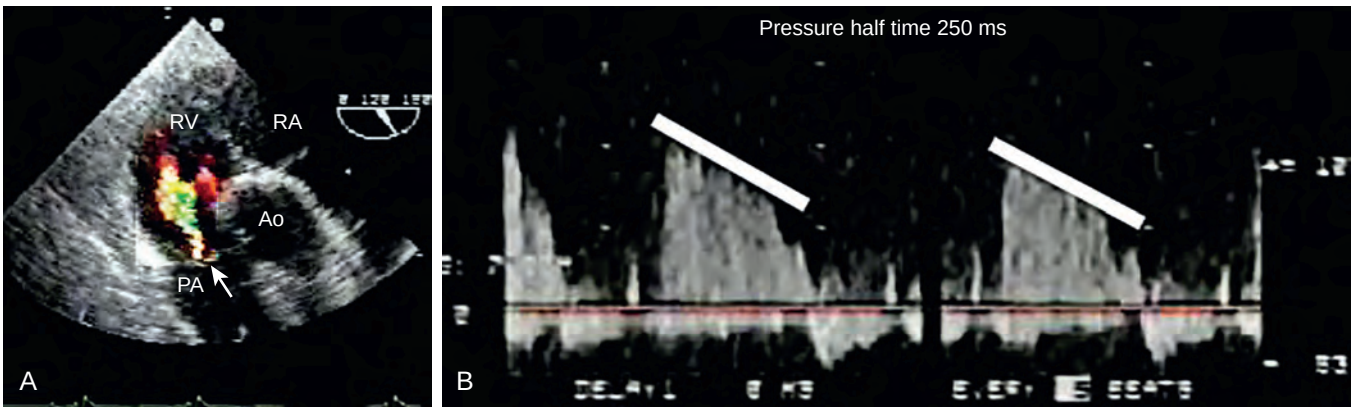

Fig. 15.93 Pulmonary insufficiency. Transgastric imaging shows right ventricular inflow and outflow. (A) Color Doppler applied to the pulmonary valve shows regurgitation as supported by (B) the pressure half time of 250 ms. *Ao*, Aorta; *PA*, pulmonary artery; *RA*, right atrium; *RV*, right ventricle.

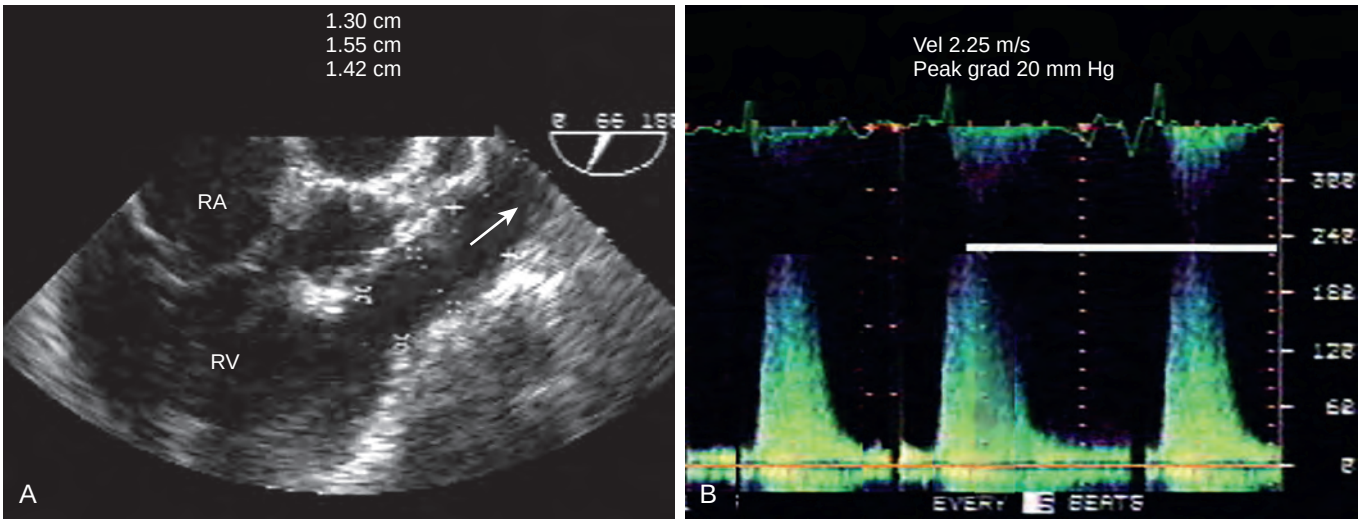

Fig. 15.94 Right ventricular outflow narrowing. From these midesophageal windows (A) the right ventricular outflow tract appears narrow. (B) Continuous-wave Doppler analysis reveals an elevated gradient of 20 mm Hg. Relief of this obstruction requires a prosthetic patch and outflow enlargement. *Peak grad,* Peak gradient; *RA,* right atrium; *RV,* right ventricle; *Vel,* velocity.

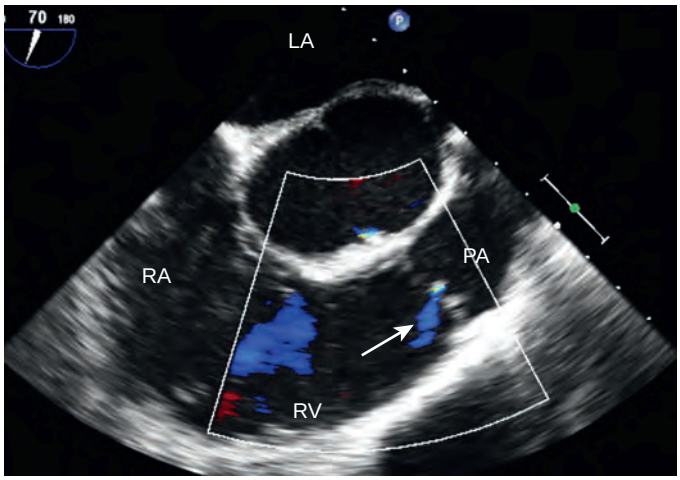

Fig. 15.95 Normal pulmonary valve insufficiency. Approximately 75% of patients have a mild pulmonary insufficiency (considered within the normal range) in the absence of disease. The pulmonary insufficiency jet is narrow *(arrow). LA,* Left atrium; *PA,* pulmonary artery; *RA,* right atrium; *RV,* right ventricle.

Grading of PI (mild, moderate, severe) is less validated compared to AI; however, since PV procedures are not likely to be performed unless severe PI exists, the echocardiography need only differentiate between severe and nonsevere PI.[24] The denser and more complete appearance of the PI TVI suggests more severe dysfunction.[18] Doppler measurements consistent with severe PI include a jet-to-RVOT width ratio of higher than 50% to 65%, PHT less than 100 ms, a regurgitant fraction greater than 60%, and Doppler diastolic flow reversal in the PA.[18,19,105,126,127]

In chronic conditions, the absence of RV dilation or dysfunction suggests that PI may not be severe. While the timing of surgery is typically based on symptomatology (fatigue, syncope, right heart failure, arrhythmias), it has been proposed to time surgery based on RV function and dimensions with the hopes of preventing long-term dysfunction. These include either an RV end-diastolic volume index greater than 163 mL/m^2 or an RV end-systolic volume index greater than 80 mL/m^2.[128]

TABLE 15.10 Pulmonary Valve Regurgitation: Degrees of Severity

	Mild	*Moderate*	*Severe*
Jet density	Incomplete/faint	Dense	Dense
Vena contracta (mm)	—	—	>6
Color Doppler jet width/ RVOT width (%)	≤25	26–50	>50
Pressure half time (ms)	500	200–500	<200
Regurgitant fraction (%)	<30	30–60	>60

Pulmonary Valve Stenosis

Pulmonary valve stenosis (PS) is less common than PI (Table 15.11). Stenosis of the native pulmonic valve is most commonly a congenital problem with the valve described as acommissural, unicommissural, bicuspid, or dysplastic.[17,105] The leaflets may appear domed-shaped and tethered to the arterial wall, while the leaflets in the latter are thickened at the leaflets' free edges[129] (Fig. 15.98). PS may also occur as part of a congenital syndrome (tetralogy of Fallot, AV canal defect, double outlet right ventricle, Noonan syndrome, or Williams syndrome). Obstruction to outflow from the right ventricle also may be nonvalvular (ie, subvalvular or supravalvular) and related to VSD, hypertrophic cardiomyopathy (HCM), or secondary to primary valve stenosis.[18,105] Forward flow may be affected by carcinoid tumor/involvement or rheumatic disease; however, these two diseases are associated with other valvular disease. Finally, thrombus or tumor can result in pulmonary outflow obstruction.

Doppler quantification of PS severity is based on transvalvular velocity and gradient.[18,25–27,105,127] A peak velocity less than 3 m/s or greater than 4 m/s is suggestive of nonsevere and severe PS, respectively. These values correlate with pressure gradients of less than 36 or greater than 64 mm Hg. Mean pressure gradients less than 20, 20 to 35, and greater than 35 mm Hg suggest mild, moderate, and severe obstruction to forward flow across the PV (see Fig. 15.98). It is important to distinguish abnormal transvalvular flow from subvalvular (RV hypertrophy), or supravalvular (pulmonary atresia) obstructions (Fig. 15.99).

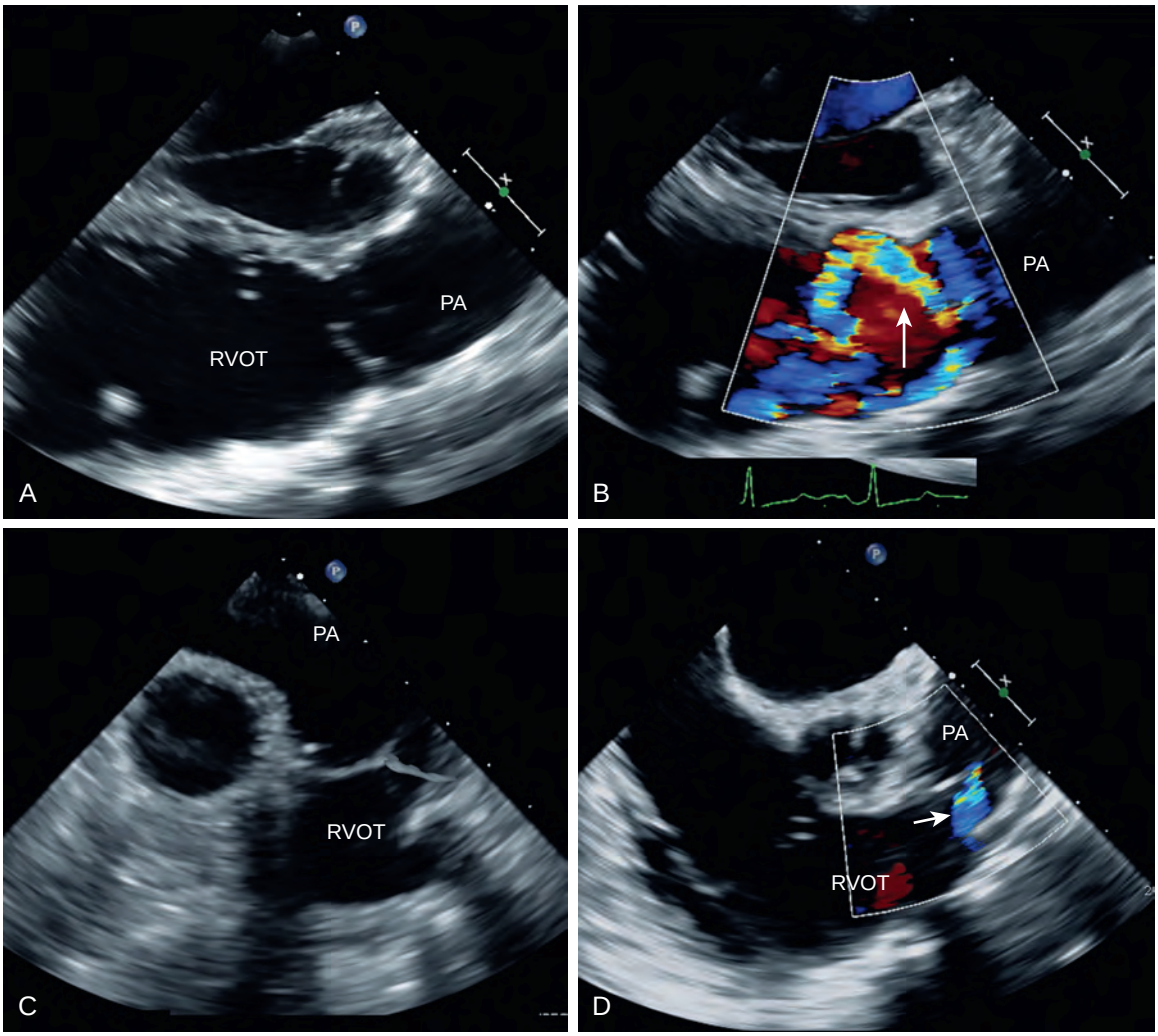

Fig. 15.96 Prolapsing or flail pulmonary valve leaflet. From these midesophageal windows (A) the pulmonary valve leaflet can be seen as prolapsed or flail and is associated with (B) severe eccentric regurgitation *(arrow)*. (C) and (D) After replacement with a bioprosthetic valve. *Arrow* indicates minimal pulmonary regurgitation. *PA,* Pulmonary artery; *RVOT,* right ventricular outflow tract.

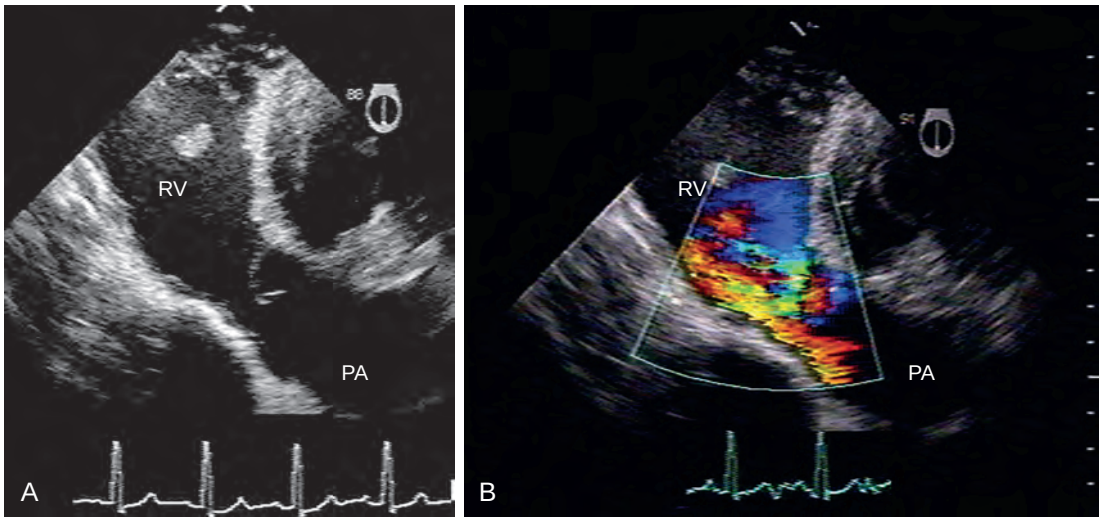

Fig. 15.97 Congenital pulmonary insufficiency. (A) Congenital pulmonary insufficiency and absence of full pulmonary valve associated with (B) severe pulmonary valve insufficiency. *PA,* pulmonary artery; *RV,* right ventricle.

TABLE 15.11 Pulmonary Valve Stenosis: Degrees of Severity

	Mild	*Moderate*	*Severe*
Peak jet velocity (m/s)	<3	3–4	>4.0
Mean pressure gradient (mm Hg)	<20	20–35	>35

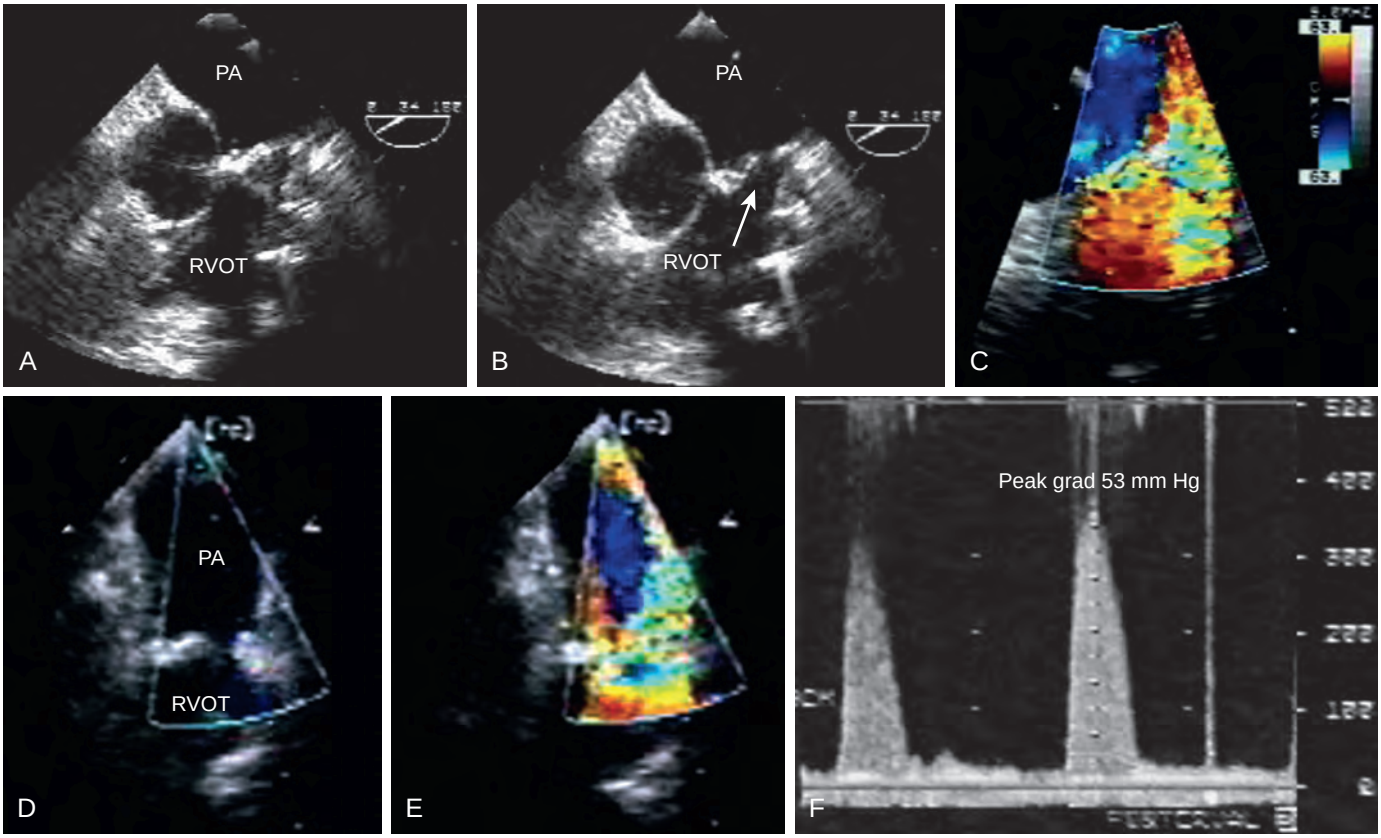

Fig. 15.98 Pulmonary valve stenosis. Images were obtained from midesophageal windows from different angles and probe rotations to visualize flow across the pulmonary valve and to align the Doppler beam with blood flow. (A) and (B) Bioprosthetic valve complicated by obstruction. (C) Color-flow Doppler image of obstruction, showing distorted valve significant turbulence. (D) Thickened leaflets. (E) Abnormal Doppler flow. (F) Continuous-wave Doppler imaging reveals a gradient greater than 50 mm Hg consistent with severe pulmonary valve stenosis. *PA,* Pulmonary artery; *Peak grad,* peak gradient; *RVOT,* right ventricular outflow tract.

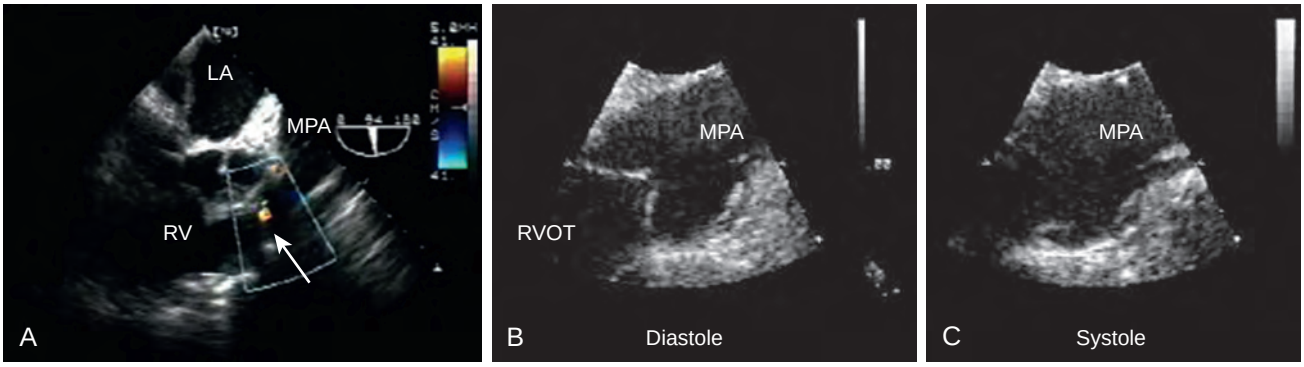

Fig. 15.99 Right ventricular failure: epicardial scanning. The images shown are those obtained after homograft replacement of the pulmonary valve as part of a Ross procedure. There was significant right-sided heart failure. Transesophageal echocardiography imaging was not possible; however, epicardial imaging showed a normal functioning pulmonary valve. Further assessment showed that the pulmonary artery anastomosis created significant narrowing and obstruction to flow.

Secondary effects of PS include RV hypertrophy (RV walls greater than 8 mm), right heart dysfunction, TR, RA enlargement, and dilated venae cavae. There are few data assessing PV area with the continuity equation; therefore, much of the assessment is based on pressure gradients.

The timing of surgery is based on symptomatology, transvalvular gradient, and secondary changes related to PS. A peak velocity greater than 4 m/s or gradient greater than 50 mm Hg predicts a significant reduction in event-free survival and intervention is recommended.[25–27,130] Valvular stenosis less than severe does not warrant intervention.[131] Although balloon valvuloplasty is most commonly performed, patients who are not suitable are considered for surgical intervention. One example is the presence of RV outflow hypertrophy and obstruction requiring enlargement.

Transesophageal Echocardiography for Interventional Procedures

In 1929, Werner Forssmann, a surgical intern (and eventually a Nobel Laureate) described the first cardiac catheterization procedure performed on himself.[132] Interventional cardiology has evolved tremendously after Andreas Gruentzig introduced the balloon angioplasty in 1976, and these procedures can now be used as an alternative or adjunct to cardiac surgery.[133] Long-term data for catheter-based interventions suggests that they may significantly reduce morbidity and mortality rates, and most believe that the need for these procedures, as well as their indications, will increase in the future[134] (see Chapters 3 and 27). Fluoroscopy has been traditionally used to guide interventional procedures, but its use is limited by significant radiation exposure and the need for intravenous contrast, with its associated potential toxicity.[135,136] Emerging interventional cardiac procedures have frequently benefited from TEE guidance, creating the need for interventional echocardiographers.[137] The current role of TEE is being transformed from a monitoring modality into an indispensable procedural adjunct, with the cardiac anesthesiologist becoming an echocardiologist.[138] TEE is now an integral part of the decision-making process during the perioperative care of patients undergoing cardiac surgical procedures.[139]

In cardiac interventional procedures, TEE is routinely used for preoperative assessment, surgical planning, procedural guidance, and evaluation of surgical results. Guidance of septal puncture, evaluation of LA appendage (LAA) thrombi, and closure of paravalvular leaks are some of the potential scenarios where TEE may be helpful in the interventional suite.[137] Some common interventional procedures that benefit from TEE guidance are summarized in Box 15.3. An important advantage of TEE over other imaging modalities is the relatively lower cost, increased portability, and its capacity to provide real-time information.[140] These characteristics make TEE a valuable resource that can enhance the safety and efficiency of percutaneous cardiac interventions.[141]

In this section we discuss the logistics associated with providing TEE service in the interventional suite, examine the implications of specific interventional procedures for the echocardiographer, and discuss the increasing importance of 3D TEE for procedural guidance. However, it is important to clarify that intra-cardiac echocardiography and TTE are also commonly used in interventional procedures.[142]

BOX 15.3 SELECTED INTERVENTIONAL CARDIAC PROCEDURES THAT BENEFIT FROM TRANSESOPHAGEAL ECHOCARDIOGRAPHIC GUIDANCE

Patent foramen ovale closure
Atrial septal defect closure
Ventricular septal defect closure
Mitral valve balloon valvuloplasty
Minimally invasive mitral valve surgery
Robotic mitral valve surgery
MitraClip
Transcatheter aortic valve implantation
Percutaneous closure of paravalvular leaks
Ventricular assist device placement
Left atrial appendage exclusion
Lead extraction

Organizing a Transesophageal Echocardiography Service for the Interventional Suite

Interventional cardiac procedures are performed either in the cardiac catheterization laboratory or in specialized hybrid operating rooms. In a large number of institutions, a cardiac anesthesiologist is responsible for providing both anesthesia and echocardiography services. Knowledge of radiation safety is also important, as interventional procedures significantly increase health care workers' radiation exposure.[143]

Role of the Echocardiographer on the Interventional Team

Echocardiographic evaluation is necessary to confirm the indication for the procedure, evaluate the patient for contraindications, provide real-time guidance during key moments (eg, septal puncture), and confirm the success of the procedure or identify its complications. When using TEE guidance for interventional procedures, the echocardiographer is the eyes of the interventionalist and provides visual and structural guidance that is missing from the fluoroscopy monitors. Therefore, in the hybrid operating room or catheterization laboratory, communication between all members of the team is essential.[144]

Echocardiographic Equipment and Setup

In general, ultrasound systems for a hybrid operating room or catheterization laboratory should have certain characteristics. Systems should have a selection of different probes: a high-frequency linear probe for vascular access, a cardiac probe for TTE, and a TEE probe with 3D imaging capabilities. The 3D imaging probe should be able to provide real-time 3D and biplane imaging, as well as performing R-wave gated reconstruction, and be equipped with on-cart software capable of multiplanar reformatting and 3D quantitative analysis. Lastly, capability of sharing images from the ultrasound system with the interventionalist's display is desirable. The need for fusion imaging capabilities is likely to increase in the future.[145] A typical setup of a hybrid room and catheterization lab with the TEE system is shown in Fig. 15.100.

Fig. 15.100 A typical hybrid operating room.

Transesophageal Echocardiography Evaluation During Specific Procedures

Interatrial Transseptal Puncture

Access to the left atrium is required during several interventional procedures, such as percutaneous MV valvuloplasty, placement of LAA occlusion devices, and radiofrequency ablation for atrial fibrillation. Unfortunately, the left atrium is the most difficult chamber to access percutaneously.[146] Puncture of the interatrial septum (IAS) allows for more direct access to the left atrium from the systemic venous system. Although transseptal puncture is relatively safe, it can be associated with life-threatening complications, especially in inexperienced hands, in repeat procedures, or in patients with difficult IAS anatomy.[147–149] TEE is a frequently used imaging modality for guidance of IAS puncture. Three-dimensional TEE allows for visualization of the IAS en face and appreciation of its spatial relationship with the surrounding structures.[150]

Echocardiographic Assessment

A comprehensive TEE examination is performed to assess cardiac structure and function, as well as the dimensions of both atria. The left atrium and LAA are interrogated to rule out thrombi. It is important to evaluate the presence of IAS aneurysm, Chiari network, eustachian valve, lipomatous IAS hypertrophy, patent foramen ovale (PFO), and ASD, all of which may impact the procedure.

Focused evaluation of the IAS is performed in different planes to identify and select the puncture site (usually in the fossa ovalis). Evaluation for IAS puncture with 3D TEE can start by obtaining an ME bicaval view.[151] After the image is obtained, the wide-angle 3D zoom function is used and the lateral and elevation planes are optimized to visualize the entire IAS. The depth plane is set to include only the left and right sides of the IAS. The relative immobility of the IAS allows for adequate visualization despite the low frame rate of the resulting image.[150] To obtain an en face view of the IAS, the 3D volume is rotated so that the superior vena cava is at the 12 o'clock position. The image can then be turned to visualize the RA or LA perspective as needed.[152] The relationship of the AV and aortic root to the IAS is particularly important to visualize, because of the potentially life-threatening consequences of perforating these structures. After visualization of the IAS, the needle, dilator, and sheath are placed near the superior vena cava and RA junction. The needle is then guided with both TEE and fluoroscopy assistance as it approaches the IAS. A tenting of the IAS is observed as the sheath exerts pressure on the fossa ovalis (Fig. 15.101). The position of the needle inside the left atrium (Fig. 15.102) can then be confirmed with TEE by injection of agitated saline or with fluoroscopy with radiographic contrast.

Regardless of the interventional procedure performed, TEE evaluation after transseptal puncture is performed to rule out pericardial

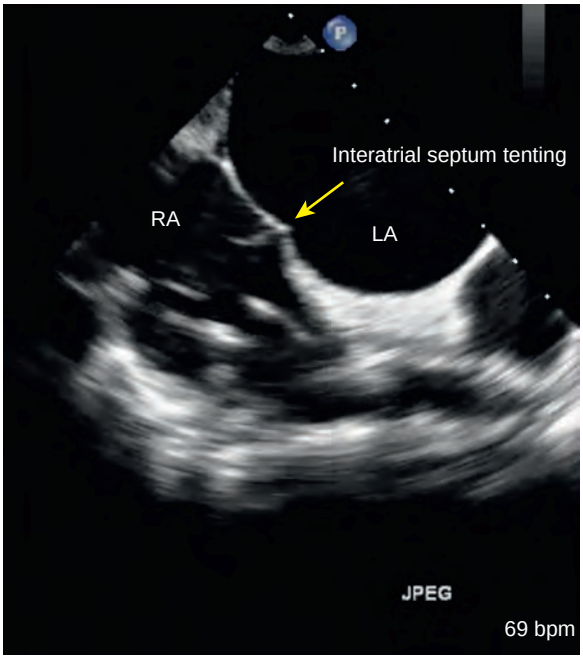

Fig. 15.101 As the needle exerts pressure, tenting of the interatrial septum is observed. *LA*, left atrium; *RA*, right atrium.

effusion or tamponade, and CFD interrogation of the IAS is also performed to evaluate the size and characteristics of the residual ASD created by the transseptal puncture (Fig. 15.103).

Patent Foramen Ovale Closure

The foramen ovale is an opening at the fossa ovalis, where the septum primum and septum secundum overlap. Functional and anatomic closure of the foramen ovale occurs after birth as a result of the difference in pressure between the atrial chambers in the newborn. A PFO occurs in a high proportion of the population.[153] In certain patients, particularly those with a history of cryptogenic stroke or transient ischemic attack, PFO closure may be recommended.[154]

Echocardiographic Assessment

TEE evaluation for PFO closure consists of confirming the diagnosis, quantifying the size of the PFO, evaluating the suitability for closure, and excluding additional disease that may affect the intervention (eg, anomalous pulmonary venous return or large IAS aneurysm).[155] Since these defects have relatively low flow of blood, reducing the Nyquist limit (20–30 cm/s) is useful to aid in their visualization.[156] Injection of agitated saline through a peripheral vein can also be used. In patients with left-to-right shunts, a washout of the contrast in the RA is seen as blood enters from the left atrium (Fig. 15.104). Release of a Valsalva maneuver transiently increases RA pressure and may demonstrate reversal with right-to-left shunting of the contrast medium. The use of agitated saline for this purpose is controversial.[157] The echocardiographic evaluation and guidance for PFO closure is very similar to that of ASD closure and is discussed in the next section.

Atrial Septal Defect Closure

ASDs constitute approximately 50% of hospital admissions for congenital heart disease in the United States.[158] Approximately 75% of ASDs are of the ostium secundum type, which is amenable to percutaneous closure.[159] In fact, percutaneous closure of secundum type ASD has been shown to result in a decreased number of perioperative complications, reduced length of stay, and a benefit in survival.[160,161] Today, the great majority of secundum type ASDs are closed percutaneously.

Echocardiographic guidance is particularly useful for ASD closure, and TEE and intracardiac echocardiography have both been used successfully.[162] Real-time 3D TEE imaging is particularly useful in evaluating ASDs with complex geometries (Fig. 15.105).[163]

Echocardiographic Assessment

CFD interrogation of the IAS with TEE is commonly used to confirm the presence of a secundum ASD or PFO. The ME AV short-axis, ME bicaval, and ME four-chamber views are frequently used to assess ASDs with 2D TEE. An evaluation of all pulmonary veins with exclusion of any congenital abnormalities of location and number should be noted.

Patients who are not suited for percutaneous closure include those with large defects (>38 mm in diameter), anomalous pulmonary venous drainage, or ASDs other than secundum type (ie, primum ASD, sinus venosus ASD, or coronary sinus defects).[164]

Complete TEE examination for ASD closure is important to exclude associated congenital abnormalities, IAS aneurysm, and atrial or LAA thrombi, and to search for signs of LA pressure overload and diastolic dysfunction. During TEE evaluation, it is also important to evaluate the diameter of the ASD rims. An inferior rim (ie, adjacent to the inferior vena cava) of more than 5 mm is required for stable device positioning.[165]

To perform percutaneous closure of the ASD, an interventionalist advances a guidewire via the RA through the ASD and toward the left atrium and anchors it at the left upper pulmonary vein. A balloon is then inflated to gauge the size of the defect (Fig. 15.106). The diameter of the waist of the inflated balloon is measured with TEE to calculate the size of the device that will be placed. CFD examination with the balloon inflated is important to demonstrate absence of flow through the ASD (Fig. 15.107). The device is then loaded on a delivery sheath and advanced. The LA disk is deployed with TEE and fluoroscopic guidance and then abutted against the atrial surface. The alignment of the disk to the IAS is confirmed with TEE and readjusted as necessary. The RA disk is then deployed, maintaining parallel alignment to the septum, and an adequate position of the device is confirmed by TEE. The device is adequately positioned when there is one hemi-disk in each atrium, the ASD ring is between the two hemi-disks, the LA disk does not move past the ASD ring with pulling of the sheath, no erosion of adjacent structures (particularly the roof of the left atrium and aortic root) is found, and no obstruction of the venae cavae inflow, coronary sinus, or right pulmonary veins is found. After the position is confirmed and satisfactory, the release mechanism is activated to liberate the device (Fig. 15.108).[166]

The patient is monitored with TEE for a few minutes after device release to evaluate for complications, such as device embolization, impingement of MV or TV, entrapment of pacing wires, and pericardial effusion or tamponade resulting from erosion of cardiac structures.[167–169] Residual flow through the ASD is evaluated with CFD. A small flow through the mesh of the device can be expected, but it will stop with endothelialization of the device.

Ventricular Septal Defect Closure

In adult patients, percutaneous closure of a VSD is usually performed for acquired postmyocardial infarction defects.[170] In rare cases, adults may require percutaneous closure of congenital muscular or perimembranous VSDs or for defects persisting after surgical repair. Despite being a relatively safe technique, percutaneous VSD closure is still associated with a significant risk of life-threatening perioperative complications and death.[171] This is due, in part, to procedural complications (eg, complete heart block) but also to the high risk of patients requiring these procedures.[172]

Procedural Echocardiographic Assessment

Real-time 2D and 3D TEE evaluation is extremely useful for delineating VSD anatomy. Three-dimensional TEE is particularly useful to assess postmyocardial infarction VSDs because of their irregular shape (Fig. 15.109).[173,174] The location of the defect and its size, as well as the spatial relationship to the tricuspid, mitral, and AVs, are important. Complete assessment of valve dysfunction, pulmonary hypertension, and LV function are some of the advantages of TEE monitoring during the procedure. The most useful views for VSD assessment with TEE are the ME four-chamber, ME long-axis, TG short-axis, and deep TG

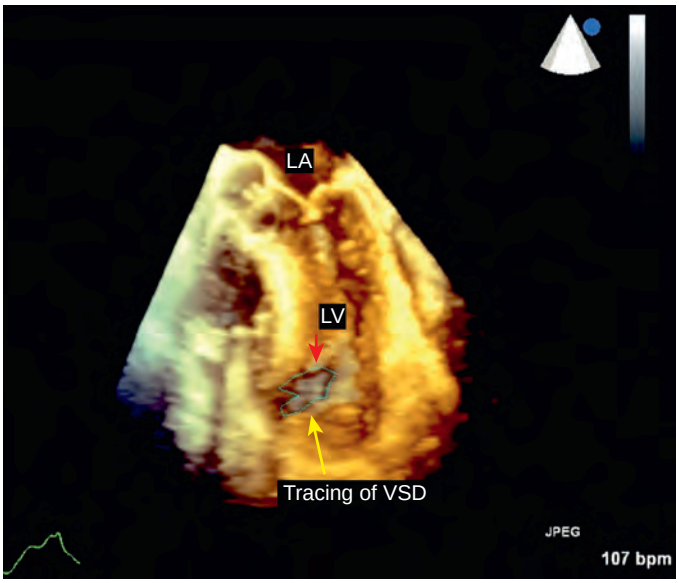

Fig. 15.109 Full volume acquisition with visualization of a postinfarction ventricular septal defect (VSD) from the left ventricular perspective. *LA,* left atrium; *LV,* left ventricle.

views (Fig. 15.110). A surgical patch or other prosthetic material can cause acoustic shadowing and make TEE visualization difficult or impossible.

During the procedure, the left ventricle is accessed with a guidewire through the femoral artery. The wire is then passed toward the venous side of the VSD. Size of the VSD is assessed with TEE or balloon inflation during diastole. Afterward, a snare is introduced through the internal jugular or femoral veins to pull the wire, creating an arteriovenous wire loop that will serve as a rail to deploy the closure device. Over this loop the catheter is introduced through the internal jugular or femoral vein and then advanced under TEE guidance into the left ventricle. Afterward, the LV disk is deployed, avoiding impingement on the MV. After confirming an adequate position, the RV disk is deployed. TEE evaluation is necessary after liberation of the device for assessing residual shunt, device stability, and MV or TV impingement.[175]

Percutaneous Coronary Sinus Catheter Placement

Minimally invasive cardiac surgery has been continuously evolving since the 1990s. Approximately 20% of MV surgery is performed with a minimally invasive approach, with 50% of these cases being robotic surgeries.[176] Although the benefits of minimally invasive cardiac surgery are still under debate, it has definite advantages in patient satisfaction rates and cosmetic appearance.[177] Some studies have also shown a decrease in length of stay, transfusion rates, and earlier return to daily activities.[178] Despite this, a clear mortality benefit has not been proved yet.[179] TEE plays an essential role in the success of minimally invasive cardiac surgery in patients who require administration of retrograde cardioplegia, and it is used to guide cannulation of the coronary sinus (see Chapters 13 and 21).[180]

Echocardiographic Assessment

A comprehensive TEE examination must be performed prior to cannulation during minimally invasive cardiac procedures. Because a great proportion of minimally invasive cardiac surgeries require single-lung ventilation, care must be exercised during probe insertion and manipulation to prevent dislodgement or malposition of lung isolating devices. Special attention should be provided to evaluate the patient for conditions that may complicate or preclude retrograde cardioplegia delivery, such as a thebesian valve, Chiari network, and persistent left-sided superior vena cava.

During minimally invasive cardiac surgery, retrograde cardioplegia is delivered using a coronary sinus catheter, which is placed through the right internal jugular vein. Cannulation of the coronary sinus ostium is performed with TEE guidance as it has been shown to be a useful adjunct to fluoroscopy in guiding coronary sinus cannulation from the right internal jugular vein.[181]

After a sheath is placed in the right internal jugular vein, a retrograde cardioplegia catheter is introduced. This catheter allows for distal pressure measurement and cardioplegia delivery and has a balloon that can be inflated to occlude the coronary sinus. After introducing the catheter, it is advanced to the RA–superior vena cava junction. Advancement of the catheter is monitored with TEE by using the ME bicaval and ME modified bicaval views. Once at the caval-atrial junction, the catheter is slowly advanced in the direction of the coronary sinus ostium, under direct visualization from the ME modified bicaval view (Fig. 15.111). Slight rotation and advancement /withdrawal of the catheter may have to be performed in order to cannulate the coronary sinus.[182] Slight retroflexion and/or advancement of the probe from an ME four-chamber view shows an additional long-axis view of the coronary sinus that may aid in confirmation of catheter position.[183]

In some patients, 3D TEE may aid in the placement of the retrograde cardioplegia catheter, particularly in those in which alignment of the catheter and coronary sinus is repeatedly difficult (Fig. 15.112). To obtain an adequate view of the coronary sinus for this purpose, an ME four-chamber view is first obtained. Centering the image on the TV, the wide-angle 3D zoom function is activated, and the ROI is enlarged to cover the RA toward the region slightly below the TV. Once the 3D image is obtained, it is rotated so that an en face view of the coronary sinus is seen.[184] Despite the advantages of this imaging modality, significant artifacts associated with manipulation of the coronary sinus catheter may obscure the image.

Because visualization of the catheter tip may be difficult with TEE, other methods may be used to confirm coronary sinus cannulation. If the balloon is inflated, a ventricularization of the pressure should occur. Fluoroscopy with injection of contrast also can be used to assess the position of the catheter tip. Success of coronary sinus cannulation is approximately 87.5%, with a relatively low incidence of complications. However, the time to successful cannulation can vary and the procedure has been shown to take approximately as long as 16.1 minutes in experienced hands, and dislodgement of the catheter occurs frequently after placement.[181] The most feared complication of the procedure is coronary sinus perforation, which may present as a new onset pericardial effusion or tamponade. In some patients, visualization of air and fluid in the left posterior atrioventricular groove around the short-axis view of the coronary sinus in the ME two-chamber view may be an early sign of coronary sinus rupture.[184]

Percutaneous Interventions on the Mitral Valve

Balloon Valvuloplasty

Although it is relatively rare in the United States, rheumatic MS occurs frequently in the developing world.[185] Since its development in the mid-1980s, percutaneous balloon mitral valvuloplasty (PBMV) has become the technique of choice for the initial treatment of isolated rheumatic MS.[186,187] In other types of MS (eg, congenital), PBMV may be considered for some specific cases. A successful PBMV results in a significant improvement in both short- and long-term outcomes. Among asymptomatic patients, PBMV is usually performed in those

TABLE 15.12 Echocardiographic Grading of Mitral Valve Characteristics (Wilkins Score)

Grade	*Mobility*	*Subvalvular Thickening*	*Thickening*	*Calcification*
1	Highly mobile, leaflet tips restricted	Minimal	4–5 mm	Single area of hyperechogenicity
2	Normal in mid and base portions	Chordal thickening up to one-third of length	5–8 mm at margins of leaflets, mid leaflets normal	Scattered hyperechoic areas but confined to leaflet margins
3	Diastolic forward movement from base	Chordal thickening in distal third	Entire leaflet thickening (5–8 mm)	Hyperechoic areas extending to mid portion of leaflets
4	Minimal diastolic leaflet mobility	Extensive thickening up to papillary muscles	Considerable leaflet thickening (>8 mm)	Majority of leaflet is hyperechoic

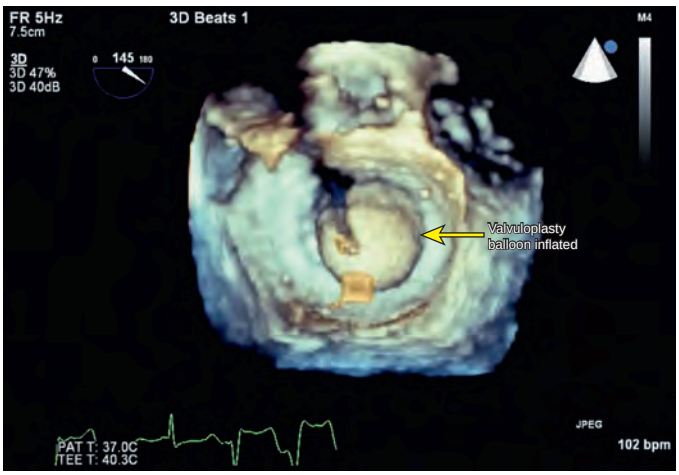

Fig. 15.113 En face view of the mitral valve demonstrating balloon inflation during percutaneous valvuloplasty.

with moderate or severe stenosis (MVA < 1.5 cm^2) with evidence of pulmonary hypertension.[26]

Although not mandatory, TEE is desirable for PBMV, especially to guide IAS puncture. Furthermore, TEE guidance has been shown to improve the placement of the balloon and reduce the total radiation time.[188] In this setting, TEE is frequently performed under mild sedation, so a clear explanation of the procedure to the patient and informed consent are extremely important.

Echocardiographic Evaluation

Intraoperative TEE evaluation should confirm that the patient is an adequate candidate for the procedure. Patients with important mitral annular calcification have poor outcomes with PBMV.[189] Furthermore, patients with LA thrombi, moderate-to-severe MR, and significant TR also are not suitable for PBMV. Three-dimensional TEE may be especially useful for measuring mitral annular diameter and calculating the size of the valvuloplasty balloon.[190] The likelihood of success of PBMV can be predicted using echocardiography-based scores (Table 15.12).[75] These scores have been also shown to correlate with overall costs.[191]

PBMV starts with an IAS puncture, used for gaining access to the left atrium. Real-time 3D TEE guidance is particularly useful for this part of the procedure. After the IAS is punctured, a balloon is advanced from the venous circulation across the IAS and inside the left atrium. The balloon is then guided through the MV orifice into the left ventricle. This portion of the procedure is preferably guided by wide-sector real-time 3D TEE. An ME four-chamber view can be used to evaluate the position of the catheter. TEE is also used to exclude subvalvular apparatus involvement prior to inflating the balloon. Afterward, the balloon is inflated under TEE guidance, ideally with real-time 3D or biplane imaging (Fig. 15.113).[192] After the balloon is inflated, commissural splitting should be confirmed and the MVA should be measured. An MVA greater than 1.5 cm^2 should be present if the procedure is successful. If the MVA is still reduced, balloon inflation may be attempted a second time. CFD imaging of the MV should also be obtained to evaluate the severity of postprocedure MR and to assess the iatrogenic IAS defect.

MitraClip

Severe MR has become an increasingly prevalent disease, with significant impact on survival.[193] Although surgery is beneficial in patients with MR due to MV prolapse or fibroelastic deficiency, the benefit is still under debate for patients with functional regurgitation.[194] Furthermore, several patients are not ideal candidates for surgery because of their increasing age, poor ventricular function, or high number of comorbidities.[195] Although various techniques for percutaneous MV repair have been proposed, the MitraClip (Abbott Vascular, Santa Clara, Calif) is currently the only US Food and Drug Administration (FDA)–approved technique for percutaneous management of MR. This device is indicated in severe (3–4+) primary MR. Inspired originally by the Alfieri edge-to-edge MV repair, it consists of a clip system that grasps the anterior and posterior leaflets together, reducing the regurgitant orifice and creating a double-orifice MV. The device is introduced through the femoral vein, across the IAS (transseptal puncture) through the MV, and into the left ventricle. A combination of TEE and fluoroscopy is used to guide the device into the left ventricle and deploy it (see Chapters 3, 21, and 27).

Echocardiographic Evaluation

Because of the proximity of the probe to the MV, TEE has been shown to be particularly useful for assessing MV structure and function. Furthermore, with 3D TEE many of the geometric assumptions and mental reconstructions required with 2D TEE to assess the complexity of the MV structure are overcome.[196] Because the MV cannot be adequately visualized with fluoroscopy, TEE is an integral part of the MitraClip procedure and the key to its success.

A TEE examination for a MitraClip procedure should first confirm the presence of MR and its severity. Since the procedure is usually performed under general anesthesia, MR severity may be decreased because of a lower peripheral vascular resistance.[197]

Evaluation of the specific scallops involved and the orientation of the regurgitant jet are also important because the MitraClip is better suited for patients with a discrete regurgitant jet originating within the central two-thirds of the line of leaflet coaptation (Fig. 15.114).[194] A planimetered MVA should be confirmed to be greater than 4.0 cm^2, and calcification of the leaflets should be minimal at the point of planned grasping. If a flail leaflet is present, the width of the flail segment should be less than 15 mm.[198] Coexisting conditions that increase the perioperative risk also should be noted, such as a highly calcified aorta or severe pulmonary hypertension.

During the procedure, guidance for IAS puncture is necessary. Once the sheath is advanced into the left atrium, the delivery system is directed perpendicular to the mitral annulus. Alignment may be confirmed with 3D TEE. When the device is perpendicular to the annulus, the grasping arms are opened and it is advanced inside the left ventricle (Fig. 15.115). The device is closed when the leaflets fall into the arms. After closure of the arms, the device's stability should be confirmed, and the MR severity should be evaluated. A successful MitraClip procedure reduces MR to a moderate degree of severity (grade 2+ or less).[199] If greater MR is present, the clip may be reopened and leaflet grasping attempted for a second time, or a second clip may

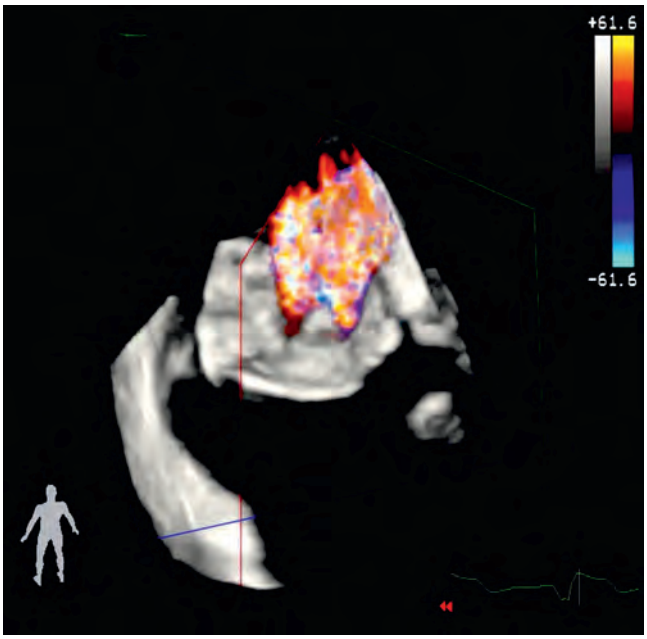

Fig. 15.114 Three-dimensional color-flow Doppler assessment of the mitral valve demonstrates a large regurgitation jet originating within the central two-thirds of the line of coaptation.

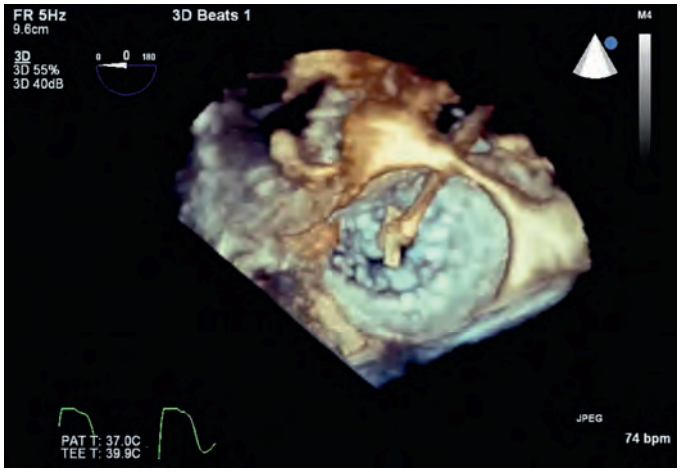

Fig. 15.115 The MitraClip device is seen inside the left atrium with its arms in the open position.

be placed.[200] Evaluation of residual MVA should be performed after clip deployment, confirming adequate transmitral inflow (Fig. 15.116). Certain methods, such as PHT, may be unreliable at this point for quantifying MVA after the MitraClip procedure.[201]

Percutaneous Interventions on the Aortic Valve

Severe AS significantly affects quality of life and is associated with a high mortality rate.[24] AVR is currently the treatment of choice for severe AS. However, AVR is also associated with a high incidence of perioperative complications and mortality in some patients. Transcatheter AVR (TAVR) is a therapeutic option in patients in whom surgery has an unacceptably high risk.[202] Furthermore, in patients in whom AVR may be technically difficult or has a high risk of complications (eg, porcelain aorta), TAVR may also be a suitable alternative.

Currently, there are two transcatheter AVs on the market, the Medtronic CoreValve (Medtronic, Minneapolis, Minn) and the Edwards SAPIEN II valve (Edwards Lifesciences, Irvine, Calif). The main features of both valves are summarized in Table 15.13.

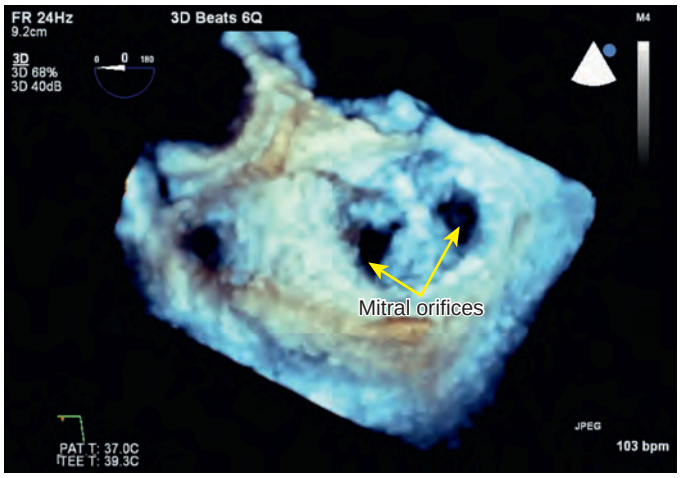

Fig. 15.116 Three-dimensional R-wave gated image demonstrating the repaired mitral valve with the resulting two orifices *(yellow arrows)* during diastole.

TABLE 15.13 Main Features of the Medtronic (Minneapolis, Minn) CoreValve and Edwards Lifesciences (Irvine, Calif) SAPIEN II Transcatheter Aortic Valves

Feature	*CoreValve*	*SAPIEN*
Frame component	Nitinol	Cobalt chromium
Leaflet component	Porcine pericardial	Bovine pericardial
Sizes available	23, 26, 29, and 31 mm	20, 23, 26, and 29 mm
Indicated for patients with annular diameters of	18–29 mm	16–27 mm
Transapical access	No	Yes
Balloon expandable	No	Yes
Self-expandable	Yes	No
Repositioning allowed	Yes	No
Annular fixation	Yes	Yes
Aortic fixation	Yes	No
Pacemaker requirement after implantation	14–40%	3–8%

These devices are usually inserted retrograde through the femoral artery; they also can be inserted through the axillary or subclavian arteries and ascending aorta in case of excessive calcification of the femoral artery. An antegrade transapical approach can also be performed (see Chapters 3, 21, and 27).[203]

Echocardiographic Evaluation

Most institutions usually prefer TEE evaluation during TAVR. In contrast to surgical AVR, during which the surgeon has direct visualization of the operative field, imaging plays an essential role for procedure guidance. A combination of TEE and fluoroscopy is commonly used for TAVR. Because of the need for TEE imaging, general anesthesia is frequently used for these procedures.

During the procedure, TEE evaluation is used to confirm the presence of a tricuspid AV. Original TAVR trials excluded patients with bicuspid AVs. Some investigators found that TAVR in the setting of a bicuspid valve is associated with a higher incidence of postprocedure AI because of the asymmetric shape of the aortic annulus and heavy calcification of aortic leaflets. Recently, this association has been debated.[204]

TEE evaluation is also necessary to accurately measure the aortic annulus diameter, because of the limited availability of valve sizes (see Table 15.13). Patients with aortic annuli less than 18 mm or greater than 27 mm are currently not adequate candidates for TAVR.[205] TEE is more accurate than TTE for aortic annulus sizing, especially in the presence of significant calcification. The aortic annulus is measured

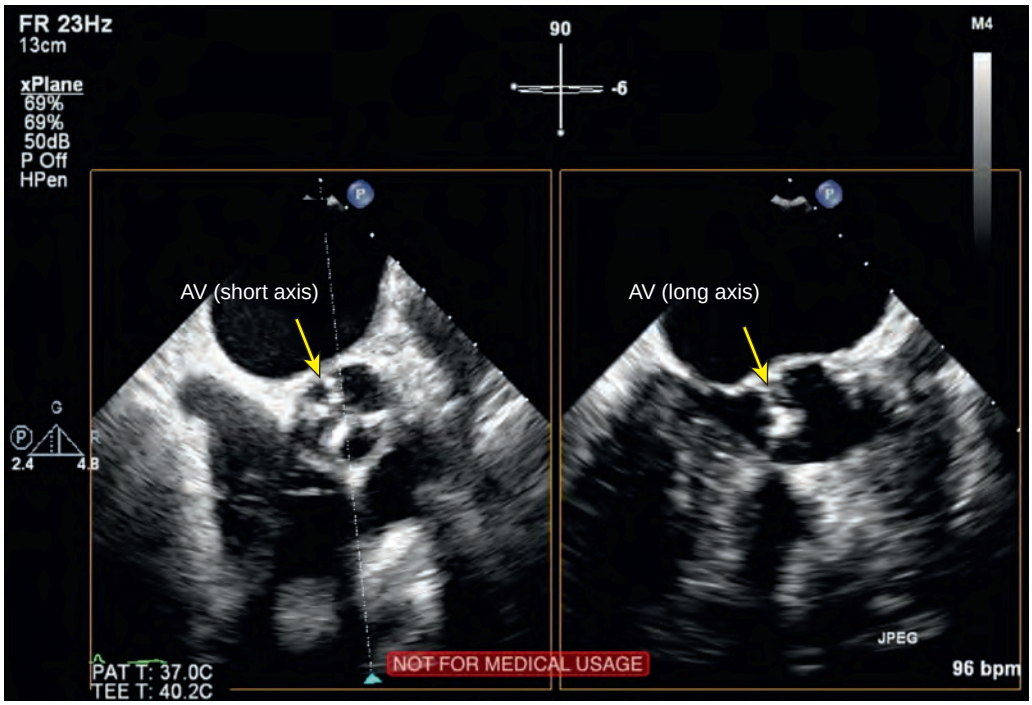

Fig. 15.117 Biplane imaging of the aortic annulus. *AV*, Aortic valve.

during systole in the ME AV long-axis view with 2D TEE between the hinge points of the AV leaflets. Biplane imaging can also be useful to ensure the anteroposterior diameter measurement is not affected by an oblique plane of view (Fig. 15.117). Some echocardiographers also prefer using 3D TEE with orthogonal alignment of multiplanar reformatting planes to obtain a more accurate annular diameter (Fig. 15.118, Video 15.1).[206,207] Some centers have advocated for a 5% to 10% oversizing of the prosthesis to decrease the probability of paravalvular leaks.[208,209]

Besides aortic annular diameter, the aortic root width between the sinuses of Valsalva, the STJ diameter, and the diameter of the ascending aorta should be measured. It is suggested that for TAVR to be successful, the diameter of the ascending aorta within 3 cm of the aortic annulus should be 43 mm or less. The ascending aorta should also be evaluated for atherosclerosis and calcification. The distance from the aortic annulus to the coronary ostia also can be determined with 3D TEE. The distance should be greater than 11 mm to decrease the risk of coronary ostium occlusion by the device after deployment.[210] Careful preprocedure evaluation of the patients' LV function and presence of MR (including severity and mechanism) are also essential so that they can be reassessed after deployment of the valve and compared to baseline.

The TAVR procedure starts by introducing a guidewire through the selected access site. The guidewire is advanced across the stenotic AV under TEE guidance (Fig. 15.119). This guidewire will be used to position the prosthesis. The guidewire should be visualized with TEE to ensure there is no impingement on the MV apparatus. The position of the prosthesis should be carefully selected, because if positioned too low it can embolize into the left ventricle or impinge on the MV, and if positioned too high it may embolize into the aorta, obstruct the coronary arteries, or cause paravalvular leak.[211]

For the SAPIEN valve, once the guidewire is in place, the balloon is advanced and positioned through the AV with fluoroscopic guidance and then confirmed with TEE. Rapid ventricular pacing is used at the time of device deployment to avoid displacement into the aorta. When the CoreValve is used, rapid ventricular pacing is not necessary.[212]

After deployment, TEE is used to ensure the valve stent is centered within the native aortic annulus and there is adequate leaflet opening. CFD is used to evaluate the degree of paravalvular leak (Fig. 15.120). Trace-to-mild central AR is expected to occur while the guidewire is in place (Fig. 15.121). In case of paravalvular leak, the prosthesis can be reballooned, or a second valve can be deployed.[213] LV function is also evaluated, and a new or worsening regional wall motion abnormality (RWMA) may indicate obstruction of a coronary ostium. The presence of pericardial effusion or tamponade and aortic dissection should also be evaluated.

AR has been associated with an increase in mortality rate after TAVR. It is difficult to evaluate AR with traditional methods after a TAVR procedure, because it is usually eccentric and associated with multiple jets (Fig. 15.122). The second Valve Academic Research Consortium described a semiquantitative method to classify AR after TAVR (Table 15.14).[214]

Percutaneous Closure of Paravalvular Leaks

Paravalvular leaks are common complications following MVR and AVR. Even though the majority of leaks are mild, significant leaks occur in 2% to 5% of patients.[215] Paravalvular leaks are twice as common in mitral as aortic prostheses, likely due to preexisting factors, such as endocarditis, mitral annulus calcification, and tissue friability. Paravalvular leaks can cause significant morbidity due to regurgitation and/or hemolysis. Hemolytic anemia is more common in mechanical than bioprosthetic valves. Reoperation after a valve replacement is associated with high morbidity and mortality rates, even greater than those associated with the initial procedure.

Echocardiographic Evaluation

Percutaneous closure of paravalvular leaks has become a suitable alternative for selected patients. As the regurgitant orifices responsible for paravalvular leaks are commonly irregular (crescent shaped or oblong), multiple, and serpiginous, 3D TEE is helpful in assessing the defect size and shape before percutaneous closure is performed.[216–218] The size of the paravalvular leak can be evaluated with 3D TEE by multiplanar reformatting and planimetry. This method measures the anatomic rather than the effective regurgitant orifice (ERO), and the size can vary with different machine settings. Three-dimensional TEE with CFD can be used to improve sizing of the ERO.[216] TEE evaluation

must note the location and number of leaks. Patients with paravalvular leaks and a dehiscence more than one-fourth the circumference of the sewing ring are unsuitable for percutaneous closure.[219]

For prosthetic mitral paravalvular leaks, an approach through an IAS puncture is usually selected. TEE is useful to guide IAS puncture and align the guidewire. Positioning of the wire in the left atrium is aided by 3D and multiplane imaging from the LA perspective. For paraaortic defects, the position of the coronary ostia should be carefully measured, as the occluder may obstruct coronary flow. After deployment of the occluding device, adequate function of the valve is reassessed and the presence of RWMAs or tamponade is ruled out.

Ventricular Assist Devices

Ventricular assist devices (VADs) are being used more frequently in patients with heart failure, either as a bridge-to-cardiac transplantation or as destination therapy. Several VADs are currently available, from short-term to long-term systems (see Chapter 28). The HeartMate II (Thoratec Corporation, Pleasanton, Calif) is the only continuous-flow LVAD that is FDA-approved for use as a bridge-to-transplantation or destination therapy; thus, it is the focus of the discussion here, although most of the same general principles apply to other devices.

The HeartMate II VAD is a flow system composed of an inflow cannula placed into the LV apex and an outflow cannula that is placed in the anterior ascending aorta. The pump housing unit is placed in a

subcutaneous pocket in the abdomen, and a percutaneous lead carries an electrical cable to the battery pack and controller that is worn on a belt and shoulder holster. The pump housing unit connects the impeller, which is the only moving part, and the motor. The flow generated depends on the pressure gradient across the device. Flow increases with higher LV pressure and with lower aortic pressures.[220]

Echocardiographic Assessment

Initially, the left ventricle is interrogated and the size and baseline ventricular function are noted. The LA pressure and volume should also be determined, as well as the dimensions of the mitral annulus. If MS is present, it is usually necessary to correct it via commissurotomy or valve replacement before VAD placement, as it could limit LV filling.[221] It is essential to exclude the presence of thrombi at the site where the LV cannula is going to be placed. Thrombosis is a frequent complication of VADs, occurring in approximately 9% to 16% of cases.[222] Preexisting LA or LV thrombi may cause embolism and precipitate pump malfunction, stroke, and end-organ or peripheral ischemia.

Careful evaluation of RV function is important for VAD procedures. Fractional area change, Tei index, and tricuspid annular plane systolic excursion are among the preferred methods for evaluating RV function.[220] Poor RV systolic function and/or the presence of TR must be noted, and the tricuspid annulus should be measured. After VAD activation, RV failure may precipitate underfilling of the left ventricle, with a decrease in LV pressure and the possibility of VAD-generated negative pressure. Collapse of the left ventricle around the inflow cannula may produce air entrainment. This can generate an air embolism to the right coronary artery, further reducing RV function. Also, collapse of the left ventricle can cause leftward shift of the intraventricular septum, exacerbating preexisting TR.[223]

A PFO can precipitate paradoxical embolism or hypoxemia after VAD activation when unloading of the left ventricle causes a reduction in LA pressure.[224] Thus, careful interrogation of the IAS for shunt lesions should be performed before VAD placement. Patients with biventricular failure frequently have an increased pressure in both atria; there may not be a significant gradient between the atria, and flow across a PFO may be undetectable. However, after activation of the device the RA pressure rises as a result of increased venous return, and the LA pressure decreases, so the IAS must be interrogated again to search for a PFO.

AR is detrimental for patients after VAD placement. The AR causes increased LV preload, which increases the pump flow, increasing blood flow through the device and outflow cannula, which in turn increases AR. This causes a futile cycle, with resultant decreased systemic perfusion. Moderate or severe AR requires surgical correction prior to VAD placement. Surgical correction may be performed through primary closure of the AV or bioprosthetic valve replacement.[225,226]

Before VAD activation, careful TEE evaluation to confirm de-airing of the heart is important to prevent air embolism. Volume status should be checked because hypovolemia can also cause LV collapse and cause the VAD to generate negative pressure. The position of the inflow cannula in the LV apex should be assessed (Fig. 15.123). The cannula should be placed immediately below the MV, and it should not impinge on any of the ventricular walls. Continuous-wave Doppler examination of the inflow cannula should demonstrate a velocity of 1 to 2 m/s. Furthermore, the position of the outflow cannula in the aorta should be evaluated. It is difficult to visualize the prosthetic graft material anastomosed to the ascending aorta, but CFD should be used to demonstrate flow inside the aorta. Continuous-wave Doppler interrogation of the outflow cannula should demonstrate a velocity of less than 2 m/s; a higher velocity should arise suspicion of kinking of the cannula.[222]

Exclusion of Left Atrial Appendage Thrombi

LAA exclusion is a percutaneous technique used to prevent systemic embolism in patients with atrial fibrillation. Recently, it has been postulated that LAA exclusion may be as effective as warfarin anticoagulation in stroke prevention.[227]

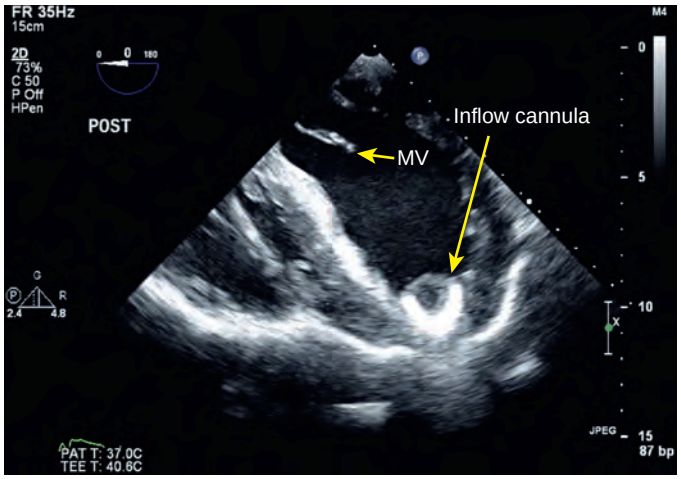

Fig. 15.123 A low midesophageal four-chamber view demonstrates an adequate apical position of the HeartMate II inflow cannula. *MV,* Mitral valve.

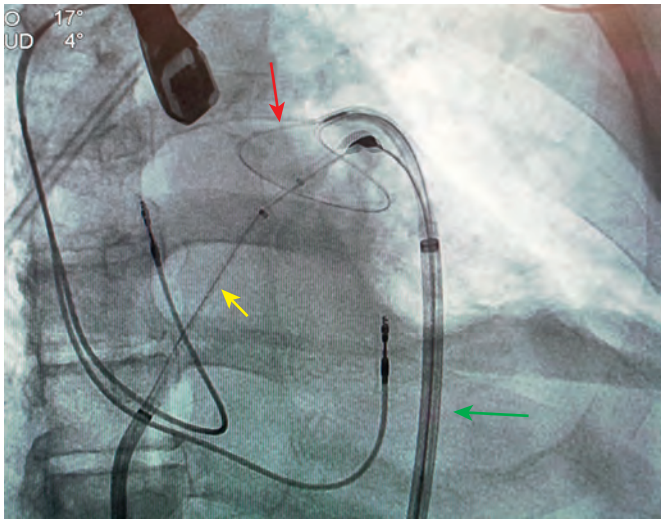

Fig. 15.124 Intraoperative fluoroscopic imaging during Lariat procedure. *Green arrow* denotes epicardial access containing magnet tipped wire near the left atrial appendage. *Yellow arrow* denotes endoluminal left atrial appendage access via a transseptal approach also containing a magnet tipped wire within the appendage. The *red arrow* denotes the LARIAT suture delivery device surrounding the left atrial appendage prior to closure.

TEE examination for LAA exclusion should evaluate LV systolic function, interrogate the IAS for PFO, and evaluate the LAA anatomy. Three-dimensional evaluation may be particularly useful for assessing the LAA morphology. There are four LAA morphologic types: the windsock, chicken wing, cactus, and cauliflower. Of these, the chicken wing is the most difficult to exclude percutaneously.[228]

For LAA exclusion with an endoluminal device (eg, Watchman LAA closure device; Boston Scientific, Marlborough, Mass), a TEE-guided IAS puncture is performed first. The device is then aligned with the LAA under TEE guidance and deployed. For LAA exclusion with an epicardial device (Lariat procedure), a TEE-guided IAS puncture is performed in addition to epicardial access (Fig. 15.124). Via both the trans-IAS access and epicardial access, magnet-tipped wires are inserted to establish continuity. A lasso-styled device (eg, the LARIAT suture delivery device; SentreHEART, Redwood City, Calif) is advanced on the epicardial wire over the appendage (the endoluminal magnet-tipped wire serves as a guide). Once in position, the

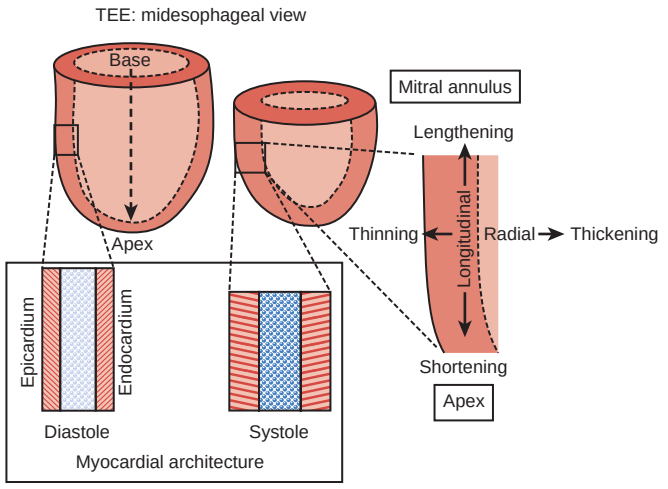

Fig. 15.126 Myocardial architecture consists of helical (left-handed in epicardium and right-handed in endocardium) and circumferential (in midmyocardium) layers of myocardial fibers. This fiber arrangement results in longitudinal (mitral annulus to apex), radial (epicardium to endocardium), and circumferential (tangentially to epicardium) motions during systole and diastole. *TEE,* Transesophageal echocardiogram.

lasso-styled LARIAT suture delivery device is cinched over the appendage. With either technique after deployment, TEE is performed to evaluate the device position and exclude thrombi. CFD examination is then performed to test for residual flow peripheral to the device. Finally, the IAS is interrogated to evaluate the residual ASD at the transseptal puncture site.

Pacing Lead Extraction

A growing number of indications have expanded the use of cardiac implantable electronic devices,[229] and the patient survival rate has increased. As a result, transvenous lead extraction is becoming more frequent for device malfunction or infection (Fig. 15.125).

TEE evaluation during transvenous lead extraction is not mandatory in all institutions. However, the immediate availability to perform TEE, TTE, or intracardiac echocardiography is recommended by the European Heart Rhythm Association and the Heart Rhythm Society.[230] TEE is particularly useful for detecting life-threatening complications of lead extraction, such as ventricular perforation, TR, embolism, and tamponade.[231]

TEE evaluation should include an assessment of RV and LV function. Many of these patients present with severely impaired LV systolic function. Baseline severity of TR and pulmonary hypertension also should be evaluated, because lead extraction can cause injury to the TV and worsen preexisting regurgitation. Evaluation of the patient for PFO or other shunt lesions is also important, particularly when laser-assisted lead extraction is performed. Laser can produce photothermal vaporization of cellular water and produce microbubbles, which may cause paradoxical embolism if a shunt lesion is present.[232] Because laceration of cardiac structures is one of the most feared complications of lead extraction, TEE monitoring can be used to evaluate accumulation of pericardial fluid or tamponade. Early detection of hemopericardium can be life-saving, as it can result in an earlier surgical treatment.

Strain, Strain Rate, and Doppler Tissue Imaging

The recent technologic advances in signal processing in Doppler (Doppler tissue imaging [DTI] and Doppler strain echocardiography) and ultrasound (2D speckle-tracking imaging [STI]) enable measurement of tissue velocity and deformation in one or two dimensions, which provide high-quality, precise, and objective information regarding regional and/or global myocardial function in real time, decrease the subjectivity of the interpretation, and increase the diagnostic accuracy.

Myocardial Structure and Motion

Myocardial fibers are organized in layers, forming a leftward helix in the subepicardium, which transitions to a rightward helix in the subendocardium (Fig. 15.126). Because LV muscle volume remains constant during the cardiac cycle, this myocardial fiber arrangement results in longitudinal (along the major axis) and circumferential (tangent to the periphery) thinning and radial (along the minor axis) thickening during systole, with opposite directed changes in diastole.[233] This 3D global cardiac motion cannot be appreciated during conventional TEE imaging, in which only radial motion (inward endocardial excursion and myocardial thickening in ME or TG views related to midmyocardial function) is evaluated. Longitudinal (ME views) and circumferential motion (TG views) are difficult to evaluate. However, both radial and longitudinal motions are important. In systole, radial thickening predominates; 40% radial thickening is accompanied by 14% longitudinal shortening.[234] On the other hand, the first myocardial layer affected by ischemia is the subendocardium, which provides for longitudinal motion.[235] The subjective evaluation of regional LV motion is also limited during conventional TEE because passive motion of a noncontracting segment, due to tethering to adjacent segments, cannot be reliably excluded. Many of these limitations can be overcome by assessing myocardial deformation (strain).

Deformation

Myocardial strain (S or e) is the (systolic) deformation of a myocardial fiber, normalized to its original length:

$$S = \frac{L_1 - L_0}{L_0} \cdot 100(\%)$$

where L_0 is the baseline (end-diastolic) length, and L_1 is the end-systolic length.[236]

By definition, strain is positive when the systolic dimension increases (the myocardial fiber lengthens or thickens) and negative when the systolic dimension decreases (the myocardial fiber shortens or thins). Therefore, radial thickening is associated with positive strain ($L_1 > L_0$), whereas longitudinal shortening and circumferential thinning are associated with negative strain ($L_1 < L_0$). Radial strain relates to motion from the endocardium to the epicardium; circumferential strain relates to motion along the circumference (curvature) of the left ventricle; and longitudinal strain relates to motion from the base to the LV apex.

Echocardiographically measured strain is measured in relation to time (t) and is called *Lagrangian strain:* $\varepsilon_l(t) = [L(t) - L(t_0)]/L(t_0)$, where $L(t_0)$ is the end-diastolic shape. For a 2D object, there is normal deformation (the motion is normal to the borders of the object and occurs along both the x-axis and y-axis) and shear deformation (motion occurs parallel to the borders of the object). For a 3D object, such as a myocardial segment, there are three *normal* strains (along the x-, y-, z-axes), and six *shear* strains (along the combinations of the different axes).[237] Because fiber contraction causes myocardial deformation, strain is a measure of myocardial contractile function. Echocardiographic deformation can be measured from velocity gradient using DTI (or non-Doppler tracking of speckles [STI]).[238,239]

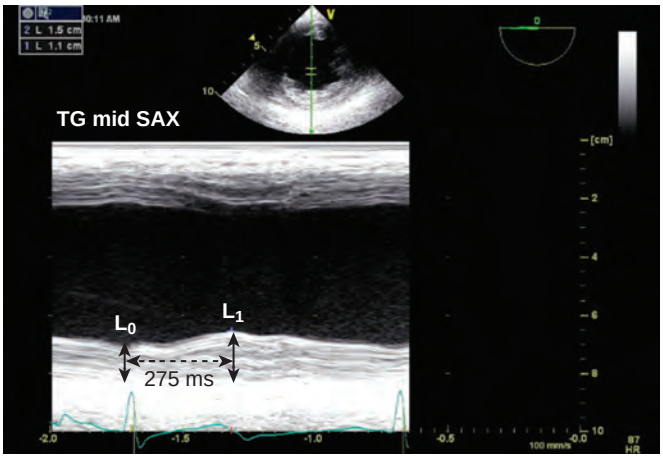
Strain rate (SR) reflects how fast regional myocardial deformation (strain) occurs; that is, SR expresses the speed of deformation:

$$SR = S/t(\%/sec)$$

where t is the time duration of this deformation (Fig. 15.127).

Echocardiographic strain measurements with either technique have been validated against sonomicrometry or MRI, with *r* values of .96 for strain and .94 for SR.[239–243] For normal myocardium, SR reflects regional contractile function because it is relatively independent of heart rate, whereas systolic strain reflects changes in SV.[244,245] Evaluated with DTI or tagged cardiac MRI, LV regional strains increased from base to apex and from endocardium to epicardium.[237,246,247] Normal values are −16% to −24% (longitudinal strain), +48% (radial strain), and −20% (circumferential strain).[248–250] Some have found significantly greater strain values in women than in men.[251] Longitudinal RV strain and SR values are inhomogeneous and greater than those of the left ventricle.[252] Strain and SR offer complementary information, and both should be measured and evaluated. For example, prolonged contraction may yield normal strain despite low SR. As such, SR is considered more sensitive than strain in revealing myocardial disease.

SR showed good correlation with +dP/dt during isovolumic contraction ($r = .74$) and with −dP/dt during isovolumic relaxation ($r = .67$).[252] Strain is load dependent and is not less load-insensitive than ejection fraction, fractional shortening, and other traditional indices of systolic function. For example, acute hypovolemia induced by withdrawal of 500 mL of blood from healthy subjects led to decreased longitudinal DTI strain (−28% ± 8% to −21% ± 4%), whereas SR remained unchanged (−1.5 ± 0.35/s to −1.4 ± 0.4/s).[243,252,253] Similarly, STI strain is preload and afterload dependent; longitudinal strain decreased after hemodialysis in patients with end-stage renal disease (−18.4% ± 2.9% to −16.9% ± 3.2%), and radial strain increased immediately after AVR surgery to treat AS (from 22.7% ± 2% to 23.7% ± 1.8%) and decreased (23.1% ± 3.5% to 21% ± 3.8%) after AVR to treat AR.[254,255] However, others have shown that longitudinal DTI strain (recorded in healthy subjects) remained unchanged during preload manipulation (baseline −18% ± 3%, increased preload with Trendelenburg −18% ± 3%, reduced preload with venodilator −17% ± 3%), whereas myocardial velocities were affected.[256] Discrepancies in previous findings are explained by study design, techniques used for strain measurement, and degrees of preload manipulation. However, it would be safer not to consider strain as a load-independent parameter of systolic function.



$$\text{Strain} = \frac{L_1 - L_0}{L_0} = \frac{1.5 - 1.1}{1.1} = 36\%$$

$$\text{Strain rate} = \frac{\text{Strain}}{\Delta t} = \frac{36}{275} = 0.13/s$$

Principles of Doppler Tissue Imaging and Doppler Strain

As discussed earlier, a shift in frequency is caused when transmitted ultrasound is reflected off a moving target (Doppler effect). In conventional echocardiography, Doppler algorithms are set up to interrogate returning signals from the blood pool only using high-gain settings (to amplify the low-amplitude signal of the fast moving blood) and a high-pass filter (to reject the noise generated by the slow-moving myocardium). Modification of these filter settings (reduction of gain amplification and bypass of the high-pass wall filter) will reject data from moving blood and permit recording of the myocardial motion signal, which is stronger (approximately 40 dB higher amplitude) but slower (<25 cm/s), respectively, thus enabling DTI and measurement of strain.[257] The principles of DTI, together with applications and limitations, have been reviewed recently and are partially summarized in the Diastolic Function section in Chapter 14.[258]

For DTI strain, color DTI is obtained as in conventional CFD, with a color sector positioned over the myocardial wall of interest. The mean myocardial velocities are computed using autocorrelation analysis, displayed in blue if directed away from and in red if directed toward the transducer and are superimposed on a grayscale 2D tomographic view (Fig. 15.128A).[259] While in color DTI mode, placement of a sample volume (see later step-by-step explanation) over the myocardial area of interest (see Fig. 15.128B) will calculate the deformation parameters SR (see Fig. 15.128C) and strain (see Fig. 15.128D) from within this sample volume:

Strain is derived by temporal integration of SR.

SR and strain can be tethered to a functioning adjacent segment that causes a segment with impaired function to give a false impression of contraction. This can be compared to the example of a towed car; although the engine of the towed car is not functioning, the car has velocity. When no velocity gradient exists within the interrogated segment, there will be no deformation and SR (and strain) will be zero.

Strain and SR calculated from myocardial velocity gradients have been validated over a wide range of strain values using sonomicrometry in animals and 3D tagged MRI in humans.[235,241,260,261] However, systolic strain correlates with MRI better in healthy than diseased individuals.[262] DTI strain and SR are strong noninvasive indices of LV contractility; DTI strain and SR increased with dobutamine, decreased

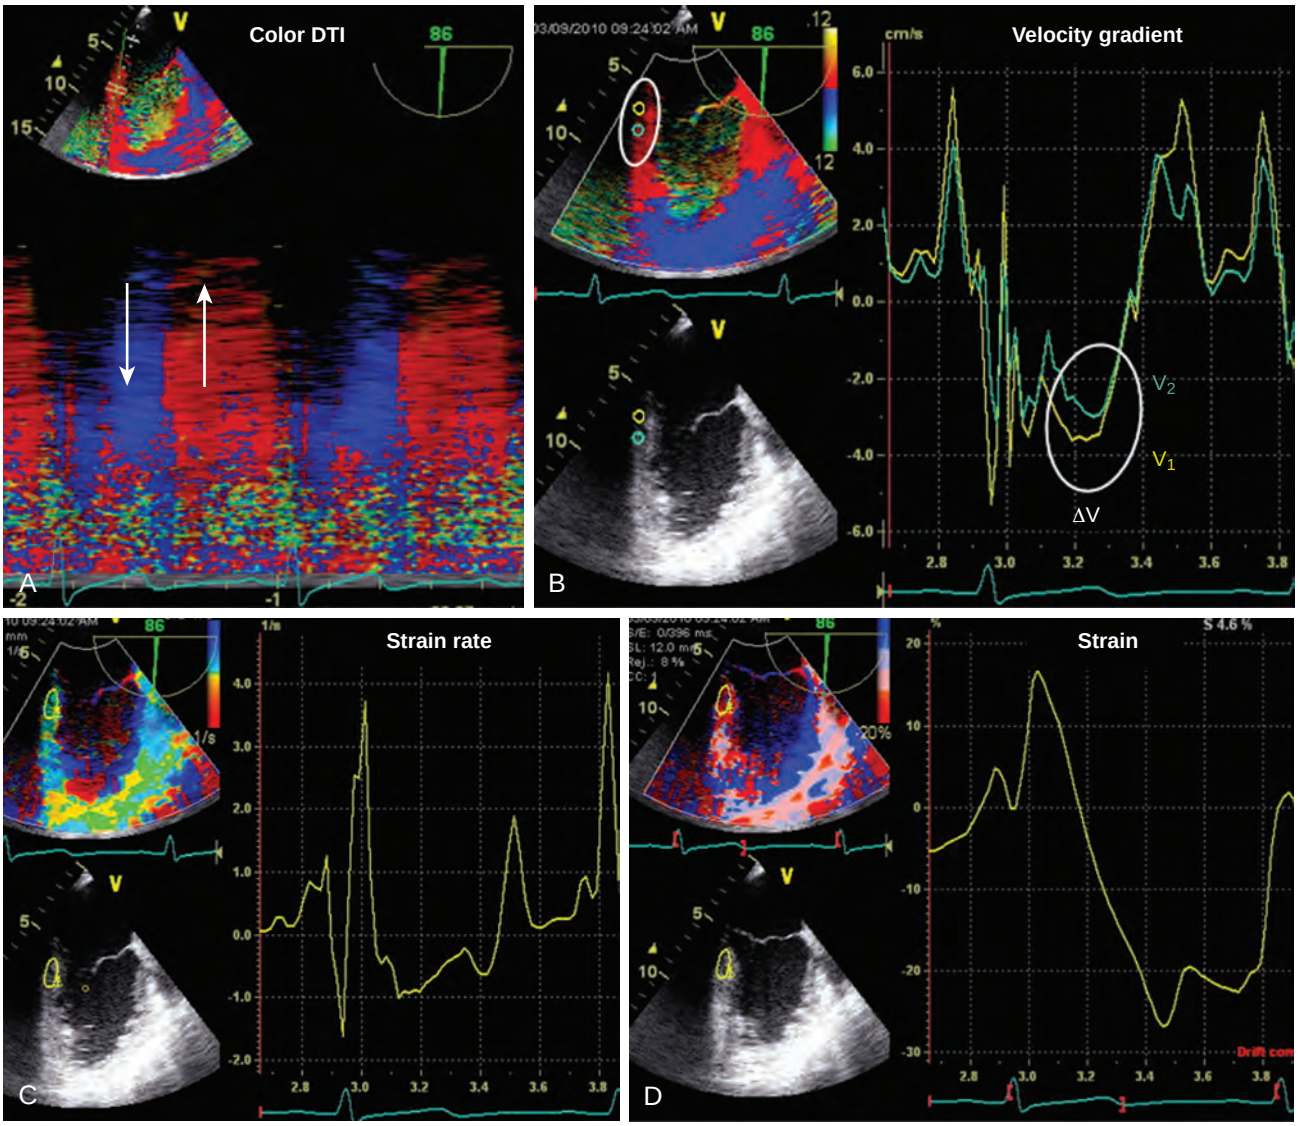

Fig. 15.128 Doppler strain and strain rate. (A) Activation of Doppler tissue imaging *(DTI)* function allows imaging of myocardial velocities in color, here with M-mode (from the inferior wall in a mid-esophageal two-chamber view). The velocities are directed away from the transducer in systole (and colored blue) and toward the transducer in diastole (and colored red). (B) Spectral display of myocardial velocities from within sample volumes (insert panel at left) demonstrates a velocity gradient *(ΔV)*. Basal velocity *(V_1)* is greater than apical velocity *(V_2)* as the inferior wall shortens along its long axis. (C) The velocity gradient (ΔV) of these points is used to calculate strain rate (SR). (D) Integration of SR over time (Δt) derives strain.

with esmolol, and correlated well with peak LV elastance in experimental settings.[245]

DTI strain is time consuming, technically demanding, and has important limitations. Reverberation or dropout artifacts from neighboring structures can affect the measured velocity gradient and interfere with calculation of deformation parameters. Most importantly, DTI strain is a Doppler technique and can display deformation along a single dimension only, that of the ultrasound plane. Therefore, the displayed value (SR and strain) may not relate to the true (longitudinal, radial, or circumferential) deformation. In ME views, when the ultrasound beam is parallel to the myocardial wall, the actual (longitudinal) velocity can be accurately measured, but the velocity of radial (transverse) deformation will be zero because radial motion will be perpendicular to the ultrasound beam. With any angle deviation from 0 degrees, the contribution of radial deformation to the measured velocity increases.[263] As a result, when using TEE, longitudinal strain and SR should be recorded only from ME views, and radial strain and SR from TG views. Furthermore, if the angle between the Doppler and motion plane is greater than 20 degrees, the true myocardial velocity gradient (and the calculated strain and SR) will be underestimated.[261] At an angle of 45 degrees, the measured DTI strain is zero.[243] This becomes more problematic in the presence of RWMAs.[264] Because of this angle dependency, DTI should be used primarily to assess longitudinal deformation parameters.

Step-by-Step Guide on How to Obtain Doppler Strain

The echocardiographic system must have a preset function to image and measure tissue velocity to obtain Doppler strain parameters. Of importance is optimal quality of 2D imaging and clear distinction between blood pool and myocardium (this may be facilitated by using second harmonic imaging, if available). High frame rates are required (usually more than 100 frames per second) to show the subtle changes

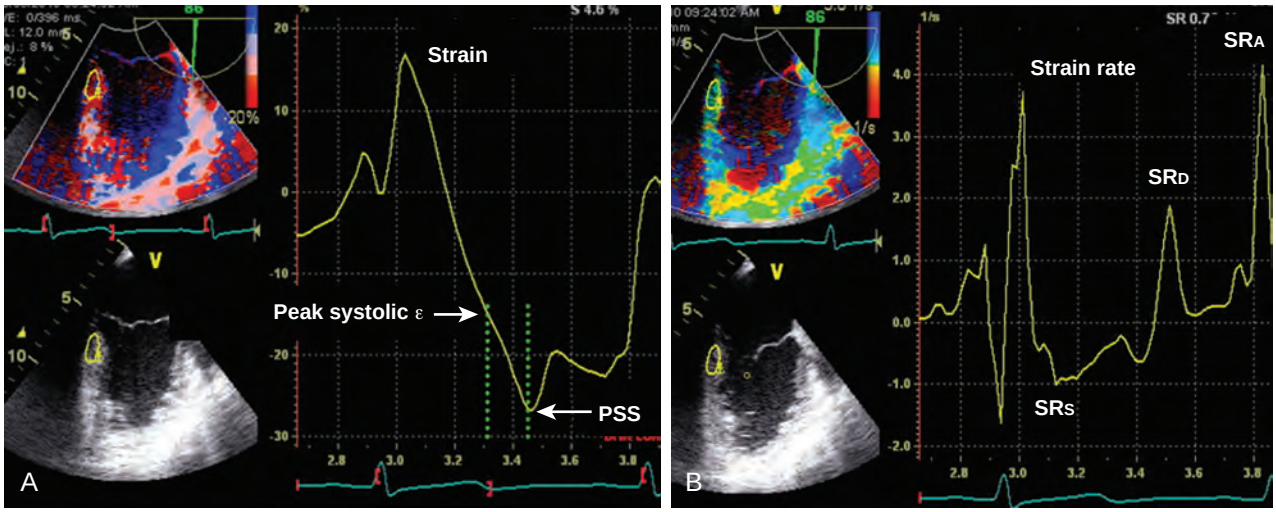

Fig. 15.129 Measurement in Doppler strain echocardiography includes (A) peak systolic *(SR_S)*, early diastolic *(SR_D)*, late diastolic *(SR_A)* strain rates, and (B) end-systolic strain. Strain recorded after aortic valve closure is called *postsystolic strain (PSS)*.

in myocardial velocity. This is accomplished by narrowing the sector width over the myocardial wall of interest. Optimal ECG tracings with clear definition of QRS and P are essential, as well as pulsed-wave or CFD echocardiography of transmitral and aortic flows (for timing of onset and end of systole). These temporal recordings should be concurrent with strain data acquisition.

First, DTI should be activated.[258] The TEE probe then is manipulated in such a way that myocardial motion and ultrasound planes are parallel to each other (or at an angle ≤ 20 degrees). The examination sequence should be standardized and the views labeled because the narrow sector removes neighboring structures used for identification. An adequate Nyquist limit is chosen, usually about ±20 cm/s, to avoid aliasing while increasing spatial and temporal resolution. Next, the sector width and depth are optimized. The operator has two options; either a conventional sector width, which enables side-by-side comparison of diametrically opposite segments/walls, or a narrow sector (with the option of shallow depth), which maximizes the frame rate (DTI strain is optimal at >180 frames per second). The ventilator may be switched off during acquisition of images, which are then reviewed and digitally stored. At least three beats (in sinus rhythm) or up to eight beats (in arrhythmia) should be captured and digitally stored.[265] TEE images used for Doppler strain are the three standard ME views (for long-axis myocardial deformation) and the basal and mid-TG and mid-short-axis views. Selection of these tomographic planes is dictated by the requirement for parallel orientation between the motion plane under examination and ultrasound direction (as described earlier). Addition of an M-mode line to the color DTI velocities displays a vertical line of color tissue velocity pattern along the M-mode beam with good temporal resolution (see Fig. 15.128A).[266]

Further analysis is performed either on the initial echocardiographic system or on a dedicated workstation. Currently, Doppler strain techniques are proprietary software and analyze digitally stored images from the same system only. An appropriately sized sample volume (6 × 10 mm) is placed on the desired LV region, keeping in mind that larger sample volumes result in smoothing of the strain signals, whereas at the same time, temporal and spatial resolution decrease. The size of the sample volume determines the length (L_0) over which the velocity gradient is calculated. To keep the ROI within the myocardial borders, L_0 is typically 10 mm for longitudinal data sets and 5 mm for radial data sets.[267] *Drift compensation* is a default setting that corrects for drift (ie, when myocardium does not return to its original length at end-diastole) in the strain curves, but it can introduce error in the evaluations and should be taken into account as well. Because strain is the temporal integral of SR, strain is a smoother curve than SR. The SR curve should be inspected as a noisy SR curve indicates suboptimal tracking of the ROI and drift. In this case, it is better to reposition the sample volume.

The sample volumes are placed along the length of the myocardial wall (basal, mid, and apical segments) toward the endocardial surface (ME views) or in the middle of the myocardium (TG views) and should track the segment throughout the cardiac cycle. The operator should verify that this happens by scrolling frame by frame and observing the concurrent motion of the sample volume with the myocardial segment. From each sample volume, SR, strain, and timing of peak values with respect to QRS are calculated (Fig. 15.129). The reproducibility of strain measurements is reported to be less than 15%.[265] Suggested measurements and calculations are shown in Table 15.15.

TABLE 15.15 Strain Echocardiography Measurements and Calculations

End-diastole	R wave of electrocardiogram
End-systole	Aortic valve closure (AVC)
End-systolic strain (S_{SYS})	Magnitude of systolic deformation between end-diastole and at end-systole (AVC)
Peak strain (S_{PEAK})	Maximum systolic deformation over a mean RR interval • Lowest value for longitudinal or circumferential strain • Highest value for radial strain
Postsystolic strain (S_{PS} or PSS)	The difference between S_{PEAK} and S_{SYS} $S_{PS} = S_{PEAK} - S_{SYS}$
Postsystolic strain index (PSI)	Represents the relative amount of ischemia-related segment thickening or shortening, found to occur after AVC $PSI = S_{PS}/S_{PEAK} = (S_{PEAK} - S_{SYS})/S_{PEAK}$ $S_{ps} - S_{es}/S_{es}$
Systolic strain rate (SR_{peak})	Maximum SR before end-systole
Peak systolic strain rate (SR_{peak})	Maximum SR
Rotation	Base rotates clockwise (initial, early systolic rotation is counterclockwise): (+)ve ° values Apex rotates counterclockwise (initial, early systolic rotation is clockwise): (−)ve ° values
Torsion	Basal rotation–apical rotation

Principles of Speckle-Tracking Imaging and Two-Dimensional Strain

Interactions of ultrasound with myocardium result in reflection and scattering. These interactions generate a finely gray-shaded, speckled pattern. This speckled pattern is unique for each myocardial region and relatively stable throughout the cardiac cycle. The speckles function as acoustic markers; they are equally distributed within the myocardium and change their position in accordance with the surrounding myocardial deformation or tissue motion. In STI, the speckles within a predefined ROI are followed automatically frame by frame, and the change in their geometric position (which corresponds to local tissue movement) is used to extract strain, SR, velocity, and displacement. Because these acoustic markers can be followed in any direction, STI is a non-Doppler, angle-independent technique for calculation of cardiac deformation along two dimensions. Therefore, radial and longitudinal deformation can be measured in the ME views, and radial and circumferential deformation in the TG short-axis views.[263]

Although considered as the only sound methodology for measuring cardiac deformation,[264] this non-Doppler technique also has limitations: (1) decreased sensitivity because of applied smoothing; (2) incorrect calculation of deformation, which is produced by erroneous tracking of stationary reverberations (when tissue moves, the speckle interference pattern may not move in exact accordance with tissue motion)[266]; (3) the necessity of clear visualization of the endocardial border for reliable radial and transverse tracking; and (4) undersampling in tachycardia because optimal frame rate should be less than 100 frames per second. Equally important, STI algorithms require that the entire myocardium is visualized throughout the cardiac cycle. Echo dropout and mitral annulus calcification attenuate myocardial appearance in the TG or ME views, respectively, and do not allow adequate tracking of echocardiographic speckles.

Shear Strain and Torsion

The myocardial architecture of epicardial and endocardial fibers will produce shear strain during the cardiac cycle (deformation parallel to the reference plane as the myocardial layers slide on each other; see Fig. 15.126). This results in the base and the apex of the heart rotating in opposite directions. From a TEE perspective, the base rotates clockwise (preceded by an early systolic counterclockwise rotation because of earlier activation of subendocardial fibers) and the apex counterclockwise (preceded by an early systolic clockwise rotation). Torsion of the ventricle is the difference in apical and basal rotation, similar to wringing a towel dry.[234] As a result, during the cardiac cycle, there is a systolic twist and an early diastolic untwist of the left ventricle along its long axis because of opposite-directed apical and basal rotations. Rotation angles and torsion can be measured with STI and measurements correlate well with sonomicrometry and tagged MRI.[268,269] Because basal and apical rotations are in opposite directions, somewhere between them is a level (referred to as the *equator*) where rotation changes from one direction to the other.[268]

LV torsion occurs mainly by the counterclockwise apical rotation. Torsion is considered the mechanical link between systolic and diastolic function: systolic twisting stores elastic energy, which, released during the isovolumic phase of diastole, produces untwisting, generates intraventricular pressure gradients, and allows LV filling to proceed at low filling pressure.[233] During systole in healthy subjects, LV torsion increases and LV volume decreases; however, the relation between rapid untwisting (uncoiling) and increasing volume is nonlinear during diastole. Initiation of untwisting is an early and key mechanism that promotes early diastolic relaxation and early diastolic filling, possibly more important than recoil of systolic basal descent.[270]

LV torsion is preload dependent and increases with inotropy.[271] Approximately 40% of LV untwisting occurs during the isovolumic relaxation period, reaching a maximum just after MV opening, when approximately 20% of the SV has entered the left ventricle. By the peak of transmitral early filling (E wave), approximately 80% to 90% of untwisting is completed and essentially finished by the end of transmitral filling E wave, with the subsequent LV volume increase because of expansion in the short and long axes. LV systolic torsion and rapid untwisting increase significantly with exercise, storing additional potential energy that is released as diastolic suction increases. That is why the heart can increase the diastolic filling rate despite the shortened diastolic period during tachycardia. Patients with HCM showed delayed untwisting that was not significantly augmented with exercise.[272] This explains the inability of patients to increase filling during exercise without a significant increase in LA pressure. The magnitude of torsion depends critically on the measurement level relative to the LV base or other reference point. A limitation of STI in recording torsion is the in-out motion of the image plane as the left ventricle moves along its longitudinal axis. Selection of reproducible anatomic landmarks is important for measuring (and reporting) reproducible values. At the basal level, the fibrous mitral ring is used for orientation and reproducible image planes are easier to obtain. For apical recordings, the image plane should be just basal to the level with luminal closure at end-systole (there should be a recognizable apical cavity at end-systole).

Step-by-Step Guide on How to Perform Speckle-Tracking Imaging

The technique of non-Doppler strain analysis has been described for ambulatory cardiac patients.[263,273] As compared with DTI, STI is less demanding and is closer to standard imaging (no Doppler is required and is performed at normal frame rate). The steps to perform STI in the anesthetized cardiac surgical patient are similar and are described in detail later. For the time being, analysis and measurements of 2D speckle strain parameters are possible off-line only, in a dedicated workstation (EchoPAC; GE Vingmed, Holton, Norway). As of this time, analysis is possible only on digitally acquired and stored images of the same vendor (there is no cross-talk between systems from different vendors).

The operator starts by acquiring 2DE images of the left ventricle, which are digitally stored. Three ME views (four-chamber, two-chamber, and long-axis) and three TG views (basal, mid, and apical) are acquired with a frame rate between 40 and 80 per second, with adequate sector width and depth to image both endocardium and epicardium. In the anesthetized patient, it is better to stop ventilating to avoid image translation. Equally important is to acquire optimal quality 2D images and eliminate any myocardial areas with echo dropout (no speckles, no analysis). Timing of systole is based on the ECG-R wave, and end-systole is defined using M-mode tracings of the AV or pulsed-wave Doppler of the trans-AV flow. This interval is used by the software to define the systolic time; therefore, it is practical to initiate postprocessing in an ME long-axis view, in which the AV is seen, and then move to the other ME and TG views. In addition, it is important to acquire images rapidly and ensure that heart rate (and rhythm), as well as hemodynamics, remain stable. Otherwise, the systolic interval needs to be redefined before each strain analysis.

In each LV view stored, the operator manually traces the LV endocardium in a systolic frame, where it is best defined/imaged. Based on this initial endocardial tracing, the software generates an ROI, which encompasses the entire thickness of the cardiac wall between the LV epicardium and endocardium. This ROI may be adjusted manually by the operator so that the inner border is tracing the endocardium and the ROI covers the entire myocardium throughout the cardiac cycle. After approval of the software-generated myocardial wall delineation, speckle-tracking analysis is done from within this region for one cardiac cycle at a time. In each view, the LV myocardium is automatically divided into six segments, and the tracking quality is scored as either acceptable or unacceptable. If more than two segments have unacceptable quality, ROI should be redefined or a different beat should be chosen. Most of the time, the more important reasons for unacceptable segments are myocardial dropout and poor-quality 2D imaging; neither can be corrected after processing.

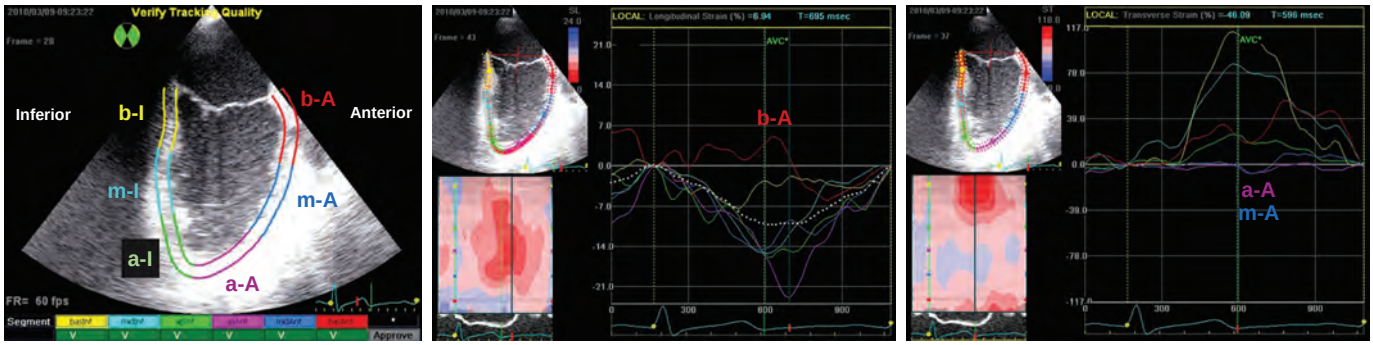

Fig. 15.130 Speckle tissue imaging. (A) Longitudinal strain and (B) transverse strain from a midesophageal four-chamber left ventricular view. *White dotted line* represents the global (average) longitudinal strain. Each myocardial segment is color coded. Longitudinal strain is abnormal in basal inferolateral segment (longitudinal expansion). Transverse strain is normal in only basal and midinferoseptal segments (transverse thickening). (C) Circumferential and (D) radial strain from a transgastric midpapillary short-axis view of the left ventricle. *White dotted line* represents the global (average) circumferential strain. Deformation is uniform (as compared with [A] and [B]). *b-A,* Basal anterior; *a-A,* apical anterior; *a-I,* apical inferior; *b-I,* basal inferior; *m-A,* midanterior; *m-I,* midinferior.

TABLE 15.16 Strain Echocardiography: Imaging Modalities

	Doppler Tissue Imaging	*Speckle-Tracking Imaging*
Technique	Manipulation of Doppler signal • Elimination of wall filter • Low-gain amplification Strain is calculated from velocity gradients, measured against a fixed reference (transducer)	Tracking of acoustic markers • Gray speckles within myocardium are tracked frame by frame Strain is directly measured from tracking of acoustic markers (speckles)
Display	Color map (±M-mode) Pulsed-wave at a specific space (regional values only)	Color map Spectral display (regional and global values)
Measurements	From color map (off-line): • Strain rate • Strain (Lagrangian) • Velocity (mean) • Displacement From pulsed-wave (real-time): • Velocity (peak) • Displacement	• Strain rate • Strain (Lagrangian) • Velocity • Displacement • Torsion
Limitations	Only deformation parallel to ultrasound beam is measured Affected by translation and tethering Requires high frame rate	Requires lower frame rate (time between collection of consecutive image frames ≥ 10 ms)—interpretation may be more reliable if tissue contains some stronger scattering structures Off-line implementation (not real time) Different image resolution in axial and lateral beam directions (long vs radial in midesophageal and radial vs circumferential in transgastric views) Dependent on optimal imaging Basal motion through image plane may result in poor spatial resolution

If tracking quality is acceptable, the operator approves the sampled segments and the software provides various deformation parameters for each segment: strain, strain rate, velocity, displacement, and rotation (torsion).[263,274] Examples of non-Doppler strain measurements are seen in Fig. 15.130. Because acquisition of 2D images (in the ME and TG views) is standard procedure during a comprehensive TEE examination, appropriately stored, good-quality 2D images can be analyzed off-line (provided that the analysis system is of the same manufacturer) and provide STI parameters.

A three-click method (automated function imaging), whereby the operator anchors three points, at each side of the mitral annulus and at the apex of the left ventricle (ME views), further simplifies the process of tracking and analyzing peak systolic strain based on 2D strain. The computerized assessment can present the data in parametric (color), anatomic M-mode, strain curves, and bull's-eye displays. The usefulness of automated function imaging is that deformation data are easily produced and can be comprehended by an inexperienced operator.

The differences between Doppler and non-Doppler strain measurements are summarized in Table 15.16.[263] Deformation values are shown in Table 15.17.[275]

Correlation of Strain Between Doppler Tissue Imaging and Speckle-Tracking Imaging

If either DTI or STI measures deformation accurately, the respective strain values should correlate and give identical values. In 30 patients without acute MI, longitudinal strain values differed only by 0.6% ± 6.0% (r = .53; P <.001), and radial strain values differed by 1.8% ± 13.4% (r = .46; P <.001).[260] Using receiver operating characteristic curves, STI showed greater area under the curve to discriminate among dysfunctional segments compared with DTI strain. Similarly, DTI and STI values were identical in healthy subjects, as well as in patients with cardiomyopathy.[242,246,248,250]

The diagnostic ability of STI (performed with TTE) in patients undergoing dobutamine stress testing was less in the right and left circumflex coronary territory than in the anterior circulation.[276] Contrary to DTI, STI depends on image quality. Poor imaging results in decreased speckled appearance and poor tracking of the myocardium.

Right Ventricular Function

The complex geometric shape and thin wall structure of the right ventricle do not allow quantification of RV function with conventional

2D and M-mode techniques. In the experimental setting, systolic strain values obtained by DTI, in either inflow or outflow tract, were found to be comparable with those obtained by sonomicrometry (a method by which the actual length change is measured), whatever the RV loading conditions were.[277] RV longitudinal function is dominant over short-axis function; and RV inflow tract, represented by the basal RV free wall, is the major contributor in global RV systolic and diastolic function. Therefore, measurement of longitudinal RV inflow deformation offers valuable insights to global RV function. DTI longitudinal strain measurements showed an insignificant decline with age (average value of 31%, in 54 healthy adults).[248,278] In laboratory experiments with opened pericardium, increased afterload after PA constriction resulted in a shift of myocardial shortening from early-mid to end-systole or even diastole (postsystolic shortening [PSS]), whereas a reduction in preload caused by inferior vena cava occlusion induced earlier systolic shortening.[277] However, in healthy ambulatory subjects, DTI strain of RV inflow (recorded from the basal segment, lateral to the tricuspid annulus) did not change with preload or afterload increase.[279] DTI and STI RV peak systolic strain values correlate well ($r = .73$), with DTI values always being greater, overestimating peak systolic SR by 0.64%.[280] The correlation for SR was better ($r = .90$).

Deformation in the Operating Room

DTI strain is a sensitive means for detecting and localizing myocardial ischemia, as opposed to myocardial velocities. Intraoperative TEE measurements of DTI strain are comparable with transthoracic assessment, and pericardiotomy does not affect them.[281] As is expected, Doppler strain measurements are not easily obtained in the radial direction because of Doppler angle and translation cardiac motion.[282] DTI strain is better suited for the study of longitudinal cardiac deformation. DTI strain was found to be superior to myocardial velocity measurements in detecting and assessing regional myocardial ischemia during off-pump left anterior descending (LAD) artery revascularization. DTI strain demonstrated systolic lengthening of the apical septum and reduced longitudinal shortening of the midseptum during interrupted LAD flow. These changes occurred with concomitant deterioration of wall motion and were confined to the LAD territory, whereas there were no changes in the basal septum, supplied by the right coronary artery.[283] At the same time, DTI velocities remained unchanged in the apical septum during interrupted LAD flow, probably explained by traction from the basal segments.

Rotation and Twist

Apical rotation (12.2 ± 3.8 degrees) represents the dominant contribution to LV twist (73% ± 15%) and reflects LV twist over a wide range of hemodynamic conditions, making it a noninvasive, feasible clinical index of LV twist.[271] Estimation of LV twist from apical rotation eliminates the requirement of two separate recordings (one for the base and one for the apex) and a possible calculation problem because of beat-to-beat variation in rotation, as well as the move-through of the LV image plane. In patients with chronic ischemia but preserved LVEF, rotation and twist were similar to healthy subjects; but in those with depressed LVEF, apical rotation and twist were reduced.[271]

In patients with diastolic dysfunction (DTI E′ < 8 cm/s), peak LV twist is increased in early-stage diastolic dysfunction, mainly because of more vigorous and increased LV apical rotation.[284] It is unknown whether the mechanism of LV twisting and untwisting is independent of the underlying myocardial relaxation in patients with diastolic heart failure or whether it is dependent on filling pressure (decreased twist with increased filling pressure).[284]

Systolic twist was depressed and diastolic untwisting prolonged in patients with anterior wall MI and abnormal LV systolic function. These abnormalities were related to reduced apical rotation and associated with the reduction of apical circumferential strain.[285] In contrast, systolic twist was maintained in patients with anterior wall MI and LVEF greater than 45%. This is a result of the mild reduction of circumferential strain in the apex that may affect LV twist behavior in a mild manner.

Ventricular Synchronization

In the normal heart, electrical activation of the ventricles occurs after atrial contraction, spreads quickly (within 40 ms) in both ventricles via conduction through the Purkinje fibers, and is associated with synchronous regional mechanical contraction of both ventricles. In mechanical dyssynchrony, there is delay in activation of the ventricles (interventricular dyssynchrony), or there is delay within the different LV segments or regions (intraventricular dyssynchrony; Fig. 15.131). Typically, there is a prolonged QRS complex on the surface electrocardiogram. A classic type of dyssynchrony is left bundle branch block, where there is early electrical activation of the interventricular septum and late activation of the inferolateral LV segments. The early septal contraction causes inferolateral stretching and late inferolateral contraction producing septal stretching. That is, one wall exerts forces on the contralateral wall and results in abnormal systolic performance, because the early septal contraction does not contribute to ejection because it occurs when LV pressure is low. Therefore, dyssynchrony is not innocuous, produces progressive dilation and distortion of the left ventricle, disrupts MV geometry, and results in inefficient LV systolic performance, increased LV end-systolic volume and wall stress, delayed relaxation, and MR. LV dyssynchrony has emerged as an important concept in patients with heart failure. It is present in a significant proportion of patients with heart failure with left bundle branch block and in patients with normal QRS duration. Presence of LV dyssynchrony has been used to predict response to cardiac resynchronization treatment (CRT) in patients with end-stage heart failure.

CRT (by biventricular pacing) results in reverse remodeling, where LV size and function progressively improve over time, with better results in nonischemic patients,[286] and reduces MR by improving temporal coordination of mechanical activation of the papillary

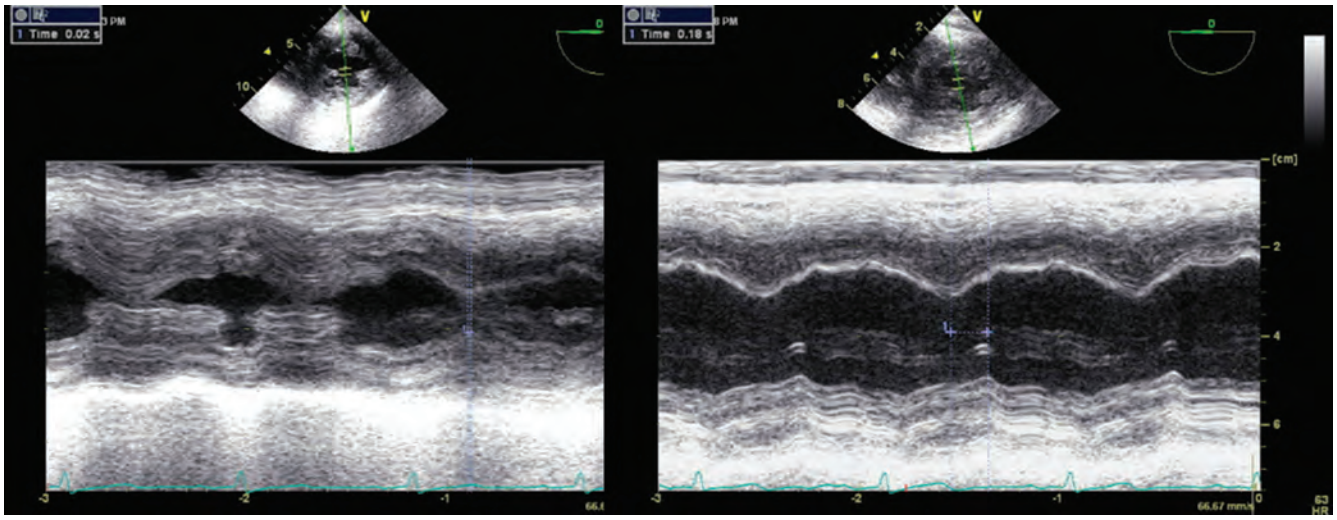

Fig. 15.131 Nonsignificant figure dyssynchrony. *Left,* Interventricular delay: 20 ms. *Right,* Interventricular delay: 180 ms.

muscles.[287] CRT is indicated for patients with severe heart failure (New York Heart Association [NYHA] class III or IV), widened QRS greater than 120 milliseconds, and LVEF less than 35%. However, mechanical dyssynchrony may also exist in patients with depressed LV function and a narrow QRS. As a result, 25% to 35% of patients undergoing CRT fail to improve, and this may be because of widened QRS being a suboptimal marker for dyssynchrony. Additional factors associated with lack of response to CRT are ischemic disease with scar tissue that prohibits reverse remodeling, subsequent MI after CRT, or suboptimal lead placement (see Chapters 4 and 5). Optimization of the techniques used to detect dyssynchrony is important to identify those patients who will respond to CRT because it appears that patients with minimal or no dyssynchrony have a lower probability of response and a poor prognosis after CRT.

Different echocardiographic modes have been used to detect dyssynchrony.[288]

1. M-mode with the cursor across the septal and inferolateral (posterior) segments. A delay between the opposing segments peak systolic excursion, usually longer than 130 milliseconds, was found to be fairly predictive for response to CRT (defined as >15% decrease in LV end-systolic volume and improvement in clinical outcome).[289] However, because of unsatisfactory reproducibility and lack of clear definition of systolic excursion of both septal and posterior walls, M-mode measurements (which are a single-dimensional assessment of LV dyssynchrony) are supplemental means to other echocardiographic modes, such as DTI.[290]
2. DTI of longitudinal myocardial velocities has been the principal method in recent studies and the preferred echocardiographic approach. With color DTI, the direction of motion is color-coded and is used to identify the transition from inward to outward motion in opposing LV segments. Placement of sample volumes in basal, septal, and lateral LV segments produces a spectral display of mean myocardial velocities. The time delay between systolic myocardial excursion is measured (two-site method), and peak systolic delay longer than 65 milliseconds is predictive of clinical response to CRT and reverse remodeling.[291] Subsequent investigators used four or six basal segments as well. A *dyssynchrony index* is the standard deviation of the 12-segment times to peak regional myocardial systolic velocity; greater than 32 milliseconds has been proposed to be the best predictor of response to CRT.[292] An automated color-coding of time-to-peak systolic velocity termed *tissue synchronization imaging* has also been developed. Myocardial systolic velocity spectra can be produced by real-time pulsed-wave DTI. However, the technique is considered time consuming and susceptible to artifacts because of breathing, patient movement, and translation. The major limitation of DTI techniques is that they cannot differentiate a passively moving segment because of tethering from an actively contracting one.
3. Cardiac deformation (strain) can differentiate active myocardial contraction or deformation from passive motion because of translation or tethering and has also been used to study dyssynchrony.[293] Longitudinal (the systolic deformation as imaged in the ME views) or radial (representing radial thickening as seen in TG views) strain can be challenging because it is affected by increased Doppler angle, whereas reproducibility of measurements is limited by the poor signal-to-noise ratio. Some believe that DTI velocities are far better than strain parameters in detecting dyssynchrony amenable to CRT.[294] Deformation studied with STI is a newer modality, which promises to bypass the limitations of DTI deformation.[295] Radial synchrony by STI is independent of clinical and echocardiographic parameters.[296]
4. The full-volume mode is capable of capturing the entire left ventricle in four beats.[297] With the use of integrated software programs, a 3D model of the left ventricle can be created within minutes, allowing the imager to view the 3D dynamics of the entire ventricle, including the timing of regional wall motion independently of its direction (Fig. 15.132). Consequently, 3DE is considered an alternative approach to TDI for the quantification of LV dyssynchrony, showing good correlation against phase analysis of gated single-photon emission computed tomography (SPECT) images.[288,298] Regional wall motion patterns can be visualized and quantified with semiautomatic contour tracing algorithms.[297] Its major limitation stems from the relatively low frame rate.

Optimal AV delay is defined as allowing completion of the atrial contribution to diastolic filling, resulting in the most favorable preload before ventricular contraction. A too-short AV delay will interrupt the late diastolic wave (A), whereas a too-long AV delay results in suboptimal LV preload. Despite these concerns, LV resynchronization is by far more important.[299]

Doppler Tissue Imaging– and Speckle-Tracking Imaging–Derived Strain

DTI-derived strain accurately measures cardiac deformation,[241] is sensitive to early ischemia, and is useful in assessing myocardial viability after MI; it provides more accurate results than DTI velocities or visual wall motion scoring.[300,301] DTI-derived strain in remote from ischemic

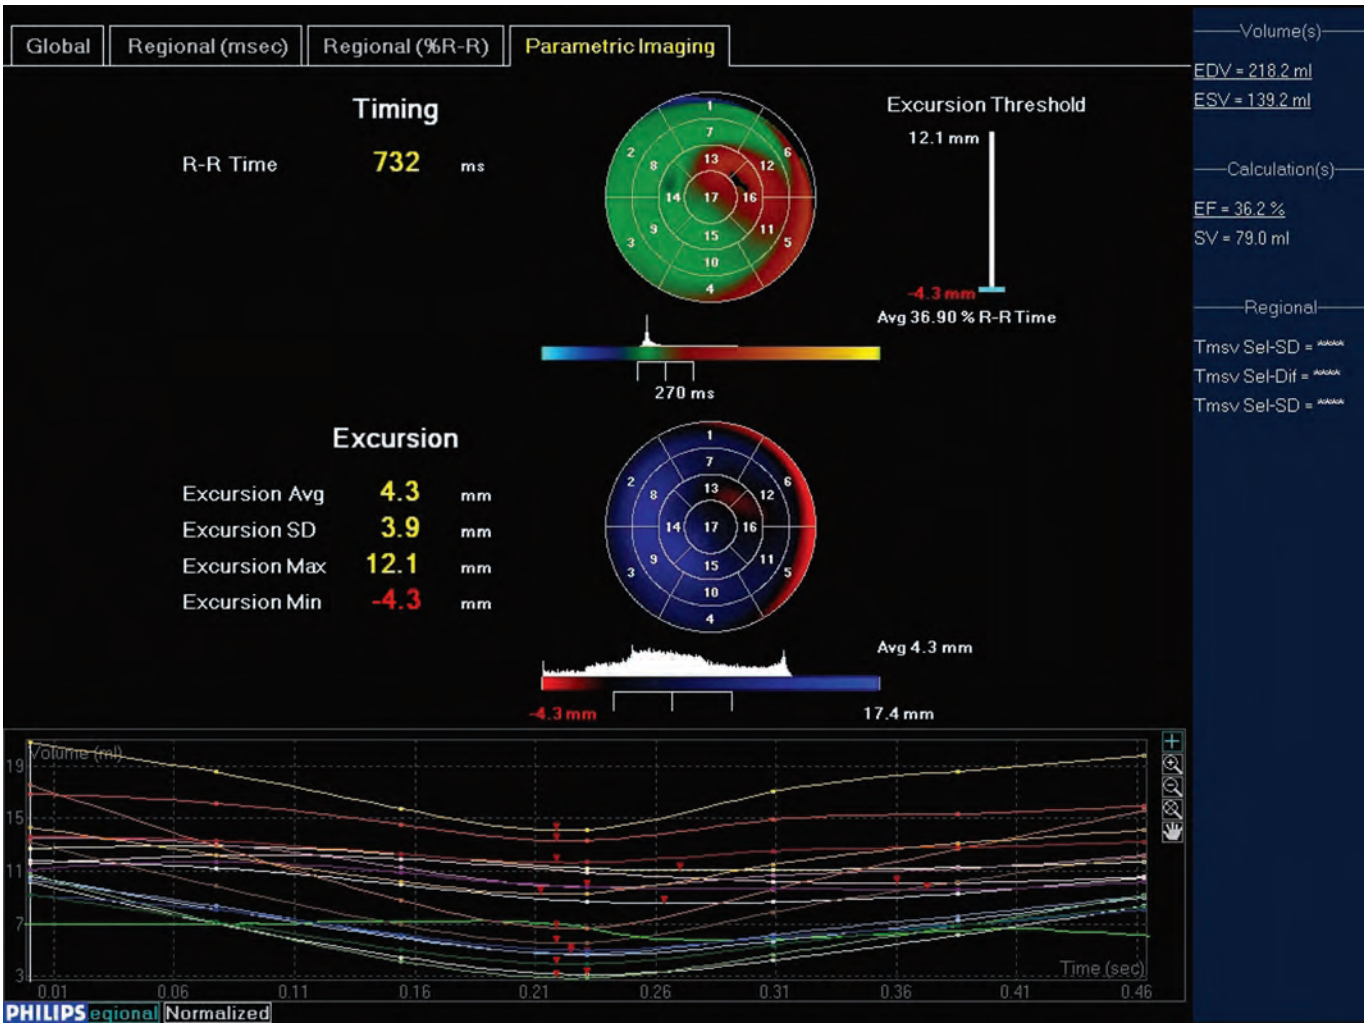

Fig. 15.132 Parametric imaging of the left ventricle. Lateral wall shows severe timing delay in contraction, but only mild decrease in excursion. This technology can be helpful in optimizing ventricular synchrony.

regions will remain normal, contrary to spectral DTI velocities, which are affected because of tethering.[243,261] Acute regional ischemia causes a rapid decrease in segmental contraction during systolic ejection, with the magnitude of regional shortening/thickening reduction in proportion to myocardial blood flow reduction. After systole, myocardial relaxation is delayed as PSS/thickening occurs.

DTI strain may be an important supplement to visual assessment of regional LV dysfunction. DTI strain and SR are more direct measures of regional function than tissue velocities, which are influenced by contractile function of other myocardial regions because of tethering.[243] In 17 patients with LAD disease (>75% obstruction), and normal baseline ejection fraction and wall motion score (WMS), DTI strain detected systolic longitudinal expansion in apical segments (baseline −17.7% ± 7.2% vs 7.5% ± 6.5%) or reduced compression in midseptal segments (baseline −21.8% ± 8.2% vs −13.1% ± 4.1%) in nearly all patients during balloon occlusion of the LAD. Segments not supplied by the LAD did not exhibit any strain changes. DTI strain was more sensitive than DTI velocities in detecting regional ischemia; the latter revealed longitudinal expansion in only two-thirds of the involved segments.[302]

DTI strain indices differentiate acutely ischemic myocardium from normal and dysfunctional myocardium, even in segments that appear visually normal. An acute reduction in regional myocardial blood flow induces a local contractile dysfunction within seconds, which alters the regional deformation pattern. Consequently, during systole, the radial thickening and circumferential/longitudinal shortening of the ischemic segment are decreased. In addition, the segmental relaxation is considerably impaired during the ischemic insult, and the physiologic early diastolic radial thinning and circumferential/longitudinal lengthening are replaced by ongoing postsystolic thickening and shortening, respectively. Such consistent changes in early diastolic deformation have been proposed as an early marker of regional ischemia.

PSS is an important feature of ischemic myocardium. When associated with systolic hypokinesis or akinesis, it indicates actively contracting, potentially viable myocardium. In view of the findings from experimental and clinical studies, PSS should be considered an expression of myocardial asynchrony. A segment that does not deform during contraction, when LV pressure increases, but does so when LV pressure decreases markedly during isovolumic relaxation, is not likely to be passive. DTI can quantify PSS. In an experimental setting, PSS was recorded during moderate (hypokinetic or akinetic myocardium), as well as severe, ischemia (dyskinetic myocardium).[303] During a 50% reduction of LAD flow, hypokinesis was accompanied by decreased longitudinal DTI systolic strain (from −12.3% ± 1.1% to −6.6% ± 1.3%) and substantial PSS (from 0.9% ± 0.2% to 5.1% ± 0.9%). Concurrent LV pressure-segment length and LV stress-segment length loop analysis indicated that PSS was active. Superimposed afterload augments those changes in a manner similar to LAD occlusion; in both cases, dyskinesis accompanied even more marked PSS.[303]

In a population of 90 consecutive patients with coronary artery disease who underwent percutaneous transluminal coronary angioplasty of a coronary artery with more than 90% obstruction, the baseline strain values in the at-risk segments (which had normal WMSs) were similar to those observed in control patients (radial: 49% ± 6.9% vs 56.3% ± 11.7%; longitudinal: −21.2% ± 4.5% vs −23.3% ± 4.7%). At-risk segments with abnormal WMSs had decreased strain values (radial: 21.9% ± 11%; longitudinal: −5.2% ± 4.5%) and increased postsystolic deformation (radial: 0.18 ± 0.14; longitudinal: 0.32 ± 0.26) as compared with normal and at-risk segments with normal WMS. Coronary occlusion resulted in a 50% reduction of radial and longitudinal strain, which peaked early in diastole, and increased postsystolic deformation in all at-risk segments (irrespective of WMS). These changes were reversible, and after 2 minutes of coronary reperfusion, segmental deformation parameters returned to the preocclusion state. Neighboring segments did not exhibit any changes, and presence of collaterals diminished the occlusion-associated strain parameter changes (less PSS).[304] DTI myocardial velocities changed during coronary occlusion only in segments with abnormal baseline function and had lower diagnostic accuracy when compared with strain.[305]

In the clinical setting, RWMAs may not be detected by DTI myocardial velocities because of tethering and translational effects. Only strain and SR offer quantitative and objective parameters indicating ischemia. As observed during dobutamine-exercise testing, DTI strain decreased and PSS markedly increased during ischemia, whereas DTI myocardial velocities did not reveal any changes.[306]

Using STI, global longitudinal strain less than −21% (normal: −24.1% ± 2.9%) and SR less than −0.9/s (normal: −1.02 ± 0.09/s) had good sensitivity and specificity (92% and 89%, and 92% and 96%, respectively) for detection of post-MI patients, with a good linear correlation with WMS index.[250] STI-derived circumferential and radial strain are sensitive to acute reduction of myocardial perfusion. During balloon occlusion, there were significant decreases in circumferential strain (baseline: −18.5% ± 7.2% to −10.5% ± 3.8%) and radial strain (baseline: 46.5% ± 19.4% to 35.7% ± 20.8%), as well as prolongation of the time to peak circumferential and radial strain.[284]

Longitudinal deformation parameters are potentially superior to visual WMS in identification and quantification of subtle ischemia-induced changes in regional contractility. When DTI strain parameters were correlated with the coronary angiogram, systolic strain and SR were significantly reduced in normokinetic segments supplied by a stenosed coronary artery (>70%), but not in normokinetic segments supplied by a coronary artery without significant lumen narrowing.[307] When compared with myocardial velocities, systolic strain and SR differentiated abnormal from normal contracting segments. Infarct-involved segments were differentiated from normal myocardium using cutoff values of less than −13% for strain and less than −0.8/s for SR.[307]

DTI radial SR agrees well with wall motion and is reduced more in hypokinetic and akinetic segments (0.6 ± 0.5/s and 0.008 ± 0.3/s, respectively) than in normokinetic segments (2 ± 0.6/s). SR reflects changes in WMS induced by dobutamine challenge; it increased in those segments that revealed augmented wall motion (from 2 ± 0.7/s to 4.7 ± 1.7/s) and decreased in those segments that showed deteriorating or unchanged wall motion (from 2.1 ± 1 to 1.7 ± 0.8/s).[308]

Radial and circumferential STI strain enable distinction among normokinetic, hypokinetic, and akinetic segments at rest (defined by cardiac MRI), in a highly reproducible manner and with small intraobserver and interobserver variability (5.3% ± 2.6% and 8.4% ± 3.7%, respectively).[309] A cutoff value of radial strain less than 29% defined hypokinetic from normokinetic segments with sensitivity and specificity of 83%, and a cutoff value of radial strain less than 21% akinetic from hypokinetic segments with sensitivity of 83% and specificity of 94%.

Similar discriminatory ability of STI radial strain was found when transmural MIs were analyzed using contrast-enhanced cardiac MRI. Radial strain decreased significantly with increased relative hyperenhancement: 27.7% ± 8% (normal segments) versus 20.5% ± 9.7% (nontransmural infarction segments) versus 11.6% ± 8.5% (transmural infarction segments). Nontransmural infarction was distinguished from transmural infarction segments by radial strain cutoff value greater than 16.5%.[310]

In an experimental model of acute LAD ischemia/reperfusion, extent of infarct correlated well with radial and circumferential STI strain. Myocardial segments with more than 50% area of infarction (verified by postmortem histology) had lower end-systolic radial and circumferential strain and longer time to peak strain versus areas with less than 50% infarction. End-systolic radial strain less than 2% had 88% sensitivity and 95% specificity for detecting infarcted area larger than 50%.[311]

The use of STI strain for combined assessment of long-axis and short-axis cardiac function may allow differentiation of transmurality of chronic infarction and, therefore, overcome DTI strain, which is angle limited and can evaluate only longitudinal function reliably. In subendocardial infarction, STI radial strain (32.4% ± 20%) and circumferential strain (−15.4% ± 6.9%) are preserved, whereas longitudinal strain is reduced (−13.2% ± 5.6%). In contrast, in transmural infarcts, both short-axis and long-axis STI strain are significantly reduced (cutoff value for circumferential strain less than −13.6%, sensitivity 73%, specificity 72%).[312]

Accurate identification of infarcted, nonviable myocardium from viable, hypokinetic segments has important clinical implications; revascularization benefits only patients with a sufficient amount of viable myocardium, whereas it is unlikely to benefit those with transmural MI. In post-MI patients, and in contrast with DTI myocardial velocities, longitudinal DTI SRs of transmural infarcted segments (−0.51 ± 0.17/s) were significantly decreased when compared with nontransmural (−1.06 ± 0.29/s), subendocardial (−1.21 ± 0.41/s) and normal segments (−1.58 ± 0.38/s). SRs also were significantly reduced in subendocardial infarction compared with normal segments. A cutoff value of SR greater than −0.59/s identified transmural from nontransmural and subendocardial MI, and a cutoff value of −0.98/s > SR > −1.26/s identified a subendocardial infarction from normal segments.[313]

STI radial strain can identify myocardial dysfunction and predict recovery of function using a cutoff value of peak radial strain greater than 17.2%. Segments that failed to recover had lower peak radial strain (15.2% ± 7.5%) than those that showed functional improvement after surgical or percutaneous revascularization (22.6% ± 6.3%). This predictive value (sensitivity of 70.2% and specificity of 85.1%) was similar to hyperenhancement by contrast-enhanced MRI.[314]

Among patients with cardiovascular risk factors but no overt cardiac disease, longitudinal strain and SR are decreased, and circumferential strain is increased in those with apparently normal mitral inflow velocities (E/A > 1). This may imply that LV systolic function and filling are compensated by circumferential shortening at ventricular systole.[315]

Myocardial Disease

Myocardial disease and *cardiomyopathies* are broad terms used to describe an array of disease states that are limited to the intrinsic function of the myocardium at a tissue level. These conditions should be separated from causes of dysfunction that are secondary such as ischemia or infarction, changes in myocardial function or mass secondary to valvular diseases, or restriction to normal function because of pericardial or extrapericardial disease.

Evaluating the myocardium can extend past the presence or absence of RWMAs related to ischemic heart disease. The cardiac anesthesiologist is often called to evaluate and assess patients with unknown causes of hemodynamic instability, and possessing a broad differential diagnosis of myocardial dysfunction is crucial. In this section we discuss common causes of myocardial disease that results in ventricular dysfunction and findings on imaging that might assist in the assessment.

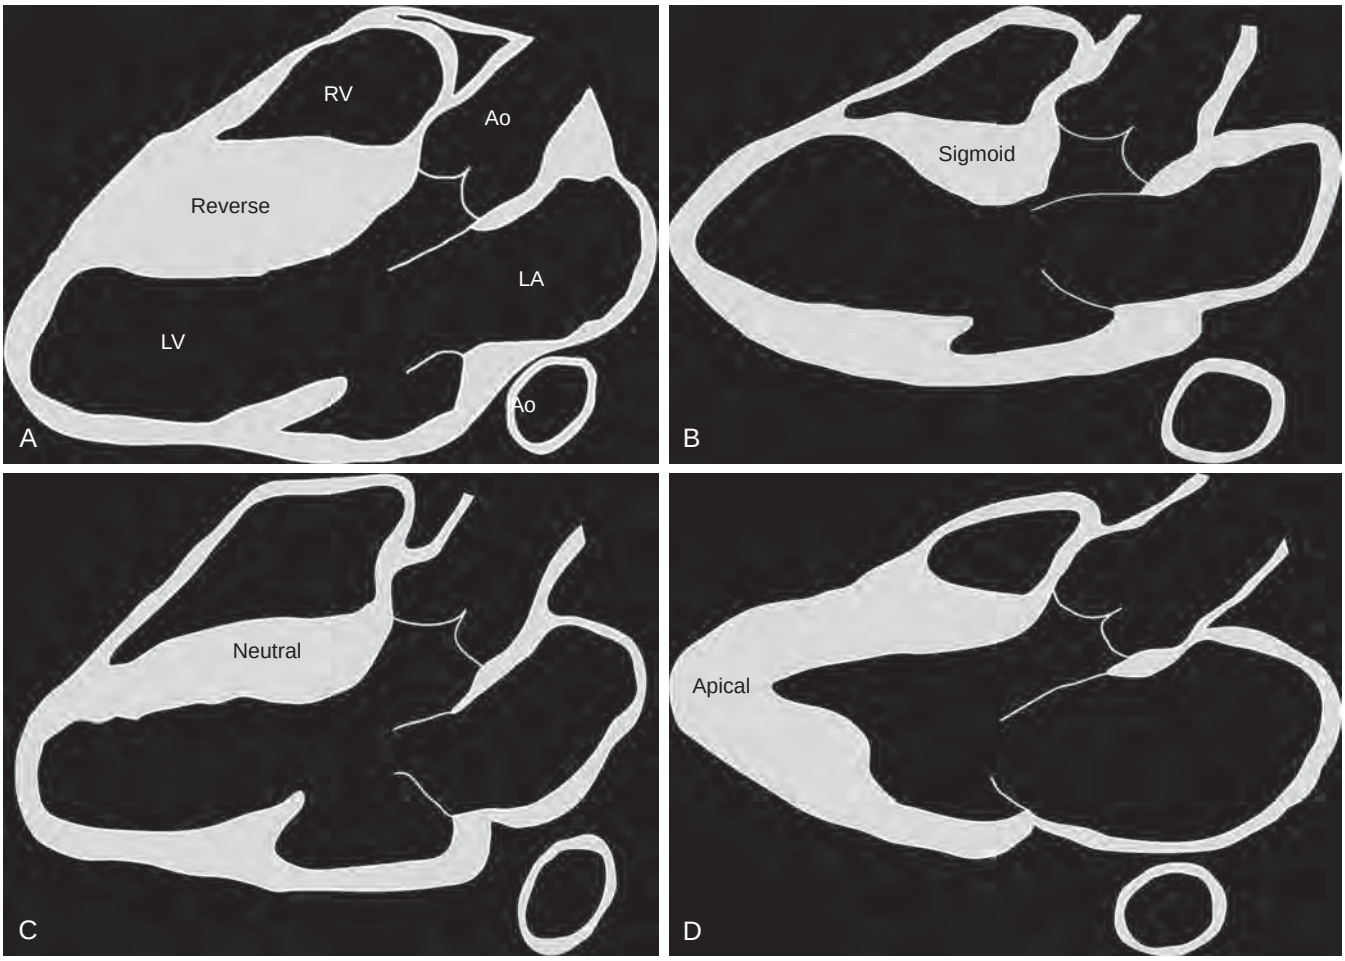

Fig. 15.133 Phenotypic variants seen on echocardiography in patients with hypertrophic cardiomyopathy. (A) The reverse curvature type shows a markedly thickened septum with the endocardial curve convex instead of the expected concave appearance. (B) The sigmoid curvature type shows a discrete region of asymmetric septal thickening near the outflow tract. (C) The neutral septum type demonstrates a uniformly thickened septum with the expected concave appearance of the septum. (D) The apical variant demonstrates asymmetric hypertrophy of the apical segments. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle; *RV,* right ventricle. *(Adapted from Syed IS, Ommen SR, Breen JF, Tajik AJ. Hypertrophic cardiomyopathy: identification of morphological subtypes by echocardiography and cardiac magnetic resonance imaging.* JACC Cardiovasc Imaging. *2008;1:377–379.)*

Hypertrophic Cardiomyopathy

HCM was initially described in the 1970s, and in addition to the presence of a murmur, syncope, and sudden death, these individuals were found to have asymmetric septal thickening. Early reports found that septal hypertrophy with a ratio of septal (anteroseptal) wall thickness to posterior (inferolateral) wall thickness of greater than 1.3 was indicative of the presence of disease.[316] It was determined that this appeared to be genetic as there were familial tendencies; however, only 30% to 40% of the family members had symptoms associated with the disease.[317] The location of the genetic mutation was first isolated to the long arm of the 14th chromosome (14q1) and encoded a protein for part of the thick chain filament.[318,319] Early evidence of genetic heterogeneity among HCM patients was suspected, and up to 18 different genes with mutations have been identified.[320,321] Overall this is the most common genetically inherited cardiomyopathy with 0.2% of the population (1 in 500) with a genetic mutation at risk for HCM[322] (see Chapters 8 and 24).

Phenotypically this presents as four different types categorized by the appearance of the septal contour, which can be recognized during echocardiography: sigmoid, neutral, reverse, and apical.

Though initially identified with M-mode echocardiography, the appearance of the septum was classified into the three different curves of the septum.[323] Later, Yamaguchi and colleagues identified a fourth phenotypic variant that demonstrates apical hypertrophy.[324] These types are summarized in Fig. 15.133. The apical variant can be confused with LV noncompaction, which appears similar on standard 2D imaging and can be differentiated with the use of microbubble echocardiographic contrast.

Genetic mutations have a more pronounced effect on diastolic filling, resulting in diastolic dysfunction (pseudonormal or restrictive) with the majority of these individuals demonstrating the presence of a diastolic L wave consistent with triphasic filling. Others may have more obstructive symptoms and a relatively thicker septal diameter and these patients tend to have thick filament mutations.

The most serious complication of increased septal thickness is obstruction to LV ejection from SAM of the MV resulting in dynamic LVOT obstruction. This obstruction is both dynamic and variable. The presence of a dynamic LVOT obstruction with a gradient greater than 30 mm Hg is significant and the variations of dynamic LVOT obstruction have been classified as (1) nonobstructive, (2) latent (inducible) obstruction, (3) labile obstruction, and (4) obstruction at rest.[325]

BOX 15.4 DEFINITIONS OF LEFT VENTRICULAR OUTFLOW TRACT OBSTRUCTION IN HYPERTROPHIC CARDIOMYOPATHY

Degrees of Obstruction Based on Hemodynamic Findings

Nonobstructive: No LVOT gradient at rest and no inducible gradient with provocation.

Latent Obstruction: No LVOT gradient at rest, but provocative maneuvers result in LVOT obstruction (gradient >30 mm Hg).

Labile Obstruction: Inconsistent LVOT obstruction at rest, occasional obstruction with gradient >30 mm Hg, and provocation provides consistent, high gradient obstruction.

Obstruction at Rest: Consistent LVOT obstruction at rest with gradient >30 mm Hg; no provocative maneuvers recommended.

Qualification of Systolic Anterior Motion of the Mitral Valve

No SAM/Chordal SAM: The anterior mitral leaflet is >10 mm from the septum, and there is no evidence of obstruction or turbulence.

Mild SAM: The anterior leaflet is drawn toward the septum, but it is always >10 mm away.

Moderate SAM: The anterior leaflet is <10 mm from the septum or briefly contacts the septum but for less than 30% of the ejection period.

Severe SAM: The anterior leaflet is in contact with the septum for >30% of the ejection period. There is significant obstruction and associated mitral regurgitation.

Box 15.4 provides a summary of definitions for LVOT obstruction and grading of SAM.

The majority of symptoms are associated with SAM and the intermittent decrease in CO with dynamic LVOT obstruction. The presence of SAM at rest, a narrow aortomitral angle, and significant septal bulge (sigmoid type) are associated with more symptomatic disease.[326] Care for these patients under anesthesia should focus on improving LV diastolic filling, maintaining low-normal heart rates, and normal vascular impedance as the low vascular resistance state can result in SAM. The presence of SAM not only results in the decrease in forward CO, and therefore, poor cellular perfusion, but also results in more significant MR.[327] This relationship of increased LVOT gradient and increased MR has potential ramifications as acute severe MR results in elevated PA pressures and can promote the formation of pulmonary edema. SAM should be treated aggressively with pharmacologic agents such as α-adrenergic agonists and β-blockade, as well as administration of intravenous fluid.

In addition to dynamic LVOT obstruction, individuals with HCM can demonstrate both systolic and diastolic dysfunction. While diastolic dysfunction is more common since there is increased wall thickness, systolic dysfunction can be seen with chronicity of obstruction. Barac and coworkers demonstrated that the slight decrease in velocity seen within the LVOT during periods of SAM directly prior to the significant rise of the LVOT velocity is an indicator of underlying systolic dysfunction, which may explain the subset of individuals who go on to develop end-stage HCM with LV dilation.[328] HCM can be mimicked by other disease states that result in global and regional increases in myocardial thickness. Box 15.5 lists many of the common diseases that can result in SAM and may mimic HCM.

Guidelines for surveillance and treatment recommend any patient suspected of having HCM should undergo TTE as part of the initial evaluation (class I, level of evidence: B).[329] Individuals with symptoms of lightheadedness and presyncope or syncope should be evaluated with TTE (appropriate use score 9).[330] Additionally, these guidelines suggest that septal wall thickness greater than 30 mm puts individuals at great risk of HCM-related death.[329] A summary of selected recommendations for echocardiography and pharmacologic therapies can be found in Box 15.6. An early nonsurgical treatment that is still used today is DDD pacing. This was demonstrated to be superior to simply pacing the RA, and the use of the RV pacing lead resulted in an improvement of symptoms and dynamic LVOT obstruction from SAM.[331] Amiodarone has shown some benefit in the reduction in sudden cardiac death in patients with HCM, but the use of β-blockers and calcium channel blockers has not shown risk reduction.[332]

Surgical myectomy is a mainstay of treatment for HCM when patients have the presence of an inducible obstruction or obstruction at rest with a gradient of 50 mm Hg or higher.[329,333] First described by Morrow and associates, this technique removes the portion of the septum through an aortotomy that the MV contacts, opening the cross-sectional area of the LVOT and reducing the incidence of SAM.[334,335] The echocardiographer should see both a reduction in the size of the septum in the region of the LVOT and a reduction in SAM. Doppler echocardiography should demonstrate the reduction (<30 mm Hg) or absence of a gradient through the LVOT. This technique can result in iatrogenic VSDs and, therefore, the absence of such a complication should be documented during imaging following cardiopulmonary bypass. Selected recommendations for invasive therapies for HCM are summarized in Box 15.7.

This technique of septal myectomy has shown good durability, especially when individuals with good prognostic factors—presence of asymmetric hypertrophy, severe SAM, and prolonged isovolumic relaxation time—are selected.[336,337] One series found that individuals undergoing surgical myectomy had improved outcomes if they were (1) younger than 50 years of age, (2) had an LA dimension less than 46 mm, and (3) had no history of atrial fibrillation.[338] Another demonstrated 90% of patients undergoing septal myectomy had an improvement of at least one NYHA heart failure class.[339] Intraoperative measurements of reduction of LVOT obstruction and lower Doppler ultrasound gradients provided surgical guidance resulting in 4% of one series returning to cardiopulmonary bypass for additional resection; however, there was a significant (39%) portion of this series that did not have adequate intraoperative imaging to measure a LVOT gradient.[340]

BOX 15.6 SELECTED CLASS I RECOMMENDATIONS FOR ECHOCARDIOGRAPHY AND PHARMACOLOGIC THERAPIES FOR SYMPTOMATIC PATIENTS WITH HYPERTROPHIC CARDIOMYOPATHY

Echocardiography
Class I Recommendations
- TTE is recommended for initial evaluation for all patients with suspected HCM. *(Level of Evidence: B)*
- Repeat TTE is recommended for the evaluation of patients with HCM with a change in clinical status or new CV event. *(Level of Evidence: B)*
- TEE is recommended for the intraoperative guidance of surgical myectomy. *(Level of Evidence: B)*
- TTE or TEE with intracoronary contrast injection of the candidate's septal perforator(s) is recommended for the intraprocedural guidance of alcohol septal ablation *(Level of Evidence: B)*
- TTE should be used to evaluate the effect of surgical myectomy or alcohol septal ablation for obstructive HCM. *(Level of Evidence: C)*

Pharmacologic Management
Class I Recommendations
- β-Blocking drugs are recommended for the treatment of symptoms (angina or dyspnea) in adult patients with obstructive or nonobstructive HCM but should be used with caution in patients with sinus bradycardia or severe conduction disease. *(Level of Evidence: B)*
- If low doses of β-blocking drugs are ineffective for controlling symptoms (angina or dyspnea) in patients with HCM, it is useful to titrate the dose to a resting heart rate of less than 60 to 65 beats/min. *(Level of Evidence: B)*
- Verapamil therapy (starting in low doses and titrating up to 480 mg/d) is recommended for the treatment of symptoms (angina or dyspnea) in patients with obstructive or nonobstructive HCM who do not respond to β-blocking drugs or who have side effects or contraindications to β-blocking drugs. However, verapamil should be used with caution in patients with high gradients, advanced heart failure, or sinus bradycardia. *(Level of Evidence: B)*
- Intravenous phenylephrine (or another pure vasoconstricting agent) is recommended for the treatment of acute hypotension in patients with obstructive HCM who do not respond to fluid administration. *(Level of Evidence: B)*

BOX 15.7 SELECTED RECOMMENDATIONS FOR INVASIVE THERAPIES IN HYPERTROPHIC CARDIOMYOPATHY

Class I
- Septal reduction therapy should be performed only by experienced operators in the context of a comprehensive HCM clinical program and only for the treatment of eligible patients with severe drug-refractory symptoms and LVOT obstruction. *(Level of Evidence: C)*

Class IIa
- Surgical septal myectomy, when performed in experienced centers, can be beneficial and is the first consideration for the majority of eligible patients with HCM with severe drug-refractory symptoms and LVOT obstruction. *(Level of Evidence: B)*
- When surgery is contraindicated or the risk is considered unacceptable because of serious comorbidities or advanced age, alcohol septal ablation, when performed in experienced centers, can be beneficial in eligible adult patients with HCM with LVOT obstruction and severe drug-refractory symptoms (usually NYHA functional classes III or IV). *(Level of Evidence: B)*

Class IIb
- Alcohol septal ablation, when performed in experienced centers, may be considered as an alternative to surgical myectomy for eligible adult patients with HCM with severe drug-refractory symptoms and LVOT obstruction when, after a balanced and thorough discussion, the patient expresses a preference for septal ablation. *(Level of Evidence: B)*
- The effectiveness of alcohol septal ablation is uncertain in patients with HCM with marked (ie, >30 mm) septal hypertrophy, and therefore the procedure is generally discouraged in such patients. *(Level of Evidence: C)*

Class III: (Harm)
- Septal reduction therapy should not be done for adult patients with HCM who are asymptomatic with normal exercise tolerance or whose symptoms are controlled or minimized on optimal medical therapy. *(Level of Evidence: C)*
- Alcohol septal ablation should not be done in patients with HCM who are younger than 21 years of age and is discouraged in adults younger than 40 years of age if myectomy is a viable option. *(Level of Evidence: C)*

HCM, Hypertrophic cardiomyopathy; *LVOT,* left ventricular outflow tract; *NYHA,* New York Heart Association.

Alcohol septal ablation is another option. Target vessel occlusion and echocardiographic contrast agents can assist in preablation confirmation that the target vessel results in necrosis of the desired region without unwanted extension.[341] Successful alcohol septal ablation will show early reduction in LVOT gradient on follow-up TTE.[342]

Myocarditis

Myocarditis is an inflammatory process of the myocardium that can be the result of a direct infection by a virus or can be the result of a host-response to the myocardium as the result of an autoimmune process. The majority of cases are associated with viral origins and the causative agents vary related to regional and temporal differences. Historically, coxsackievirus B was the most common cause until the 1990s when adenovirus became more common.[343,344] More recently, parvovirus B19 has become a more frequently occurring cause, although there is a whole array of viruses that have been related to chronic forms of myocarditis; these include human immunodeficiency virus, hepatitis C virus, cytomegalovirus, human herpesvirus 6, and the Epstein-Barr virus.[4,344,345] Additional causes, both viral and nonviral, are summarized in Box 15.8.

Variability occurs in presentation and the clinicopathologic classification of myocarditis is divided into four distinct groups. These four groups are (1) fulminant, (2) acute, (3) chronic active, and (4) chronic persistent. Table 15.18 includes the clinical findings, natural history, and findings on echocardiography for these four presentations of myocarditis. Fulminant myocarditis and acute myocarditis are the two most commonly presenting forms with acute deterioration of myocardial function, although the two types have distinct characteristics that separate them.

Fulminant myocarditis has a distinct onset of symptoms and the individual presents in extremis as the result of severe LV dysfunction.[346,347] The LV walls are thickened, with severely reduced LV systolic function, and there can be RWMAs on imaging that are not

BOX 15.8 CAUSES OF MYOCARDITIS

in a standard coronary distribution.[347] One hallmark of fulminant myocarditis is the extremely thickened LV wall with severely reduced systolic function, which is the result of a hyperacute inflammatory process leading to edema of the myocardium. As the myocardium recovers, the edema resolves and there is simultaneous improvement in wall thickness and LV systolic function.[348] Fig. 15.134 demonstrates a patient with fulminant myocarditis; following recovery of systolic function there is improvement in wall thickness. More sophisticated ultrasound techniques, such as the use of integrated backscatter to look at the myocardial architecture, suggest that the backscatter pattern will normalize before systolic function returns, but this has not gained wide application.[349]

The ability of individuals with fulminant myocarditis to recover a significant portion of their cardiac function over a 2- to 4-week period following acute decompensation has led to aggressive interventions. In 2000, McCarthy and colleagues presented a series of 15 patients with fulminant myocarditis; all but one patient had a successful recovery without the need for heart transplantation.[350] While McCarthy's experience showed only one patient required mechanical circulatory support, subsequent series demonstrated the applicability and success of aggressive mechanical circulatory support with fulminant myocarditis.[351] The approach was to initiate mechanical circulatory support for fulminant myocarditis patients and then perform daily serial echocardiograms to evaluate myocardial recovery, both in wall thickness

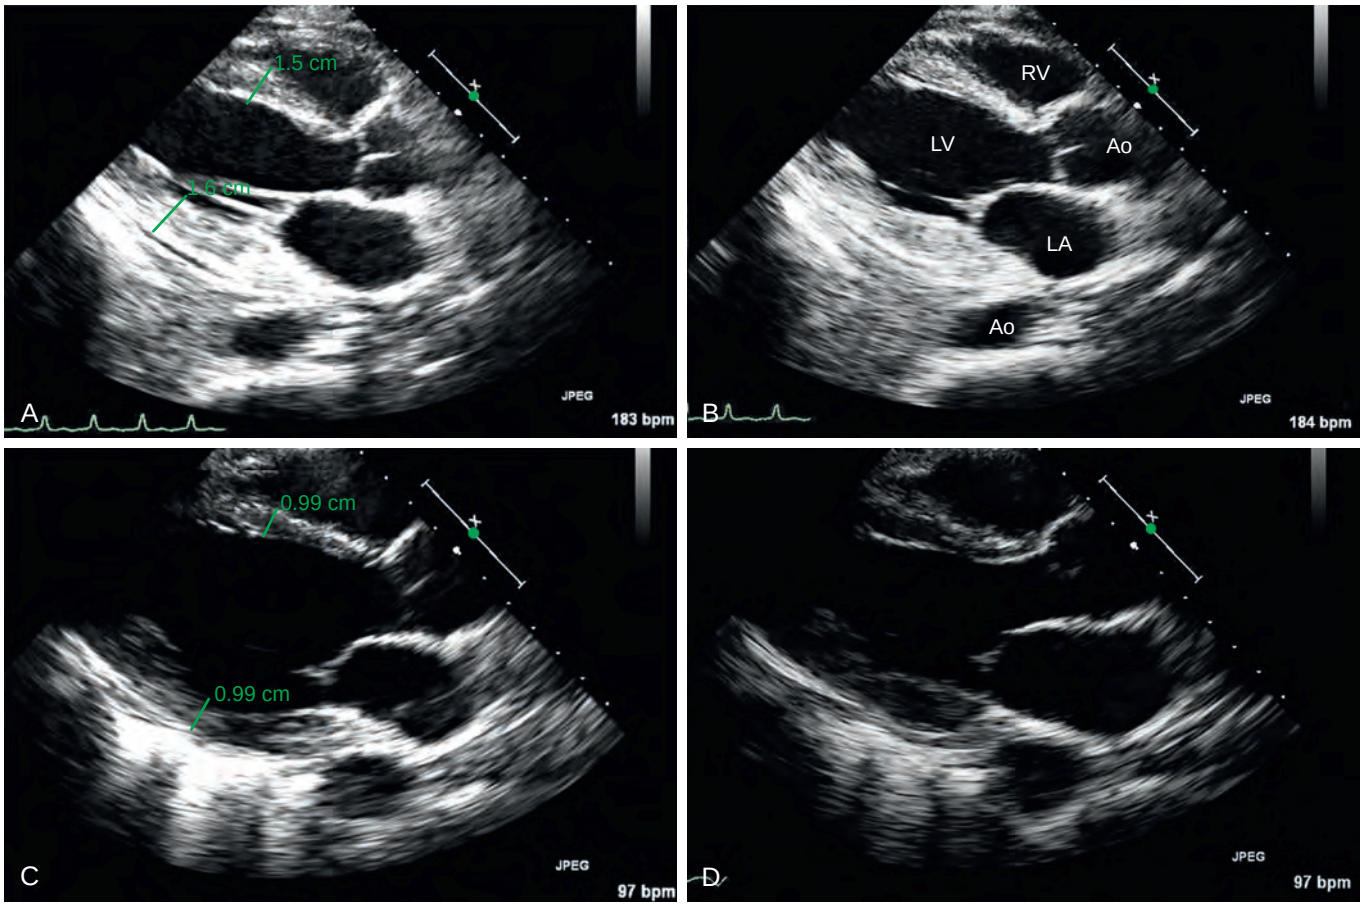

Fig. 15.134 Initial imaging at presentation of a patient with fulminant myocarditis. All images are transthoracic echocardiography images of the parasternal long-axis view. (A) End-diastolic frame with severely thickened myocardium. (B) End-systolic frame of the same clip demonstrating poor systolic function with minimal change in chamber size. (C) End-diastolic frame taken 34 days later demonstrating a resolution of myocardial edema with normal wall thickness. (D) End-systolic frame demonstrating improved systolic function in the form of an improved end-systolic dimension. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle; *RV,* right ventricle.

and LV systolic function, and then initiate weaning from mechanical support when myocardial recovery was seen in up to 2 weeks.[351]

In differentiating fulminant myocarditis from acute myocarditis, one series of patients showed that all patients with the fulminant type demonstrated increased septal thickness, normal LV diastolic dimensions, and depressed LVEF.[352] As acute myocarditis is a different clinical entity, the use of imaging can assist in the differentiation. Clinically, acute myocarditis manifests with normal wall thickness, dilation of the LV cavity, and depressed systolic function in which the onset can often be indistinct. It is usually preceded by some infectious process and the recovery is delayed because of poor myocardial performance and heart failure.[346] Unfortunately, recovery from acute myocarditis is often incomplete with less than half of a large group of patients recovering normal myocardial function and avoiding heart transplantation.

The role of imaging in myocarditis is important not only to assist in the care of these often critically ill and decompensated patients, but also to differentiate the cause of deterioration from other common causes. As mentioned, the presence of myocardial edema, normal chamber size, and reduced LVEF should differentiate fulminant from acute myocarditis, but often the diagnosis of myocarditis is unknown or underrecognized. In one series of 45 patients who presented for typical chest pain consistent with acute coronary syndrome but normal coronary angiography, 35 had myocarditis on endomyocardial biopsy.[353] This is further complicated by the fact that within this series, 62% had RWMAs and a depressed LVEF (<50%).[353] Though these findings of RWMAs in the absence of coronary artery disease in the setting of myocarditis have been known since the 1980s, it is not always in a coronary distribution.[354] This has led to a recommendation that multiple imaging modalities, including myocardial strain imaging, cardiac MRI, and the use of antimyosin antibody titers, should be used to evaluate the myocardium if myocarditis is suspected.[355–357]

Despite a much better understanding of the pathophysiology of myocarditis and its clinical progression over the past 2 decades, significant improvement in treatment options and outcomes have not occurred.[358] Biopsy-proven myocarditis has a nearly 20% mortality rate within 5 years despite treatment, which further highlights the need for myocarditis to be on the differential diagnosis of all clinicians when evaluating a patient with abnormal myocardial function.[359] Autoimmune processes involved in myocarditis and diseases such as cardiac sarcoidosis have a better prognosis than other causes of myocarditis, further supporting the need for a broad list of causes of ventricular dysfunction.[360] Causes of myocarditis are summarized in Box 15.8.

One predicative factor associated with postmyocarditis recovery was found to be premyocarditis LV systolic function.[361] Unfortunately, a significant number of individuals do not recover and the long-term result is a transition to a DCM. This dilation is the result of impaired myocardial function and is proposed to be secondary to microvascular spasm within the inflamed myocardium leading to fibrosis and dilation over time.[362]

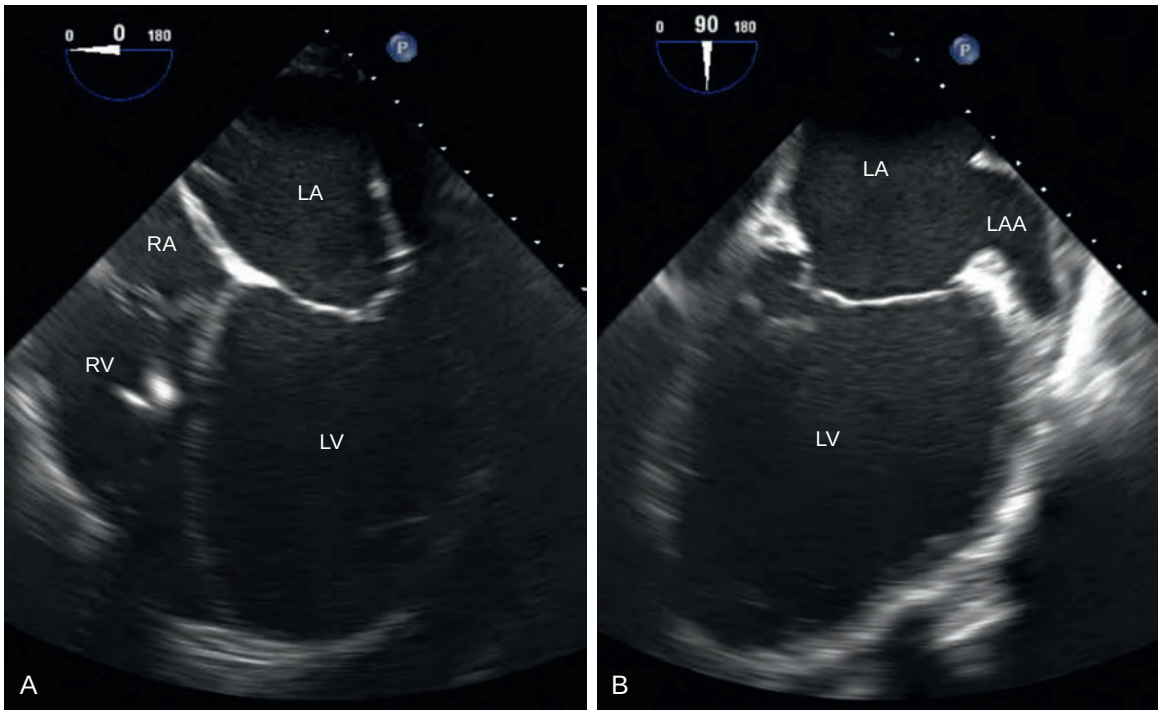

Fig. 15.135 Transesophageal echocardiographic still frames in the (A) midesophageal four-chamber view and (B) midesophageal two-chamber view of a patient with postviral myocarditis dilated cardiomyopathy. Note the large left ventricle *(LV)* with apical tenting of the mitral valve. *LA,* Left atrium; *LAA,* left atrial appendage; *RA,* right atrium; *RV,* right ventricle.

Dilated Cardiomyopathy

DCM is the final common pathway for a number of conditions that result in systolic dysfunction of the left ventricle. Up to 50% of individuals with myocarditis can progress to a DCM, with approximately 20% thought to be the result of viral myocarditis.[362–364] Persistence of certain types of viruses, such as coxsackievirus B, has been seen in one-third of patients with idiopathic DCM.[365] The remaining causes are from ischemic changes, diabetic alterations to the microvasculature, familial causes, and others.

Following an injury to the myocardium (infectious, ischemic, traumatic, metabolic), the remaining viable tissue within the heart begins to remodel and the LV cavity dilates over time.[366] Alterations in myocardial blood flow, myocardial energetics, and the renin-angiotensin-aldosterone system all contribute to elevated LV end-diastolic pressure and subsequent enlargement of the LV chamber with reduction in LV systolic function.[367–369]

The echocardiographer should be aware of the derangements that are associated with DCM as patients will have reduced systolic function and reduced functional reserve. Fig. 15.135 shows a TEE image of a patient with DCM undergoing LVAD implantation as treatment for systolic heart failure. These individuals often have elevated LV end-diastolic pressure that increases the risk for pulmonary edema formation. The derangements to the myocardium that initialed the DCM may not be isolated to the left ventricle, and the right ventricle may have clinical or subclinical dysfunction. Large ventricular chamber size and the relative hypokinesis or RWMAs associated with the cardiomyopathy may support thrombus formation in both the left ventricle and LAA. Dilation of the left ventricle can also promote ventricular and atrial arrhythmias that are often not well tolerated.

Infiltrative Cardiomyopathy

Infiltrative cardiomyopathies are disease processes in which something becomes intercalated within the myocardium that is not expected to be there. Eosinophilic processes can result in infiltration and the deposition of abnormal proteins. Amyloidosis is an infiltrative process that results in cardiac dysfunction from abnormal deposition of amyloid fibrils within tissue. Amyloid is categorized into systemic AA amyloidosis, which traditionally has renal involvement and not much cardiac involvement when compared with the systemic AL amyloidosis, which has 90% cardiac involvement, and the TTR type of amyloidosis, which has 100% cardiac involvement.[370] The deposition of amyloid fibrils within the wall of the ventricles is responsible for the clinical manifestations of amyloidosis. There is impaired diastolic relaxation as a result and subsequent diastolic heart failure in the latter stages.[371] As amyloidosis is generally a progressive diastolic disease it has been named *stiff heart syndrome,* which is characterized by a restrictive process.[372,373] The more the disease infiltrates the myocardium, the worse the diastolic dysfunction becomes, until in the latest stages of disease there also is systolic dysfunction as a result of the infiltration.

Echocardiography has long been a helpful technique to determine the presence and extent of amyloid cardiac disease. In the 1980s, it was shown that any identifiable abnormality of the myocardium on TTE was associated with an increased risk of arrhythmia, especially with the AL variant.[374] Subsequently, it was shown that amyloid has a typical appearance with increased wall thickness, sparkling myocardium, and diastolic dysfunction. When compared to individuals screened for amyloid, but with a negative biopsy, the amyloid patients had smaller end-diastolic and end-systolic sizes, comparable LVEF, and increased rates of restrictive diastolic filling.[375] Common echocardiographic findings in the setting of cardiac amyloidosis are summarized in Table 15.19. The diastolic dysfunction of the myocardium is not isolated to the left ventricle; RV diastolic abnormalities are seen as well.[371] When the LV end-diastolic pressure increases and the LA pressure increases, the pulmonary venous flow becomes diastolic dominant.[376] This is true for the right ventricle as well, but the normal quadriphasic pattern within the hepatic veins make it more challenging to appreciate. The presence of thickened myocardium and diastolic filling abnormalities makes cardiac amyloidosis appear like HCM; this is true for other types of infiltrative cardiomyopathies as well.[372] Infiltrative cardiomyopathies

that mimic HCM presenting with thickened ventricles and increased LV mass are summarized in Table 15.20.

Acute eosinophilic myocarditis is a diagnosis that can be confused clinically with an acute MI because of chest pain and nondescript ST changes on the electrocardiogram.[377] The absolute eosinophil count will help to make the diagnosis, and the administration of steroids should be timely as the mortality rate for this condition approaches 100%.[377] Other diseases that can present with an infarction-like clinical presentation are summarized in Table 15.21. Knowledge of these causal factors are important since prompt diagnosis and treatment of infiltrative cardiomyopathies can be critical to improving their clinical course.

TABLE 15.19 Echocardiographic Findings in Amyloidosis Compared to Suspected but Biopsy-Negative Subjects

Echocardiography Findings	*Amyloidosis (n = 47)*	*Nonamyloid Subjects (n = 115)*
LV diastolic diameter (average)	4.2 cm	5.2 cm
LV systolic diameter (average)	3.1 cm	3.7 cm
LV EF (average)	44%	42%
Anteroseptal wall thickness (average)	1.6 cm	1.2 cm
Inferolateral wall thickness (average)	1.6 cm	1.2 cm
Restrictive diastolic filling	30 % of group	11% of group
Sparkling appearance	26% of group	4 % of group

EF, Ejection fraction; *LV,* left ventricular.

Aortic Evaluation

Because of the intimate anatomic relationship of the aorta and the esophagus, TEE is useful in the diagnosis of aortic disease. The normal aorta consists of three layers: intima, media, and adventitia. The intima is a thin endothelial-lined structure that is easily damaged. The media is composed of smooth muscle and multiple layers of elastic laminae that provide tensile strength, distensibility, and elasticity.[378] The adventitia contains primarily collagen and the vasa vasorum. While the aorta may be divided into five main anatomic components (aortic root, tubular ascending aorta, arch, descending thoracic, and abdominal aorta), it is common to divide it into eight segments (Fig. 15.136). Segment I is the aortic root, which consists of the AV annulus, aortic cusps, and the sinuses of Valsalva. The ascending aorta is divided into two segments: IIa extends from the STJ to the level of the pulmonary arteries, and IIb extends to the origin of the brachiocephalic artery. Segment III is the aortic arch. The descending thoracic aorta is divided into two segments: the proximal descending thoracic aorta to the level of the pulmonary arteries is designated as segment IVa, and the more distal portion is designated as IVb. The proximal abdominal aorta to the renal arteries is segment Va and the distal abdominal aorta is Vb (see Chapter 23).

The normal aortic diameters vary according to location and gender and are summarized in Table 15.22. It should be noted that these values are strongly related to BSA and age.[379] Of the aortic segments, aortic root measurements are most plentiful in the literature and are presented in Table 15.23. In addition to their dependence on size and age, aortic root dimensions may also be increased by the hemodynamic

TABLE 15.20 Infiltrative Cardiomyopathies That Mimic Hypertrophic Cardiomyopathy

Diagnosis	*Age at Presentation*	*Clinical Presentation*	*Echocardiography Findings*	*Electrocardiogram Findings*
Amyloid	>30 years	Heart failure, nephrotic syndrome, hepatomegaly	Symmetric biventricular thickening, biatrial enlargement, speckled appearance of myocardium	Decreased QRS voltage
Hypertension	Adult population	Hypertension	Symmetric LV thickening, normal LV EF	Increased QRS voltage
Fabry disease	Male: 11 years Female: 23 years	Neuropathic pain, impaired sweating	Symmetric biventricular thickening, normal LV EF	Normal to increased QRS voltage
Friedreich ataxia	2–50 years	Gait abnormality	Increased LV wall thickness, preserved LV EF	Normal QRS voltage, ventricular tachycardia
Cardiac oxalosis	>20 years	Juvenile urolithiasis, nephrocalcinosis	Speckled appearance, symmetric biventricular thickening, normal LV EF	Normal to increased QRS voltage, complete heart block
Mucopolysaccharidoses	1–24 years	Developmental delay, course facial features, skeletal deformities	Asymmetric septal hypertrophy, normal LV EF	Variable QRS voltage, malignant arrhythmias
Danon disease	<20 years	Mental retardation, skeletal myopathy	Very thick LV (20–60 mm) Variable RV hypertrophy	Normal to increased QRS voltage, delta wave

EF, Ejection fraction; *LV,* left ventricle.

effects of training in competitive athletes.[380] This increase in aortic root diameters is relatively small, so marked enlargement should be considered a sign of a pathologic process. The aortic annulus, sinus of Valsalva, and the STJ diameters should be accurately measured (Fig. 15.137). Aortic annular diameters should be performed using the inner diameter along the hinge points of the aortic leaflet during systole.[379] Although the annulus is usually circular, it may become elliptical in older adults; 3D echocardiographic imaging in multiple planes is necessary if accurate measurements are required. Measurements should ensure the maximal aortic diameter in a plane parallel to the long axis of the aorta.[381] In patients with a trileaflet valve, the closure line should be in the center of the aorta and the closed leaflets should be visualized on the aortic side of a line connecting the AV hinge points (Fig. 15.138). If the point of closure is not central, the image is most likely oblique. While some practitioners favor measurements of internal diameters of the remaining aortic segments, both the 2010 European Association of Echocardiography and the 2015 guidelines from the American Society of Echocardiography suggest leading edge to leading edge measurements during end-diastole.[378,379,381] These leading edge to leading edge measurements produce values comparable to the inner edge to inner edge measurements of CT and MRI, are reproducible, and link a large body of historic data.[378] Nonetheless, with recent improvements in echocardiographic imaging and quality, the differences between the

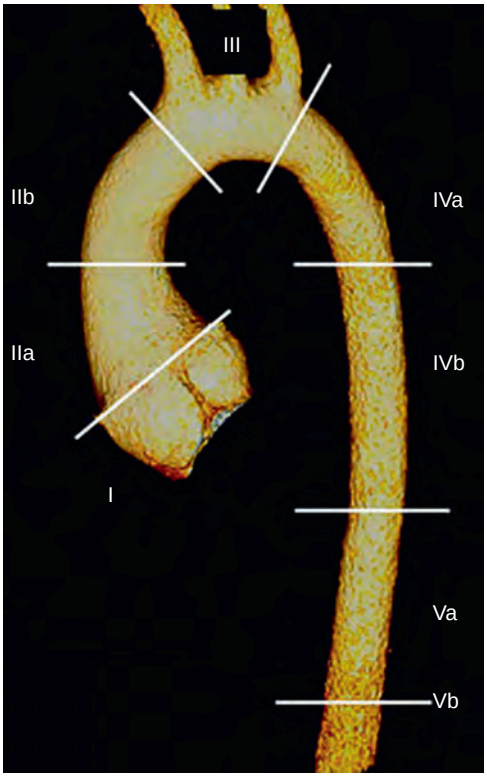

Fig. 15.136 Computed tomographic reconstruction of aorta illustrates the subdivision of aortic segments: segment I, aortic root; segment II, tubular ascending aorta (subdivided into IIa [sinotubular junction to the pulmonary artery (PA) level] and IIb [from the PA level to the brachiocephalic artery]); segment III, aortic arch; segment IV, descending thoracic aorta (subdivided into IVa [from the left subclavian artery to the level of the PA] and IVb [from the level of the PA to the diaphragm]); and segment V, abdominal aorta (subdivided into Va [upper abdominal aorta from the diaphragm to the renal arteries] and Vb [from the renal arteries to the iliac bifurcation]). *(Reproduced with permission from Goldstein SA, Evangelista A, Abbara S, et al. Multimodality imaging of diseases of the thoracic aorta in adults: from the American Society of Echocardiography and the European Association of Cardiovascular Imaging.* J Am Soc Echocardiogr. *2015;28[2]:119–182.)*

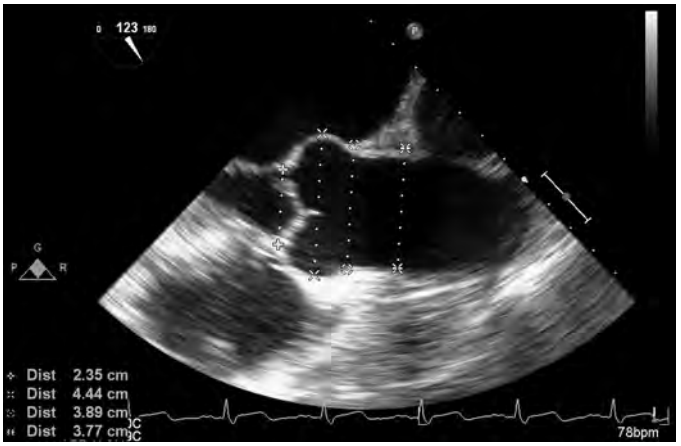

Fig. 15.137 Ascending aortic diameters. The measurements of the aortic annulus, sinus of Valsalva, sinotubular junction (STJ) and ascending aorta diameters are demonstrated. The aortic annular diameter is measured across the inner diameter at the aortic leaflet hinge points. The STJ, sinus of Valsalva, and ascending aorta are measured near edge to near edge.

TABLE 15.22 Normal Aortic Diameters

Location	*Reported Mean Diameters (cm)*
Root (female)	3.50–3.72 ± 0.38
Root (male)	3.63–3.91 ± 0.38
Ascending (male and female)	2.86 (SD not reported)
Middescending (female)	2.45–2.64 ± 0.31
Middescending (male)	2.39–2.98 ± 0.31
Diaphragmatic (female)	2.40–2.44 ± 0.32

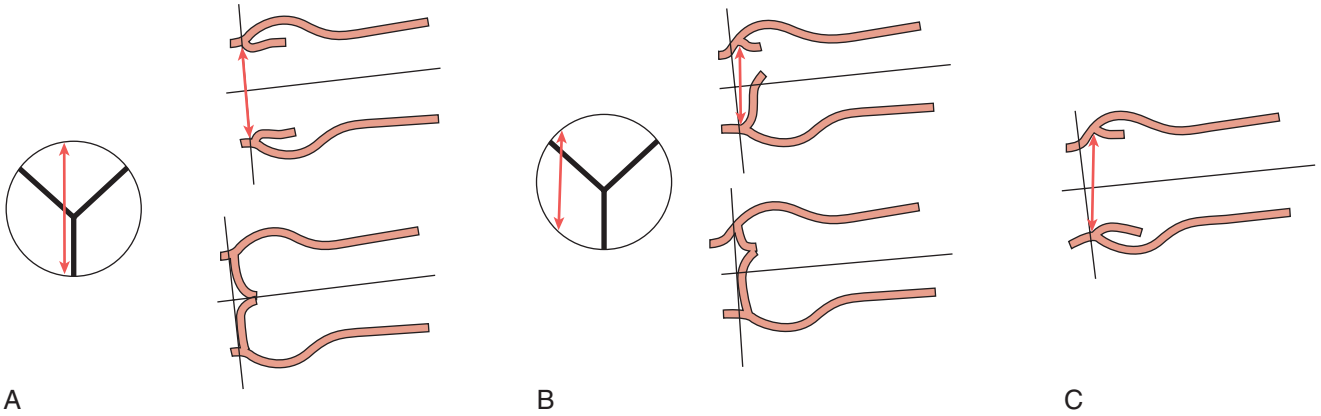

Fig. 15.138 Correct and incorrect measurements of the aortic annulus *(double arrows).* (A) Correct measurement. Centrally positioned diameter and central closure of leaflets. Thin lines correspond to the long axis of the ascending aorta and, orthogonally, to correct orientation of the annular diameter. (B) Incorrect, eccentric annular measurement. The hinge points are slightly displaced upward and do not correspond to the nadir of the cusp attachments, with incomplete opening and closing of leaflets. (C) Incorrect, oblique annular measurement. The annulus is "virtual" and only defined by the hinge points of the three aortic valve leaflets. As such, much of the ring is without a visible anatomic structure. However, its location on any long-axis two-dimensional view can be approximated since the plane of the virtual annulus is approximately perpendicular to the long-axis of the aorta. When bisecting the maximum dimension of the annulus in the sagittal plane, the echocardiographer will image the right coronary cusp (RCC) anteriorly and the fibrous trigone between the left and noncoronary cusps posteriorly. Because only one anatomic marker (the RCC hinge point) is seen, the opposing annulus must be approximated with a measurement that is perpendicular to the long axis of the aorta. Attempting to measure what is believed to be two hinge points typically will measure within the sinuses of Valsalva and overestimate the annulus. *(Reproduced from Lang RM, Badano LP, Mor-Avi V, et al. Recommendations for cardiac chamber quantification by echocardiography in adults: an update from the American Society of Echocardiography and the European Association of Cardiovascular Imaging.* J Am Soc Echocardiogr. *2015;28:1–39.e14.)*

leading edge to leading edge versus internal diameter measurements are becoming minimal.[379] The use of end-diastolic values increase the reproducibility of measurements (since aortic pressure is most stable during this period). All measurements should be performed to the long axis of the aorta. Ideally, measurements should reference other structures such as the STJ or the PA.[378] Sinus of Valsalva diameters should be measured from the anterior right coronary sinus to one of the posterior sinuses (usually the noncoronary). The largest diameter should be sought that is parallel to the aortic annulus and perpendicular to the aortic long axis.

Aortic disease may be classified as aneurysmal, atherosclerotic, dissection, or traumatic. Multiple elements must be included when imaging the aorta (Box 15.9).[382] The location of the aortic abnormality must be accurately identified. In the case of aortic dilation or aneurysmal disease, the maximum diameters should be reported. The array angle should be carefully controlled to ensure that a true short-axis image is obtained; an oblique cut will give a falsely greater diameter. If an acute aortic syndrome is suspected, the extent and character of the dissection should be defined, and the severity and mechanism of AI should be described; there should be a high index of suspicion for evidence of aortic rupture, such as pseudoaneurysm, hemopericardium, or hemothorax.

BOX 15.9 ESSENTIAL ELEMENTS OF ULTRASONOGRAPHIC AORTA IMAGING

- The location of the aortic abnormality
- The maximum diameter of any dilation measured from the internal diameter perpendicular to the direction of flow
- For patients at risk of aortic root disease, measurements of the aortic annulus, sinuses of Valsalva, sinotubular junction, and ascending aorta should be attempted
- Evidence of thrombus or atheroma
- The presence of intramural hematoma, penetrating aortic ulcer, and calcification
- Extension of aortic abnormalities into branch vessels
- Evidence of aortic rupture such as pseudoaneurysm, hemopericardium, or hemothorax

Adapted from Lang RM, Badano LP, Mor-Avi V, et al. Recommendations for cardiac chamber quantification by echocardiography in adults: an update from the American Society of Echocardiography and the European Association of Cardiovascular Imaging. *J Am Soc Echocardiogr.* 2015;28:1–39.e14.

Aortic Aneurysms

An aneurysm, or true aneurysm, is a localized dilation of at least 50% encompassing all three layers (intima, media, and adventitia) of a given artery. Other accepted terms include *ectasia,* which is arterial dilation less than 50% of the normal artery, and *arteriomegaly,* which is a diffuse arterial dilation of greater than 50% of multiple segments.[382] It is acceptable to use the nonspecific term *aortic dilation* to describe both ectasia and aneurysmal disease. In the ascending aorta, 5 cm is usually considered the threshold for aortic aneurysmal disease, even though it is less than the classical threshold aneurysm definition. In contrast, a pseudoaneurysm or false aneurysm, results in the disruption of the arterial wall with extravasation of blood contained by the periarterial connective tissue; this pseudoaneurysm wall does not contain the normal three arterial layers.

As opposed to other modalities, TEE is considered a third-line recommendation for the evaluation of thoracic aortic aneurysmal disease.[378] While it is an excellent modality for the evaluation of AI mechanisms and the aortic root, proximal ascending aorta, arch, and descending aorta, it has many disadvantages compared with CT and MRI; the distal ascending aorta and arch vessels are poorly visualized,

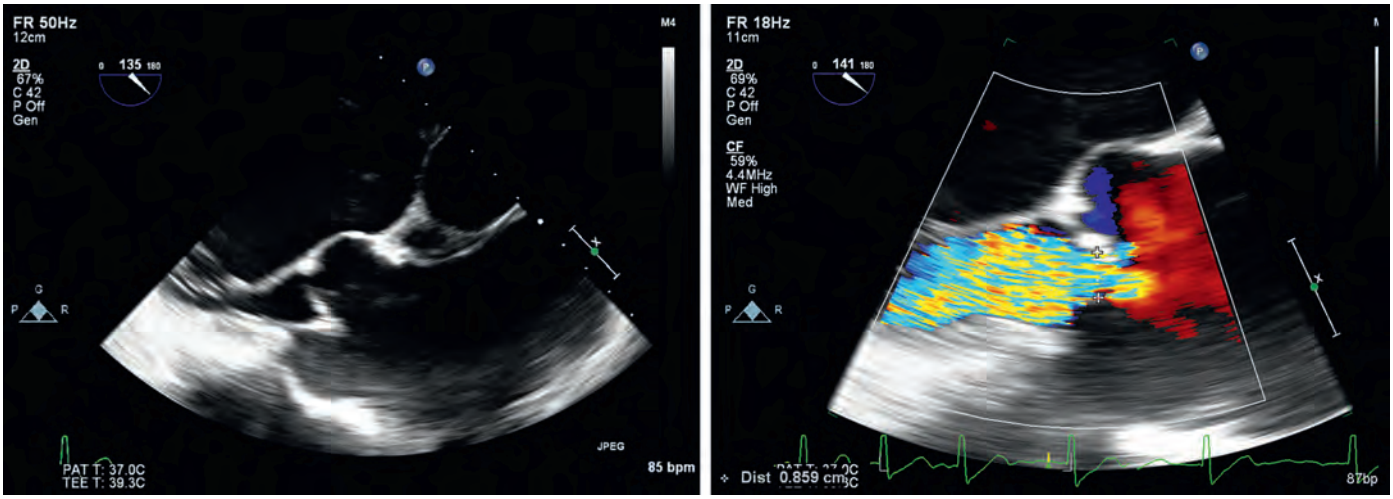

Fig. 15.139 Functional aortic regurgitation (AR) secondary to an ascending aortic aneurysm. Midesophageal aortic valve (AV) long-axis view *(left)*. The sinus of Valsalva is very enlarged with respect to the AV annulus. This enlargement results in tethering of the AV. The coaptation plane of the aortic leaflets is significantly distal to the plane of the aortic annulus *(right)*. Addition of color-flow Doppler demonstrates severe AR.

TABLE 15.24 Quantification of Aortic Atherosclerotic Disease

Grade	*Severity*	*Description Katz et al*[386]	*ASE 2015 Guidelines*[381]
I	Normal	Normal to mild intimal thickening (1–3 mm)	Intimal thickness <2 mm
II	Mild	Severe intimal thickening (3–5 mm) without protruding atheroma	Mild intimal thickness 2–3 mm
III	Moderate	Atheroma protruding <5 mm into lumen	Atheroma 3–5 mm
IV	Severe	Atheroma protruding ≥5 mm into lumen	Atheroma >5 mm
V	Complex	Any thickness with mobile component or components	Grade 2, 3, or 4 plus mobile or ulcerated components

and landmarks are limited for serial examinations. If the aorta is tortuous, measurements of diameters may be difficult.

AR may occur as a result of aortic dilation; therefore, if present, the mechanism of AR/AI should be carefully elucidated. A common mechanism for functional AR is tethering of the AV cusps as a result of a mismatch between AV annular and the STJ diameters (Fig. 15.139 and Video 15.2).[383] This tethering results in a retraction of the AV cusps, insufficient leaflet coaptation, and hence regurgitation. The echocardiographic determinants of functional AR with an anatomically normal AV include a coaptation leaflet height (ie, maximum distance between point of cusp coaptation and the annular plane) greater than 8 to 10 mm and a STJ-to-annulus ratio greater than 1.6. With repair of the aortic aneurysm, there may be restoration of aortic root geometry with improved leaflet coaptation and decreases in the severity of AR.

Aortic Atherosclerosis

Neurologic injury after cardiopulmonary bypass remains a devastating complication of cardiac surgery. Possible causes include hypoperfusion and cerebral embolization of gaseous or particulate matter, primarily from atherosclerotic disease. The thoracic aorta is a potential source of such emboli, since it often contains atherosclerotic plaques and may be instrumented multiple times during cardiac operations. Atherosclerosis is normally characterized by the presence of intimal lesions called *atheroma.* These lesions may protrude into the vessel lumen, be calcific, and compromise the integrity of the vessel wall. Abdominal aortic atherosclerosis is more common than descending aortic atherosclerosis, which is more common than ascending aortic atherosclerosis. These atherosclerotic lesions are dynamic, with both progression and regression over time.[384] In addition to defining anatomic locations, TEE may provide information on plaque mobility, ulceration, and composition with excellent interobserver and intraobserver reliability.[385] Grading systems for the severity of atherosclerotic disease rely on the greatest intimal or atheromata thickness, complexity, and presence of an ulcerated or mobile component. Katz and coworkers[386] described a classification system, which was updated by the American Society of Echocardiography in 2015. Both are summarized in Table 15.24 and illustrated in Fig. 15.140. A normal aorta consists of less than 2 mm of intimal thickness and is graded as 1. Increasing degrees of intimal thickening and atheroma are graded from 2 to 4 (ie, mild, moderate, severe) depending on the greatest thickness of the atheroma. If there is a mobile or ulcerated component, it is classified as a grade 5 lesion. The severity of atherosclerotic disease and the presence of a mobile component are highly associated with adverse neurologic outcomes after cardiac surgery.[387] This semiquantitative measurement of plaque thickness was found to be relatively objective and reproducible.

While TEE is a sensitive modality for the proximal ascending aorta, distal arch, and descending aorta, the distal ascending and proximal aorta arch are not consistently well visualized.[388] Nonetheless, TEE can serve as a screen to detect aortic atherosclerotic debris.[389] The presence of atherosclerotic disease in the visualized portions increases the likelihood of finding atherosclerotic changes in the nonvisualized portion of the aorta. The sensitivity of TEE for the detection of distal ascending atherosclerosis may be substantially increased by the introduction of a saline-filled balloon into the trachea and left main bronchus (A-View; Cordatec Inc, Zoersel, Belgium).[390] This technique allows for a significant improvement in the ability to image the distal ascending and

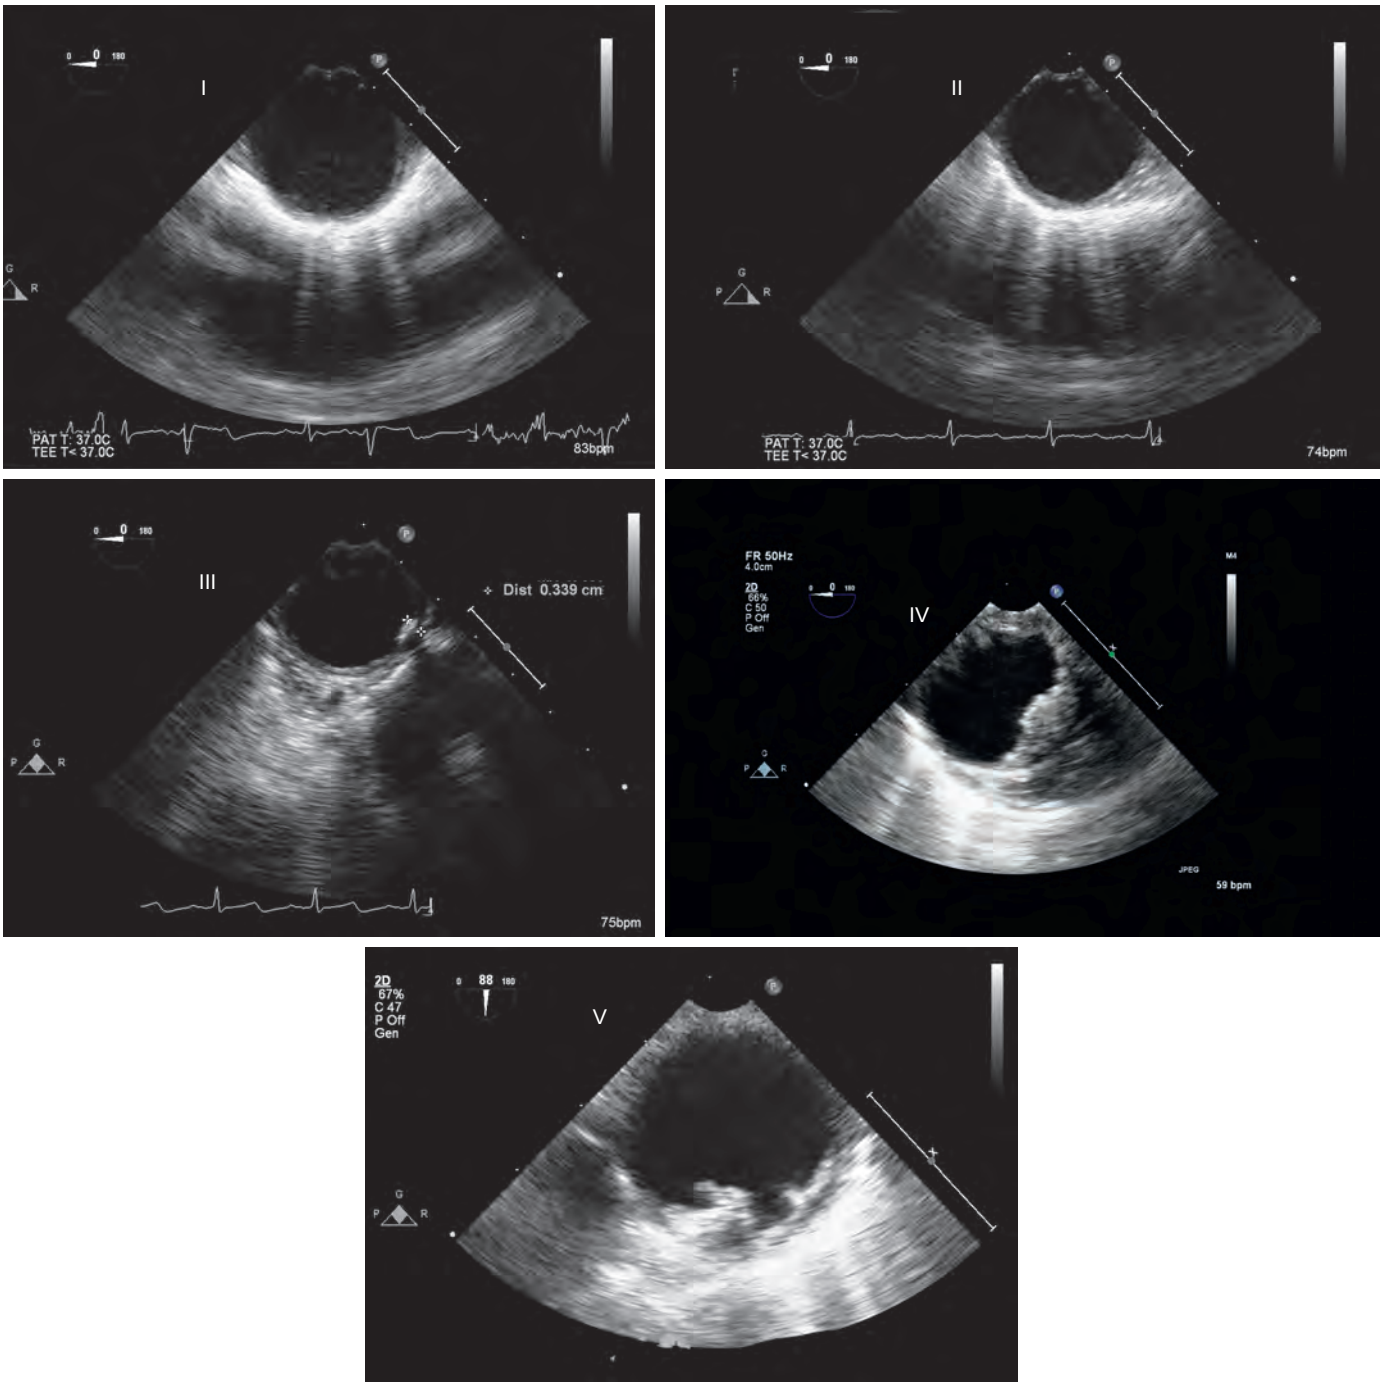

Fig. 15.140 The grading of atherosclerotic disease. I. Normal to mild intimal thickening. II. Mild severity: severe intimal thickening. III. Moderate severity: atheroma protruding less than 5 mm. IV. Severe severity: atheroma greater than 5 mm. V. Complex: large atheroma with a mobile component.

proximal aortic arch. In another study, the right innominate artery was visible in all patients with this saline-filled balloon compared with 5% by TEE without this balloon.[391] This technique is not without complications. Because it requires manipulation of the balloon within the endotracheal tube, there may be minor tracheal mucosal injury. In one case, the endotracheal tube was dislodged with substantial hypoxemia.[391]

Intraoperatively, it is more common to use epiaortic ultrasonography to image potential aortotomy and cross-clamp sites. Compared with TEE, epiaortic scanning provides improved resolution, fewer artifacts, no blind spots, and superior localization of atherosclerotic disease within the middle and distal ascending aorta.[392] Epiaortic scanning is more sensitive than digital palpation in the detection of atherosclerotic disease, and its use has modified surgical management during the conduct of cardiac surgery.[393] While epiaortic scanning may be justified for all patients undergoing cardiac surgical procedures, its use should be seriously considered in those patients with increased risk for embolic stroke (including a history of cerebrovascular or peripheral vascular disease) and evidence of aortic disease by any modality.[394] In a study of 100 patients, 90% of patients had aortic atheroma detected by epiaortic ultrasonography, but only 16% had detectable atheroma by manual palpation.[395] While epiaortic ultrasonography identified 38

separate segments of severe atheroma, manual palpation and TEE were only able to identify severe disease in two and three segments, respectively. In a small study of 105 patients undergoing coronary artery bypass graft surgery, epiaortic ultrasonography changed the conduct of the surgical procedure in 28% of patients,[396] while in a larger study of more than 6000 patients, it changed surgical decisions in 4.1% of cases.[397] These changes included decisions concerning the induction of cardiac arrest, need for atherectomy, requirements for off-pump procedures, and details of aortic cross-clamping and cannulation.

Epiaortic ultrasonography may be performed by placing a sterilely wrapped probe directly on the aorta. Once the disease is defined, it can often be avoided during instrumentation, and hopefully neurologic injury can be prevented. High resolution (ie, greater than 7 MHz) should be used to optimize resolution. Either phase or linear array probes may be used to image the ascending aorta. Phase array probes produce a fan-shaped sector. Because of this fan-shaped sector displayed, the most anterior aspect of the aorta cannot be adequately visualized unless a standoff is used between the transducer and the aorta. This may be accomplished with a dedicated standoff device, but it is usually most convenient to fill the pericardial cradle with saline and hold the probe approximately 1 cm anterior to the aorta while scanning. The entire width of the aorta can usually be seen in the sector. Alternatively, linear array probes may be used. The linear array probes increase the ability to image the near field (ie, the area of the aorta next to the probe itself), while decreasing the need for the standoff required for the phase array probes. Their major disadvantage is the decreased lateral visualization of the aorta; the probe needs to be moved from side to side to visualize the entire area of interest.

A complete epiaortic examination should include short-axis views of the proximal, middle, and distal ascending aorta and long-axis views of both the ascending aorta and arch.[394] These views will allow for evaluation of the 12 areas of the aorta: anterior, posterior, left and right lateral walls of the proximal, middle, and distal ascending aorta. The proximal ascending aorta is defined as the region from the STJ to the proximal intersection of the right PA. The midascending aorta includes that portion of the aorta that is adjacent to the right PA. The distal ascending aorta extends from the distal intersection of the right PA to the origin of the innominate artery.

The epiaortic probe is placed initially on the proximal aspect of the ascending aorta close to the AV.[394] The probe should be manipulated to ensure that the aorta is centered in the field and rotated to ensure a true short-axis view; the anteroposterior and the medial-lateral dimensions should be similar. The probe is advanced cephalad to visualize the middle and distal ascending aorta. During this transit, the probe may need to be rotated clockwise to ensure a true short-axis orientation. After obtaining these short-axis views, the probe is positioned proximally and rotated to obtain a long-axis view of the ascending aorta. The probe is once again advanced cephalad to the aortic arch. The arch as well as the origins of the innominate, left carotid, and left subclavian arteries should be obtained. During the examination, the following should be noted for each segment of the ascending aorta and the arch: (1) the maximal plaque thickness, (2) the location of the maximum plaque within the ascending aorta, and (3) the presence of mobile plaque. The severity of the atherosclerosis should be classified as described in Table 15.24. All information should be communicated with the surgical team.

Aortic Dissection

In the diagnosis of aortic dissection, TEE has overcome some of the major disadvantages of the alternative diagnostic modalities (CT, MRI). The diagnosis of dissection is based on the presence of an intimal flap. In comparison to these other modalities, TEE has been shown to have high sensitivity and specificity.[398,399] According to the 2010 guidelines for the diagnosis and management of aortic disease, TEE, CT, and MRI are recommended as definitive methods for the identification or exclusion of thoracic aortic dissection.[382] Others have recommended that TEE is the modality of choice in the diagnosis of aortic disseccton.[379] The sensitivity for the detection of proximal aortic dissection is 88% to 98% with a specificity of 90% to 95%.[400] With further improvement in technology, the sensitivity of TEE in detecting aortic dissections approaches 100%.[378] As opposed to CT or MRI, it is portable and does not require ionizing radiation or intravenous contrast. An examination can be performed within about 15 to 20 minutes and a diagnosis can usually be obtained at the same time.

TEE should be performed on all patients in the operating room presenting for type A dissections. The diagnostic goals of echocardiography in the evaluation of aortic dissections are summarized in Table 15.25. The hallmark of an aortic dissection is an intimal flap (Fig. 15.141, Video 15.3). Several angles and echocardiographic windows should be used to confirm the flap. Typically, the dissection flap will have an independent motion compared with the surrounding structures, and the intimal flaps should be contained within the aortic lumen. CFD should be used to identify two separate flow patterns within each lumen; flow should not appear to pass easily through the dissection flap. The true and false aortic lumens should be identified (Fig. 15.142, Video 15.4). The false lumen is typically larger, and it expands during diastole. Flow in the false lumen may be absent, delayed, or reversed while the true lumen usually has laminar flow. This slower flow may be seen as spontaneous echo contrast or thrombus. Flow in both true and false lumens may be analyzed with CFD imaging.

The intimal tear appears as a break or discontinuity of the intimal flap (Fig. 15.143, Video 15.5). Ideally the specific locations of the entry and exit sites are also identifiable. During systole, there is flow through

TABLE 15.25 The Role of Echocardiography in the Evaluation of Aortic Dissections

Diagnostic Goals	*Definition by Echocardiography*
Identification of intimal flap	Flap dividing two lumens
Definition of extent of aortic dissection	Extension of the flap and true/false lumens in the aortic root (ascending/arch/descending abdominal aorta)
Identification of true lumen	Systolic expansion, diastolic collapse, systolic jet directed away from the lumen, absence of spontaneous contrast, forward systolic flow
Identification of false lumen	Diastolic diameter increase, spontaneous contrast and or thrombus formation, reverse/delayed or absent flow
Identification of false luminal thrombosis	Mass separated from the intimal flap and aortic wall inside the false lumen
Localize entry and exit tears	Disruption of the flap continuity with fluttering or ruptured intimal borders; color Doppler shows flow through the tear
Assessment presence, severity, and mechanism of aortic insufficiency	Anatomic definition of the valve (bicuspid, degenerated, normal with/without prolapse of one cusp); dilation of different segments of the aorta; flap invagination into the valve; severity by classic echocardiographic criteria
Assessment coronary artery involvement	Flap invaginated into the coronary ostium, flap obstructing the ostium, absence of coronary flow, new regional wall motion abnormalities
Assessment of side-branch involvement	Flap invaginated into the aortic branches
Detection of pericardial or pleural effusion	Echo-free space in the pericardium/pleura
Detection of signs of pericardial tamponade	Classic echocardiographic and Doppler signs of tamponade

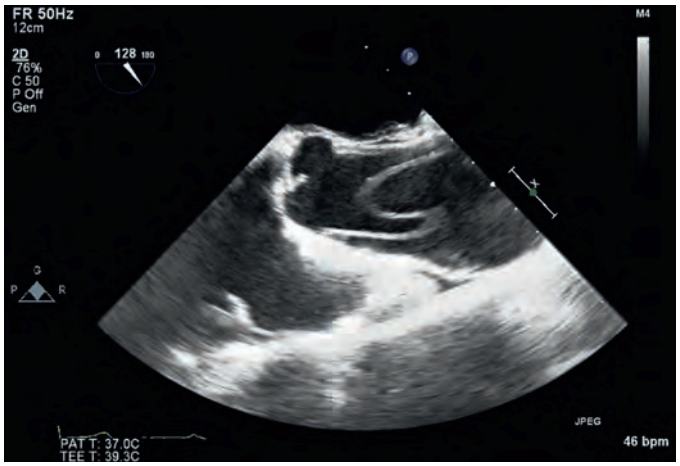

Fig. 15.141 Intimal flap. Midesophageal ascending aorta long-axis view. A large complex intimal flap is seen extending from the sinotubular junction distally through the ascending aorta.

the intimal tear from the true lumen into the false lumen. The identification of the site of the intimal tear may be made in 78% to 100% of cases by TEE.[401] It is important to differentiate the main intimal tear from smaller communications. The primary tear usually has a diameter of over 5 mm.[378] It is frequently located in the proximal part of the ascending aorta in type A dissections and immediately below the origin of the left subclavian artery in type B dissections. Multiple smaller secondary communications may be appreciated in the descending aorta that may correspond to the origin of intercostal or visceral arteries.

TEE is performed in real time allowing for its unique ability to give functional and hemodynamic information. This enables the detection of the common complications of aortic dissection: AR, pericardial and pleural effusions, and LV dysfunction secondary to coronary artery involvement in the dissection process. The mechanism of AR should be defined to assist in the planning of the surgical procedure. These mechanisms are graphically illustrated in Fig. 15.144. There are multiple distinct mechanisms of AR associated with aortic dissection.[402] The most common mechanism is aortic dilation by the false lumen with resultant leaflet tethering resulting in incomplete AV cusp coaptation and secondary or function regurgitation. If the dissection flap extends

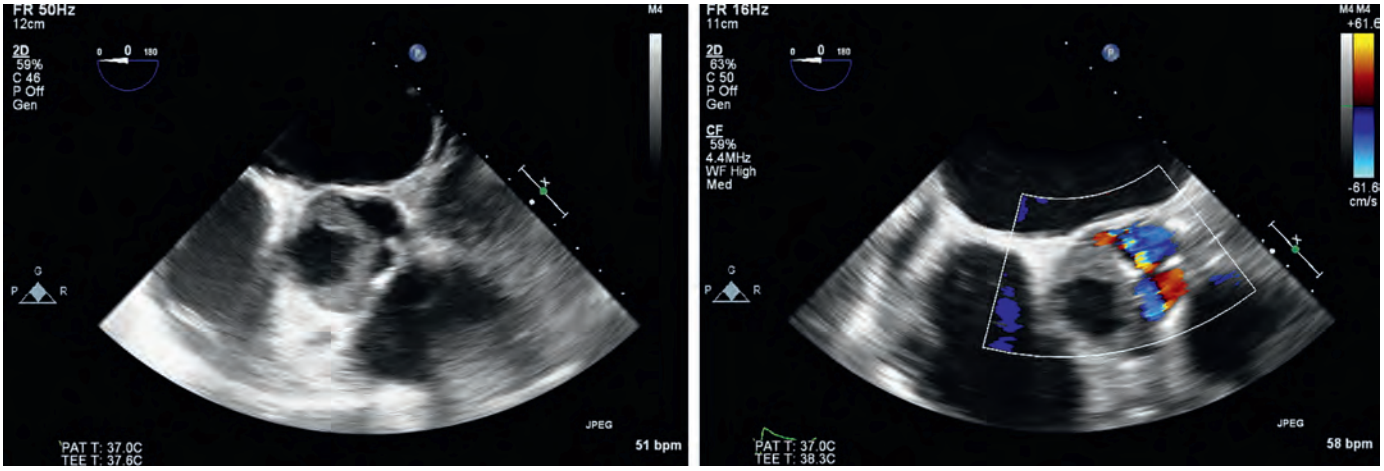

Fig. 15.142 Aortic dissection with demonstration of the true versus false lumen. *Left,* Type A aortic dissection. The larger false lumen is seen on the left of the screen containing thrombus. *Right,* Superimposition of color-flow Doppler demonstrating flow in the true lumen during systole.

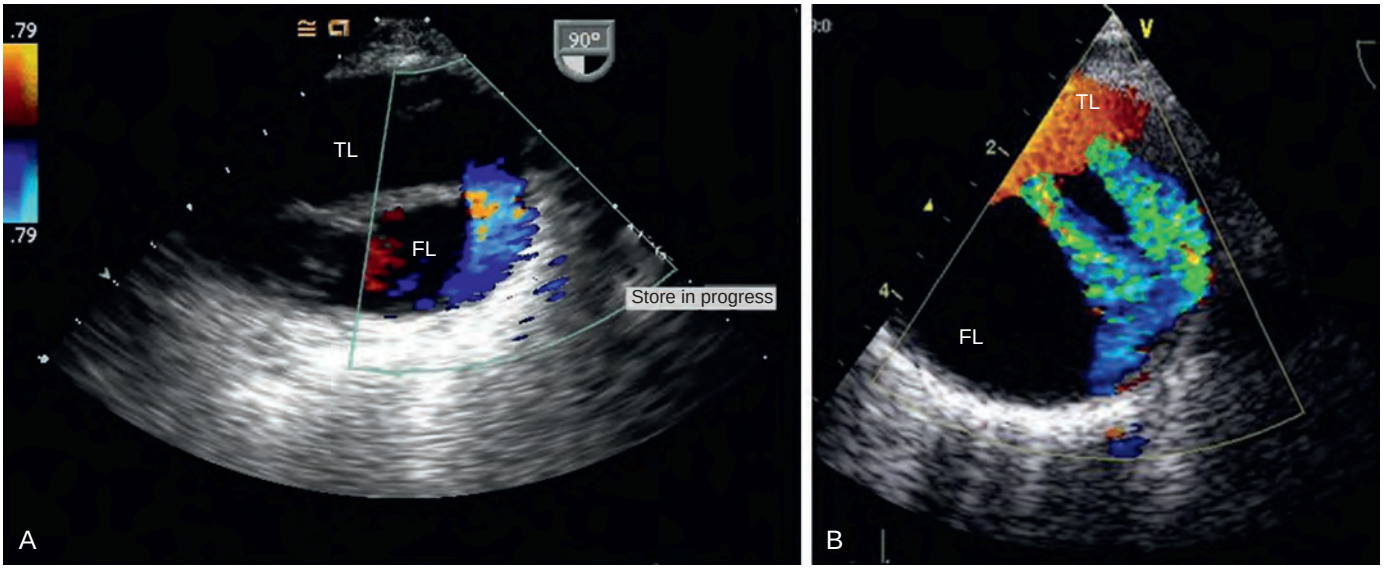

Fig. 15.143 Intimal tear. (A) Primary dissection flap. Descending aortic long-axis view immediately distal to the left subclavian artery. A large dissection flap is visualized with nonrestricted blood flow from the true lumen *(TL)* to the false lumen *(FL).* (B) Secondary communications. Several smaller communications from the TL to the FL are seen from the true to FL, which probably represent the origin of intercostal arteries. *(From Evangelista A, Flachskampf FA, Erbel R, et al. Echocardiography in aortic diseases: EAE recommendations for clinical practice.* Eur J Echocardiogr. *2010;11:645–658.)*

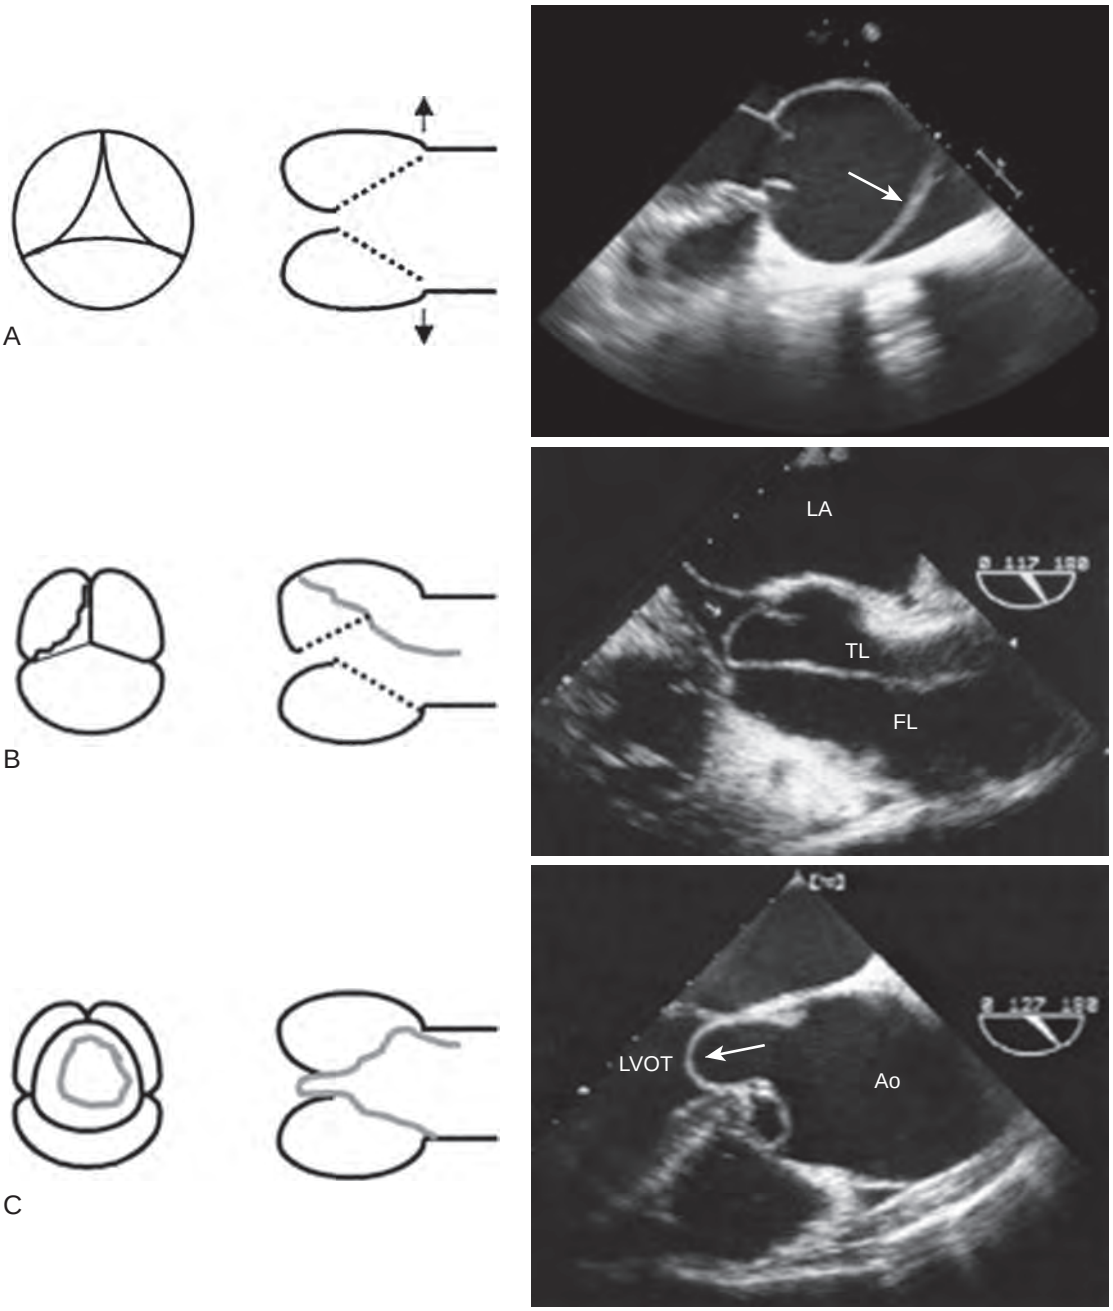

Fig. 15.144 Mechanisms of aortic insufficiency with aortic dissection. Mechanisms of aortic regurgitation (AR) in type A aortic dissection. The *dotted lines* represent the attachment of the leaflet tips to the sinotubular junction (STJ). Normally the leaflet tips coapt fully in diastole (short-axis view) and the diameter of the STJ is similar to that at the base of the annulus. (A) Incomplete leaflet closure when the STJ dilates *(arrows)* relative to the aortic annulus resulting in leaflet tethering and a persistent diastolic orifice. (B) Aortic leaflet prolapse that occurs when the dissection extends into the aortic root and disrupts normal leaflet attachments to the aortic wall, thereby resulting in abnormal leaflet coaptation and eccentric AR. This is usually best visualized in the long-axis view where one or more leaflets are seen prolapsing into the left ventricular outflow tract *(LVOT)* in diastole. (C) Dissection flap prolapse that occurs when a redundant dissection flap prolapses through intrinsically normal aortic leaflets resulting in AR that is often short-lived and may be intermittent. *Ao,* Aorta; *FL,* false lumen; *TL,* true lumen. *(Reproduced with permission from Goldstein SA, Evangelista A, Abbara S, et al. Multimodality imaging of diseases of the thoracic aorta in adults: from the American Society of Echocardiography and the European Association of Cardiovascular Imaging.* J Am Soc Echocardiogr. *2015;28:119–182; and Movsowitz HD, Levine RA, Hilgenberg AD, Isselbacher EM. Transesophageal echocardiographic description of the mechanisms of aortic regurgitation in acute type A aortic dissection: implications for aortic valve repair.* J Am Coll Cardiol. *2000;36:884–890.)*

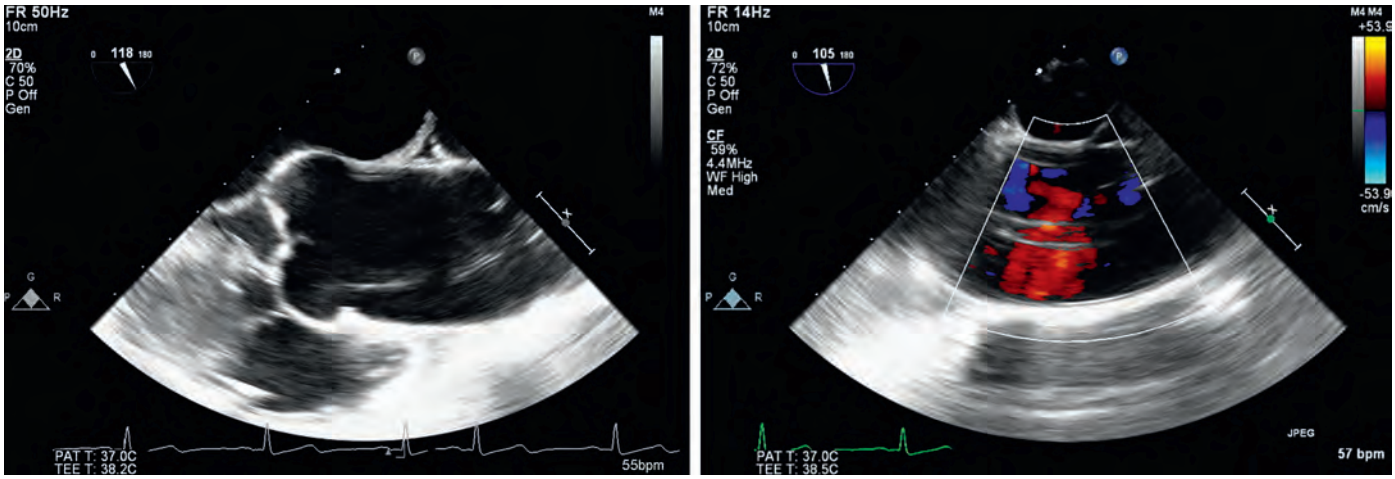

Fig. 15.145 Linear reverberation artifact. Midesophageal ascending aortic long-axis view. A linear reverberation artifact is seen in the ascending aorta. Color-flow Doppler does not demonstrate any effect of the artifact on blood flow patterns.

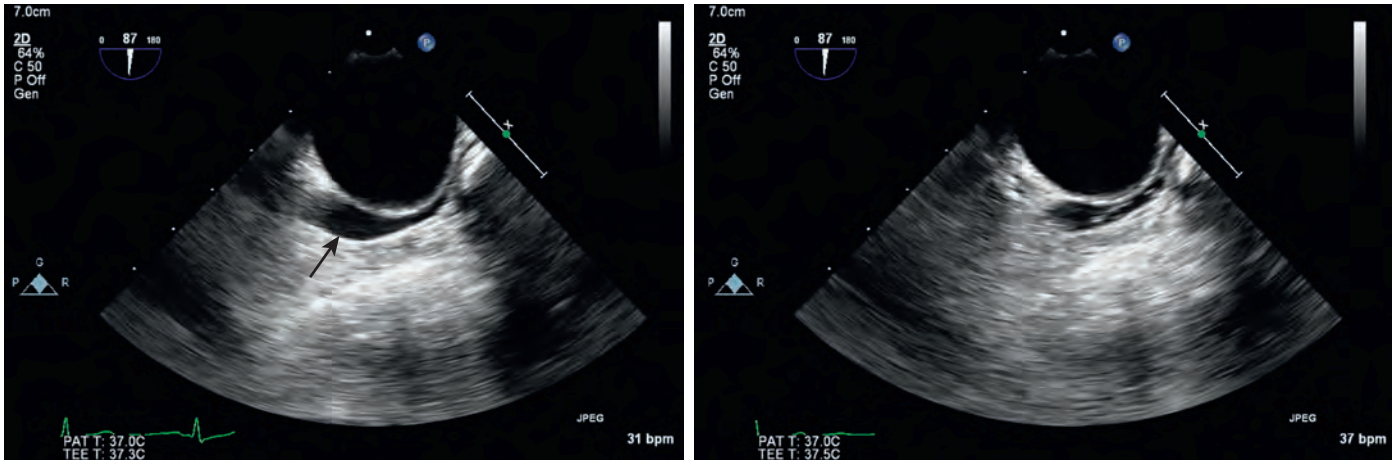

Fig. 15.146 Left innominate vein. Upper esophageal short-axis arch. The left innominate vein *(black arrow)* is visualized along the lesser curvature of the aortic arch. Injection of saline in a left-sided upper extremity vein demonstrates spontaneous echo contrast.

proximal to the STJ into the sinus of Valsalva, the AV commissure may become disrupted from the aortic wall. If the commissure is disrupted, the aortic leaflets are not suspended from the STJ and they prolapse with resultant AR. If there is a long complex proximal dissection flap, the flap itself may prolapse through the AV and interfere with normal AV function. Finally, patients may have preexisting structural AI not related to the dissection.

Pericardial effusions are commonly seen with acute aortic dissection.[382] The most common cause of pericardial effusion is the transudation of fluid across the thin wall false lumen into the pericardium. This transudate is usually mild and does not lead to a hemodynamically significant pericardial effusion. Alternatively, the aorta may rupture directly into the pericardium with resultant pericardial tamponade and hemodynamic collapse. The presence of a significant pericardial effusion carries a poor prognosis. Compromise of coronary blood flow may occur as a result of an expanding false lumen compressing the proximal coronary artery or by extension of the dissection flap into the coronary artery.[403] While challenging, CFD may detect the presence or absence of coronary artery flow. Alternatively, RWMAs may provide information concerning coronary blood flow. In addition to the common sequelae of aortic dissection, TEE can also identify a rare but potentially lethal complication of aortic intimal intussusception.[404] Although TEE may provide information concerning visceral malperfusion, CT is the better diagnostic modality to define this complication.

The major limitation of TEE is the appearance of reverberation or mirroring artifacts that may appear as an intimal flap (Fig. 15.145, Video 15.6). In the ascending aorta, linear reverberation artifacts may be seen in 44% to 55% of TEE studies.[405] These artifacts may mimic the dissection flap, making diagnosis difficult. They are most common in patients with a dilated ascending aorta. In the proximal ascending aorta, these reverberation artifacts may originate from the anterior wall of the left atrium; in the middle aspect of the ascending aorta, they may originate from the posterior wall of the right PA. Intraluminal reverberations in the aortic root are located twice as far from the transducer to the posterior aortic wall; reverberation in the ascending aorta are located twice the distance from the posterior wall of the right PA to the posterior wall of the aorta.[405] The other major limitations of TEE include the potential lack of availability and the operator dependency on accurate diagnosis. Because the left innominate vein runs parallel to the aortic arch, this vein may be mistaken for an arch dissection (Fig. 15.146, Video 15.7). Significant sedation may be necessary; inadequate sedation may result in significant sympathetic

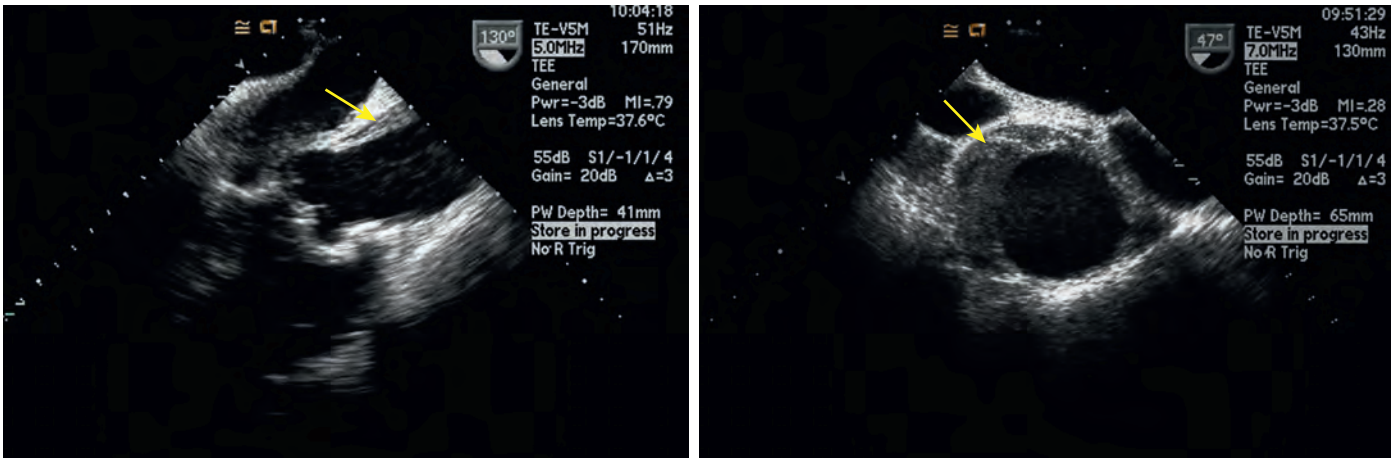

Fig. 15.147 Intramural hematoma (IMH). Midesophageal ascending aorta long-axis *(left)* and short-axis *(right)* views. An IMH *(arrow)* is seen in the posterior and rightward portion of the ascending aorta from the aortic root extending distally. As opposed to atherosclerotic changes, it is crescent shaped with a smooth intimal surface.

outflow. Although isolated cases of aortic rupture have been reported during TEE, the incidence is very low and mostly likely related to the intrinsic disease progression as opposed to the diagnostic modality.[380] The distal ascending aorta and proximal aortic arch may not be adequately visualized because of the interposition of the trachea or left main bronchus between the esophagus and trachea. As opposed to CT or MRI, TEE does not produce consistent visualization of the abdominal branch vessels.

Intramural Hematoma and Penetrating Ulcers

Intramural hematoma (IMH) may be a very challenging echocardiographic diagnosis (Fig. 15.147, Video 15.8). As opposed to classic aortic dissections, a distinct intimal flap is usually not appreciated. These IMHs appear as long echodense crescent-shaped or concentric structures extending along a length of the aortic wall, and in contrast to classical dissections, these IMHs are more localized. Since they appear as areas of aortic thickening, it is sometimes difficult to distinguish IMH from diffuse aortic atherosclerosis or a long aortic mural thrombus. Typically, IMHs greater than 5 mm in thickening of the aortic wall; IMH thickness greater than 10, 12, or 15 mm (depending upon study); and maximal aortic diameter greater than 40 to 50 mm predict risk for progression.[378] The aortic surface of an IMH tends to be smooth, while the internal surface of an aortic atherosclerotic plaque is more irregular. Although there is usually no Doppler evidence of communication between the hematoma and true lumen, some CFD activity may be appreciated in the lumen. In contrast to an IMH, a mural thrombus may have an irregular surface, narrows the aortic lumen, and does not extend as far.

A penetrating atherosclerotic aortic ulcer is characterized as an ulceration of an atherosclerotic lesion that penetrates the internal elastic lamina into the media (Fig. 15.148, Video 15.9).[406,407] Penetrating ulcers appear as crater-like outpouchings of the aortic wall with extensive aortic atherosclerosis. Although the luminal surface of the aorta may appear smooth in some patients, generally there are protruding fibrotic or calcific plaques representing complex atherosclerotic disease. These lesions are associated with a variable degree of IMH formation, either limited or extensive aortic dissection, aneurysmal dilation, pseudoaneurysm, or aortic rupture. The limited aortic dissection secondary to these ulcers are characterized by (1) a markedly thickened dissection flap (0.8 to 1.1 cm), which is calcified, irregular, nonoscillating, or of low motility; (2) a limited longitudinal extension (less than 10 cm); and (3) a true lumen similar to or larger than the false lumen.[407]

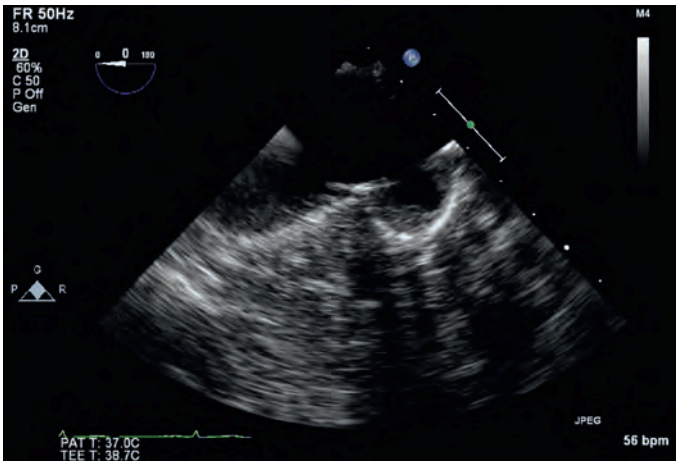

Fig. 15.148 Penetrating aortic ulcer. A penetrating aortic ulcer is seen on the inferior aspect of the aortic arch. It is characterized by an outpouching of the aortic wall, which is filled with thrombus.

Transesophageal Echocardiography During Intraaortic Balloon Pump Placement

The intraaortic balloon pump (IABP) is a catheter-based balloon, which is placed in the descending thoracic aorta distal to the left subclavian artery. The helium-filled balloon inflates during diastole and deflates during systole to increase coronary and visceral blood flow and decrease systemic vascular resistance and ventricular preload. It is important that the distal tip of the catheter does not occlude the arch branch arteries with resultant upper extremity or cerebral ischemia. Ideally, the catheter should be positioned 1 to 2 cm distal to the left subclavian artery.[408] Placement of the IABP farther from the left subclavian artery increases the risk of occlusion of the aortic abdominal branches with resultant visceral ischemia. Whereas fluoroscopy is the standard modality for the position of the IABP, TEE is the more convenient modality during the perioperative period[409] (see Chapters 28 and 36).

Prior to placement of an IABP, contraindications to its placement should be ruled out. The severity of AI should be evaluated carefully. The descending thoracic aorta should be examined for severe atherosclerotic disease that may become dislodged with balloon placement. Furthermore, although reports of IABP placement in the presence of

aortic dissection exist,[410] the presence of an aortic dissection should be considered as a contraindication to balloon placement.

After cannulation of the femoral artery, a wire is advanced into the descending aorta. It may be identified as a thin echogenic structure. Whereas a short-axis descending aortic view accurately shows the presence or absence of the wire, a long-axis image more accurately demonstrates the location of the wire. Aggressive advancement of the wire into the arch branches or the ascending aorta should be avoided. Once the wire is accurately seen in the descending aorta, the IABP may be passed over the wire into the descending aorta (Fig. 15.149, Video 15.10). Since it is difficult to differentiate the balloon from the wire, the wire should be removed before confirmation of the final IABP placement. As discussed earlier, the distal tip of the balloon should be positioned 1 to 2 cm distal to the left subclavian artery. This distance can be measured by identifying the tip of the IABP using the long-axis descending aortic view and withdrawing the TEE probe until the transition to the upper esophageal aortic arch short-axis view with the left subclavian artery is visualized.[403] The distance may be judged based on the distance the TEE probe is withdrawn. Alternatively, the IABP tip may be positioned at the lesser curvature of the aortic arch.[411] In a descending thoracic aortic short-axis view, the IABP is visualized. As the TEE probe is withdrawn, the tip of the IABP should be visualized and then disappear as the aortic arch becomes visible on the patient's right side. In the descending aortic long-axis view, the position of the distal tip may be compared to the level of the lesser curvature by turning the probe to the patient's right side. After placement, the inflating and deflating balloon may be visualized. Because there is a 0.5% incidence of iatrogenic aortic dissection after IABP placement, the descending aorta and aortic arch should be reexamined.[412]

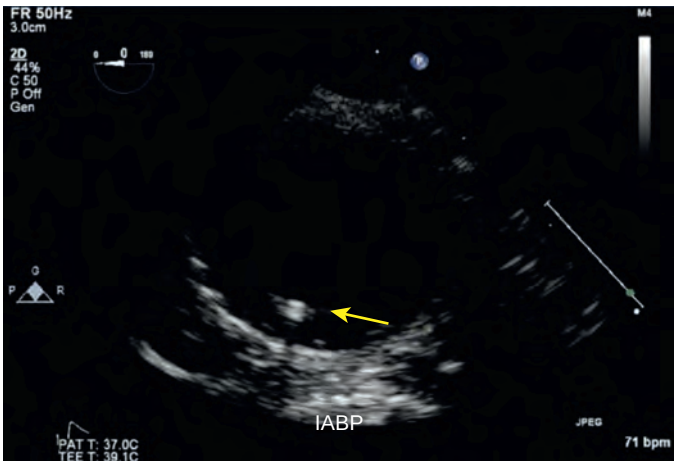

Fig. 15.149 Positioning of an intraaortic balloon pump *(IABP; arrow)*.

Perioperative Transesophageal Echocardiography During Endovascular Thoracic Aortic Stenting

TEE has distinct advantages over perioperative angiography during endovascular thoracic aortic repair.[413] (see Chapters 23 and 48). TEE may provide exact vessel and lesion sizing and localization, which is difficult to obtain during single plane angiography. With the esophagus in close proximity to the aorta, TEE is an excellent tool for diagnosing aortic disease. TEE can provide instantaneous views of the aorta, as well as location of guidewires and endografts prior to deployment in relation to the normal and diseased thoracic aorta. This is particularly important during repair of type B aortic dissections, during which it is critical to ensure that the wire and delivery device remain in the true lumen. The stent-graft delivery system may be distinguished from the guidewire by differences in thickness and echogenicity (Fig. 15.150, Video 15.11). Similarly the stent-graft may be distinguished from the stent-graft delivery system by its unique echogenic pattern and shadow that is cast by the metallic stent. By distinguishing the stent-graft from the delivery system, TEE can be used to ensure that the endograft bridges the diseased aortic segment. Although not imaged in all patients, large intercostal arteries have been imaged, thus avoiding inadvertent obstruction by the aortic stent-graft; however, consistent visualization of intercostal arteries may not be ensured in all patients. Although TEE can visualize the undeployed stent-graft in relation to the aortic disease, there is significant interference by the TEE probe during fluoroscopy; therefore, TEE can only be used between fluoroscopic examinations. After stent-graft placement, exclusion of flow from the aorta into the aneurysm usually can be confirmed with CFD imaging.

Endoleak is the continued pressurization of an aneurysmal sac after endovascular exclusion. This may be a result of a leak at the graft ends (type 1), sac filling via branch arteries (type 2), leak through the graft material secondary to mechanical failure (type 3), an intentionally porous graft (type 4), or endotension (type 5). An example of an endoleak between graft components is illustrated in Fig. 15.151 and Video 15.12. The reported sensitivity and specificity of TEE assessment of endoleak is 100%, which was identical to postoperative CT or angiography.[414] In a series of 25 patients undergoing descending aortic endovascular repair, 8 patients had endoleaks; all of these endoleaks were detected by perioperative TEE, but only 2 of them were detected by angiography.[415] These detected leaks were at the graft ends or between segments of the graft. TEE-diagnosed exclusion was predictive

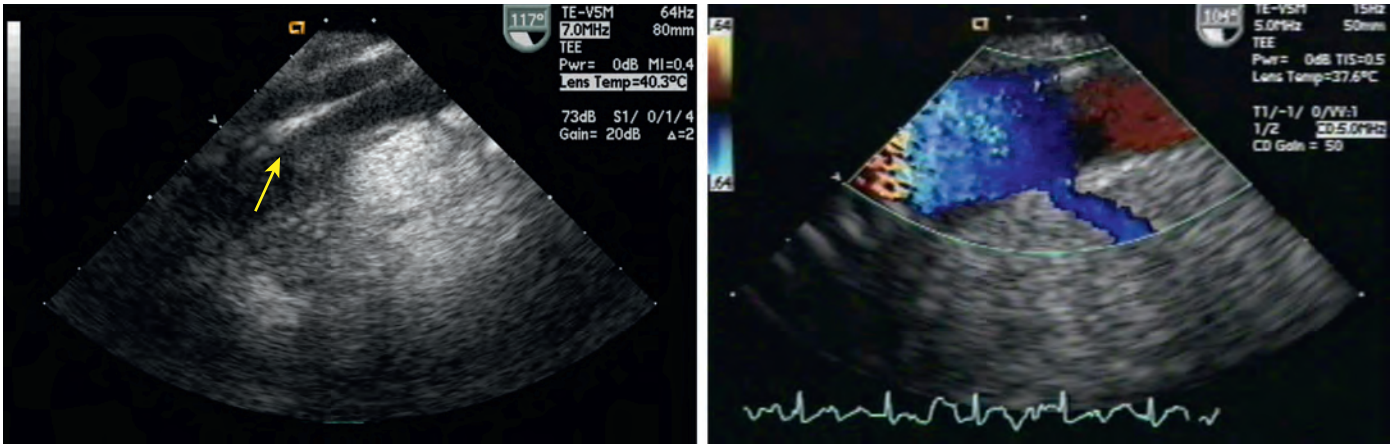

Fig. 15.150 Endovascular stent-graft delivery system. *Left,* An endovascular stent-graft *(arrow)* is seen being advanced into the descending thoracic aorta through a pseudoaneurysm. *Right,* After deployment, there is excellent flow exclusion of the pseudoaneurysm with a patent intercostal artery.

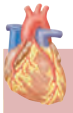
of mid-term aneurysm regression.[414] In a separate study of 9 patients with thoracic aortic aneurysms and 2 with chronic type B dissections, both aortography and TEE detected type 1 endoleak after deployment in 9 of the 11 patients.[416] The use of this technique may be useful for the evaluation of perigraft leakage and thrombus formation, in addition to decreasing the need for intravenous contrast administration.

Blunt Thoracic Aortic Injury

Blunt aortic injury (BAI) occurs as a result of rapid deceleration at an interface of fixed and mobile aortic segments, since they have the greatest exposure to the sheer and hydrostatic forces associated with the trauma.[417] Motor vehicle accidents account for 75% of cases of BAI; other causes include falls from heights, crush injuries, explosions, and direct blows to the chest. The most common location for this injury is the aortic isthmus just distal to the left subclavian artery, followed by the supravalvular portion of the ascending aorta. This injury is usually a damage of the aortic intima with extension to the adventitia. The 2015 guidelines describe a variety of aortic lesions that can result from BAI:[378]

1. Subadventitial aortic rupture involving the intima and media with incomplete circumferential extension. In this most frequent lesion encountered by imagers, there is a discrete tear involving the intima and underlying media. The disrupted aortic wall (intima and media) usually protrudes into the aortic lumen and, through the disrupted wall, the aortic lumen communicates with a cavity (saccular false aneurysm) whose wall is composed only of adventitia. The inner surface of the aorta shows an abrupt discontinuation, and the outer contour is deformed by the false aneurysm. The protrusion of the torn aortic wall into the aortic lumen may produce "stenosis" with flow acceleration and a gradient (pseudocoarctation).
2. Subadventitial aortic rupture involving the intima and media with complete circumferential extension (aortic transection). This lesion results in a fusiform pseudoaneurysm. Because the intima and media tear is circumferential, protrusion into the lumen does not occur. The inner surface of the aneurysm is smooth, formed solely by adventitia. As a consequence, the aortic wall is extremely thin and fragile. Imaging typically reveals an abrupt change in aortic diameter.
3. IMH. Accumulation of blood within the media may result from blunt aortic trauma secondary to disruption of the vasa vasorum or the development of small intimal tears. The aortic wall shows a localized, usually crescent-shaped thickening (usually >5 mm). The inner aortic surface is smooth, the aortic lumen is partially reduced, and the outer aortic contour is unaltered. There is no flap and no flow signals within the hematoma.



BOX 15.10 TRANSESOPHAGEAL ECHOCARDIOGRAPHIC CHARACTERISTICS OF BLUNT AORTIC INJURIES

- Dilatation in the region of the isthmus
- Abnormal aortic contour
- Intraluminal medial flap
- Pseudoaneurysm
- Crescentic or circumferential thickening of the aortic wall (intramural hematoma)
- Mobile linear echodensities attached to the aortic wall consistent with an intimal tear or a thrombus

From Goldstein SA, Evangelista A, Abbara S, et al. Multimodality imaging of diseases of the thoracic aorta in adults: from the American Society of Echocardiography and the European Association of Cardiovascular Imaging. *J Am Soc Echocardiogr.* 2015;28:119–182.

4. Traumatic aortic dissection. The elastic and collagen fibers of the aortic wall are remarkably strong radially but may be relatively easily split when exposed to transaxial stress. As is true of spontaneous aortic dissection, aortic trauma may produce separation of the media. This lesion is uncommon and can mimic spontaneous aortic dissection but has significant differences. It is usually localized to the area of the aortic injury and does not propagate distally toward the iliac arteries. It typically fails to create two channels and may have a direction transverse to the longitudinal axis of the aorta. Consequently, the resulting "flap" is usually thicker and less mobile than the classical intimal flap. The aorta is usually symmetrically enlarged.
5. Lesion of the aortic branches. Partial or total avulsion, pseudoaneurysm, dissection, and thrombosis may occur as isolated injuries to branch arteries in association with BAI.
6. Superficial lesions involving only the intima. With improvements in imaging technology, ever more subtle lesions are being identified. The term *minimal aortic injury* is often used to describe a lesion that carries a relatively low risk for rupture. Ten percent of patients with BAIs diagnosed through use of high-resolution techniques have minimal aortic injuries. Although most of these intimal injuries heal spontaneously, and, hence, may not require surgical repair, the natural history of these injuries is unknown. Frank tears produced by BAI, but limited to the intima, appear as thin, linear, mobile intraluminal projections from the aortic wall. No alterations of the diameter or external contour of the aorta are present. Thrombi, often mobile, may be present within the aortic lumen, presumably in areas of exposed collagen. Minimal aortic injury from an imaging standpoint is an injury with the intimal flap less than10 mm, accompanied by minimal or no periaortic mediastinal hematoma.

TEE is considered a second-line modality for the evaluation of BAI. The aortic isthmus is usually well visualized. TEE may be useful following small intimal injuries that are not well defined by CT or aortography. As discussed earlier, however, the distal arch and the arch vessels are not easily visualized. The modality is operator dependent and may not be safe in patients with unstable cervical, oropharyngeal, or esophageal injuries. The TEE findings in patients with BAI are summarized in Box 15.10. There are similar findings in patients with spontaneous aortic dissections.[378]

Pericardial Disease

The pericardium is a thin (1 to 2 mm) two-layered structure reflecting from a serosal visceral layer to a fibrous parietal layer. Superiorly, it is approximately 1 to 2 cm distal to the origin of the great vessels and around the pulmonary veins, and inferiorly it is attached to the central tendon of the diaphragm.[418,419] Anteriorly, the pericardium attaches to the sternum by sternopericardial ligaments. The fibrous parietal layer

TABLE 15.26 Strengths and Limitations of Modalities in the Evaluation of Pericardial Disease

	Echocardiography	*Cardiac CT*	*CMR*
Strengths	• First-line imaging for diagnosis and follow-up • Widely available • Low cost • Safe • May be performed at the bedside	• Need for better anatomic description • Evaluation of extracardiac disease • Preoperative planning • Detection of pericardial calcification	• Need for better anatomic description • Superior tissue characterization
Limitations	• Limited windows with narrow field of view • Technical difficulties with obesity, obstructive lung disease • Operator dependent • Low signal-to-noise ratio of the pericardium • Limited tissue characterization	• Use of ionizing radiation • Use of iodinated contrast • Functional studies only possible with retrospectively gated studies • Difficulties with tachyarrhythmias or unstable rhythm • Need for breath-hold • Hemodynamically stable patients only	• Time consuming, high cost • Preferably with stable heart rhythms • Contraindicated with pacemakers or defibrillators • Lung tissue less well visualized • Calcification less well visualized • Use of gadolinium contrast contraindicated with advanced renal dysfunction • Use of some breath-hold sequences • Hemodynamically stable patients only

is composed of collagen fibers with interspersed short elastic fibrils. The serosal layer, also known as the epicardium, consists of a single layer of mesothelium. Significant amounts of epicardial fat may be found between the visceral pericardium and myocardium and is most abundant along the atrioventricular and interventricular grooves, as well as over the right ventricle.

Under normal circumstances less than 50 mL of fluid is contained within the pericardial sack allowing for practically frictionless motion of the heart during the cardiac cycle.[420] The pericardial fluid is an ultrafiltrate of plasma from the epicardial and parietal capillaries.[421] It also contains prostaglandins secreted by the mesothelial and endothelial cells that modulate cardiac reflexes and coronary tone.[422] In addition, the pericardium limits short-term chamber distention and helps to maintain ventricular chamber geometry.

As discussed earlier, the parietal layer of the pericardium is rich in collagen fibers making it a low compliance structure confining the volume of the four cardiac chambers. The influence of the normal pericardial confinement contributes more than 50% of the normal diastolic pressure of the right-sided structures.[421] This low compliance system results in a ventricular interdependency during systole, where a volume increase of one chamber requires a reduction of volume within another chamber. With normal quantities of pericardial fluid (and hence a normal pericardial pressure), this interdependent ventricular filling is not clinically significant. This interdependence becomes more significant with increases in pericardial fluid volume and serves as an important diagnostic feature.[423]

Although both cardiac CT and cardiac MRI may be used to evaluate pericardial disease, echocardiography is still considered the first-line diagnostic modality.[424] As described in Table 15.26, the major advantages of echocardiography include its wide availability, assessment of both anatomic and physiologic features, low cost, safety, and portability allowing its use at the bedside with hemodynamically unstable patients.[421] With these advantages, TEE is an excellent modality for the screening and follow-up of pericardial effusions and cardiac tamponade and for assessment of constrictive pericarditis.

Pericardial diseases can be grouped into a variety of disease entities, including pericardial effusion and tamponade, acute and recurrent pericarditis, constrictive pericarditis, pericardial masses, and congenital anomalies of the pericardium. The etiologic classification of pericardial diseases includes infectious, autoimmune, post-MI, postsurgical, and autoreactive causes.[425]

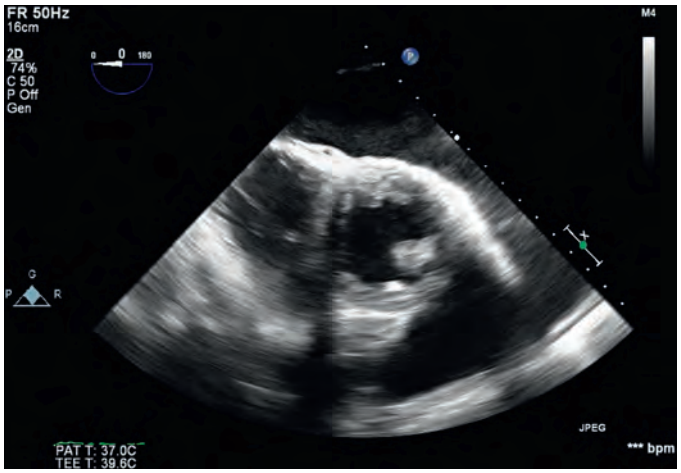

Fig. 15.152 Large pericardial effusion. Transgastric short-axis midpapillary view. There is a large pericardial effusion around the inferior, lateral and anterior aspect of the left ventricle.

Pericardial Effusions

Under normal circumstances, the echocardiographer is unable to visualize the fluid film between the two layers. Under disease conditions, fluid accumulation can occur resulting in the development of a pericardial effusion (Fig. 15.152 and Video 15.13) Typical causes leading to pericardial effusions are listed in Table 15.27. These effusions may be transudates, exudates, hemopericardium, or pyopericardium. An exudative effusion may show stranding, adhesions, or an uneven distribution. According to the 2013 guidelines, small effusions are usually defined as 50 to 100 mL, moderate as 100 to 500 mL, and large as more than 500 mL.[421] The size of the effusion correlates poorly with its hemodynamic effect; the rapidity of accumulation has a greater effect on hemodynamics. Pericardial effusions of different origins

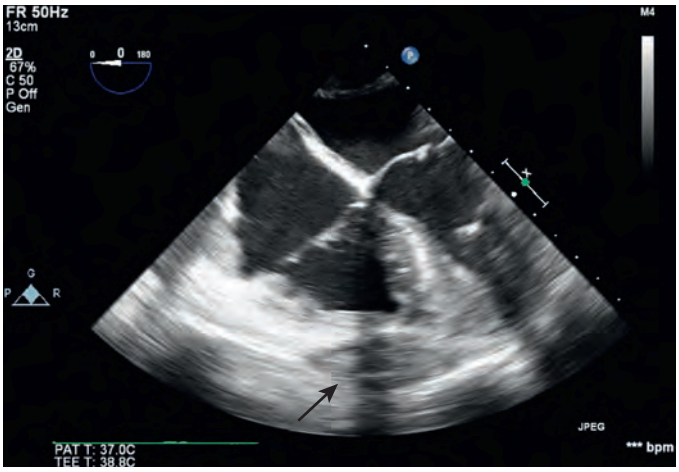

Fig. 15.153 Loculated pericardial effusion. Midesophageal four-chamber view. After cardiac surgery, a pericardial thrombus *(black arrow)* is visualized compressing the lateral and inferior free wall of the right ventricle.

TABLE 15.28 Severity of Pericardial Effusions

Severity	*Width of Effusion*
Trivial	Only seen during systole
Mild	<10 mm
Moderate	10–20 mm
Large	>20 mm
Very large	>25 mm

Adapted from Klein AL, Abbara S, Agler DA, et al. American Society of Echocardiography clinical recommendations for multimodality cardiovascular imaging of patients with pericardial disease. *J Am Soc Echocardiogr.* 2013;26:965–1012.e1015.

have characteristic sizes and progression. Idiopathic or viral infections may result in small pericardial effusions, while large effusions may be associated with hypothyroidism, tuberculosis, or neoplasms. Rapid pericardial blood accumulation may be from blunt trauma, ascending aortic dissection, or cardiac rupture (either secondary to MI or iatrogenic, such as during invasive cardiac procedures).[426] Free effusions are more typically seen in medical conditions, whereas loculated effusions are seen after surgery or inflammatory processes (Fig. 15.153, Video 15.14). In many patients, however, the origin of pericardial effusions must be classified as idiopathic.

A qualitative grading system is often used to characterize the quantity of the pericardial effusion present. This qualitative grading uses the diameter of the effusion in two dimensions. The 2013 guidelines are summarized in Table 15.28. Trivial effusions are only seen during systole, mild effusions are less than 1 cm, and large effusions are greater than 2 cm in diameter. Additionally, the effusion can either encompass the entire heart (free) or be loculated. TEE has been demonstrated to be a more sensitive modality for the detection of loculated effusions or intrapericardial clots compared with TTE.[427] It is important to define the anatomic relationship of the effusion. A loculated effusion found primarily at the inferior aspect of the heart can lead to inadvertent injury of the right ventricle if a subxiphoid approach is chosen for drainage.

It can be difficult to differentiate a left-sided pleural effusion from a pericardial effusion. A left pleural effusion may be identified as fluid between the descending aorta and the heart. A good clue is to identify the descending thoracic aorta; since the reflection of the pericardium is typically anterior to the descending thoracic aorta, pericardial effusions are generally seen anterior and to the right of the aorta. A dilated thoracic aorta, giant atrium or atrial appendage, or an enlarged coronary sinus must be considered as part of the differential diagnosis.[428]

Cardiac Tamponade

Cardiac tamponade and pericardial effusion are not synonymous. A pericardial effusion is an anatomic diagnosis that may or may not lead to hemodynamic alterations. Cardiac tamponade is a pathophysiologic diagnosis.

The fibrous pericardium constrains the cardiac chambers. This fibrous constriction results in a nonlinear intrapericardial pressure-volume relationship. The normal pericardium has a 150- to 250-mL capacitance reserve, where initial increases in pericardial sac volume produce negligible increases in intrapericardial pressure.[428,429] At low volumes, the curve is flat with minor increases in pericardial pressure. At a given inflection point, the curve becomes steeper; further small increases in fluid result in a significant increase in pericardial pressure. Acutely, small increases in pericardial fluid may result in clinically significant cardiac tamponade. In contrast, if pericardial fluid accumulation is gradual, the pericardium may stretch, increasing the compliance and shifting this pressure-volume curve to the right. This slow accumulation of fluid can go undetected for long periods of time resulting in volumes exceeding one liter. However, once the limits of pericardial stretch are exceeded, the rise in pericardial pressures will limit diastolic filling.[429]

Intrapericardial pressure is usually similar to pleural pressure; during spontaneous ventilation, it may be −6 mm Hg during end-inspiration and −3 mm Hg during end-expiration.[423] This decrease in pericardial pressure during inspiration increases the transmural pressure on the right side of the heart, thus increasing RV inflow (ie, transtricuspid flow). There is a slight decrease in LV inflow (ie, transmitral flow) due to increased aortic transmitral pressures and delayed pulmonary transit. The opposite changes occur with positive-pressure ventilation.

As the pressure increases within the pericardial sac, the total blood volume within the heart becomes limited, leading to an exaggerated response to the respiratory cycle. Because of the low compliance of the pericardial sac, any increases in ventricular size result in a significant increase in pericardial pressure limiting contralateral ventricular filling: increases in RV filling limits LV filling and vice versa. Under normal circumstances respiratory variation of arterial pressure is less than 10 mm Hg. *Pulsus paradoxus* is a more than 10 mm Hg change in systolic arterial pressure with respiration. If the intrapericardial fluid is not relieved, an equalization will occur among diastolic pressures within the heart. With increasing pericardial pressures, LA and RA pressures must increase to maintain ventricular filling. When compensatory mechanisms are unable to support preload with higher filling pressures, decompensation occurs (see Chapters 24 and 38).

Echocardiographically, cardiac tamponade may be identified as RA and RV collapse during the relaxation phase. This collapse occurs when the intrapericardial pressure exceeds the intrachamber pressure. Maximum RA collapse occurs during early ventricular systole after discharging the atrial kick near the QRS complex, when the RA pressure is lowest. RV collapse is greatest during early ventricular relaxation after the T wave. The severity and duration of this collapse increase with further increases in the pericardial pressure. RA collapse duration that exceeds one-third of the cardiac cycle is nearly 100% sensitive and specific for clinical cardiac tamponade.[430] Since the right ventricle is thicker than the RA, a higher pericardial pressure is required for RV diastolic collapse; RV collapse is a more specific but less sensitive sign of pericardial tamponade.[431] Hypovolemia may result in chamber collapse without tamponade, and significant RV hypertrophy with decreased compliance or pulmonary hypertension may prevent chamber collapse in the presence of high pericardial pressures.[418] A loculated or isolated effusion may also result in local tamponade. This local tamponade is most commonly seen after cardiac surgery or MI. In addition to the presence of a pericardial effusion, other signs of tamponade include a dilated inferior vena cava, hepatic venous fullness with systolic blunting of hepatic blood flow velocities, excessive ventricular septal movement with respiration, and a small left ventricle. An inferior vena cava greater than 2.1 cm with less than a 50% reduction

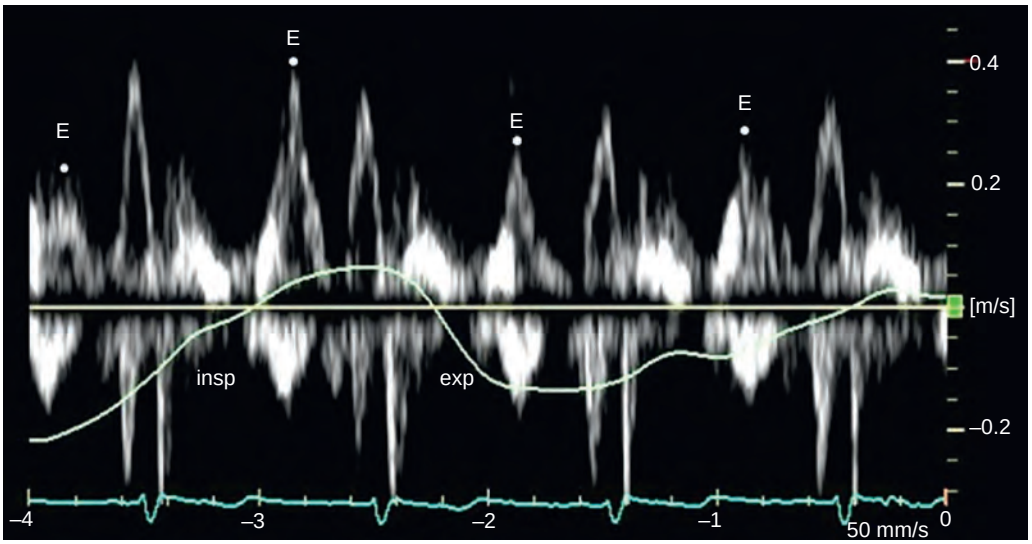

Fig. 15.154 Doppler spectrum of through tricuspid valve during spontaneous respiration during cardiac tamponade. Since transthoracic imaging is used, flows are in the opposite direction compared with transesophageal echocardiography. There is increased E-wave velocity during inspiration *(insp)* compared with the lower velocity E waves during expiration *(exp)*. (*From Klein AL, Abbara S, Agler DA, et al. American Society of Echocardiography clinical recommendations for multimodality cardiovascular imaging of patients with pericardial disease.* J Am Soc Echocardiogr. *2013;26:965–1012.e1015.)*

in diameter during inspiration is indicative of an elevation in systemic venous pressure that occurs with increases in pericardial pressure.[432]

More subtle signs of pericardial tamponade can be detected with Doppler modalities (Fig. 15.154). As discussed earlier, with cardiac tamponade, filling of one side of the heart will only occur at the expense of the other side. This phenomenon may be demonstrated by significant respiratory variation of transmitral or tricuspid inflow velocities. Respiratory variation should be calculated by:

(E wave expiration – E wave inspiration)/E wave expiration

Normally, the respiratory variation is 5% with spontaneous ventilation. The 2013 guidelines from the American Society of Echocardiography suggest that a respiratory variation of 30% or more in peak early transmitral flow or a 60% or more variation in transtricuspid diastolic valve flow velocity is diagnostic of cardiac tamponade.[421] This measurement can be achieved by positioning the pulse wave gate just at the leaflet tips of the MV or TV. Although a large pericardial effusion is associated frequently with pericardial tamponade, other factors can be responsible for respiratory variation in transvalvular flow velocities (eg, high airway pressures, hematoma, hypovolemia); the diagnosis of pericardial tamponade should not be made in the presence of respiratory variation without other supporting evidence of tamponade.

In addition to Doppler changes in transtricuspid and transmitral flow, associated changes with hepatic venous blood flow velocities can be found. Normally, hepatic systolic venous flow is approximately 50 cm/s and is greater than hepatic diastolic venous flow.[433] With inhibition of filling, systolic venous flow decreases to 20 to 40 cm/s.[421] With moderate tamponade, diastolic flow is nearly absent but still may display respiratory variation. With severe tamponade, diastolic flow disappears completely. When no hepatic flow is seen except during inspiration (with spontaneous ventilation) or expiration (during controlled ventilation), cardiac arrest is imminent.

Pericarditis

Echocardiographic signs of pericarditis are nonspecific. Many patients with acute pericarditis have normal echocardiographic examinations.[421] More commonly, patients may have pericardial effusions that are small, large, generalized, or localized. In some patients, this pericardial effusion may result in tamponade. Intrapericardial fibrinous strands suggest either an inflammatory cause or clotted blood, while intrapericardial masses may be seen with primary or secondary pericardial tumors or with inflammatory processes. Approximately 5% of patients with acute pericarditis will have RWMAs.

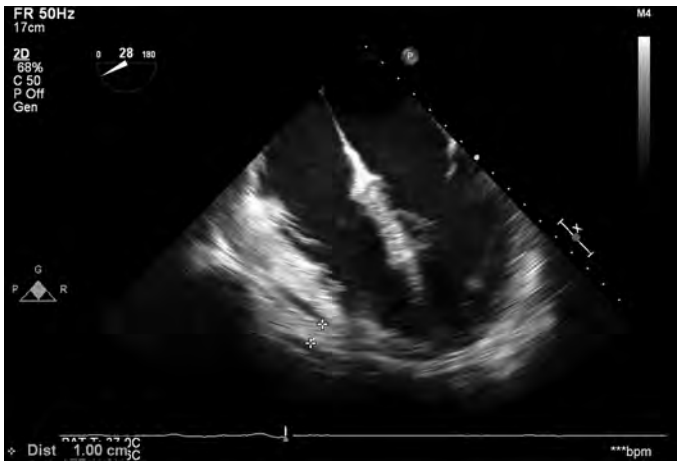

Fig. 15.155 Constrictive pericarditis. Midesophageal four-chamber view. A thickened pericardium is indicated between the curser crosshairs, resulting in constrictive pericarditis.

Constrictive Pericarditis

Constrictive pericarditis is defined as a chronic fibrous thickening and calcification of the pericardium (Fig. 15.155, Video 15.15). This thickening results in a decrease in pericardial compliance, which limits ventricular filling with raised filling pressures.[434] Although commonly idiopathic, other causes of constrictive pericarditis in developed countries include previous cardiac surgery, mediastinal radiation, and hemorrhagic pericarditis. In developing countries, scarring from tuberculous pericarditis is more common. Myocardial encasement by the pericardium isolates the heart from the normal intrathoracic pressure changes during respiration. This ventricular isolation results in both the dissociation of intracardiac and intrathoracic pressures

TABLE 15.29 Differentiation of Constrictive Pericarditis From Restrictive Cardiomyopathy

Variable	*Restriction*	*Constriction*
Septal motion	Normal	Respiratory shift
Mitral E/A ratio	>1.5	>1.5
Mitral DT (ms)	<160	<160
Mitral inflow respiratory variation	Absent	Usually present
Hepatic vein Doppler	Inspiratory diastolic flow reversal	Expiratory diastolic flow reversal
Mitral septal annular e′	Usually <7 cm/s	Usually >7 cm/s
Mitral lateral annular e′	Higher than septal e′	Lower than septal e′
Ventricular septal strain	Reduced	Usually normal

Adapted from Nagueh SF, Appleton CP, Gillebert TC, et al. Recommendations for the evaluation of left ventricular diastolic function by echocardiography. *J Am Soc Echocardiogr.* 2009;22:107–133.

during respiration and the interdependence of ventricular filling.[435,436] According to Troughton and coworkers, "on inspiration, intrathoracic pressure decreases, but is not transmitted to the left atrium. A reduced pulmonary vein to LA pressure gradient produces a fall in flow into the left atrium, and across the MV into the left ventricle. Decreased LV filling during diastole allows more room for RV filling, which leads to a septal shift and an increase in right-sided inflow. The exact opposite sequence occurs in expiration."[418] Similar to cardiac tamponade physiology, constrictive pericarditis results in an exaggerated respiratory variation during ventricular inflow in diastole. Unlike cardiac tamponade, early diastolic filling in constrictive pericarditis is more rapid than normal, because the restraining effects of the pericardium do not occur until middiastole, after which little ventricular filling is seen, even with atrial contraction. The comparison of cardiac tamponade and constrictive pericarditis are summarized in Table 15.29.[376] Other characteristic features include pericardial thickening, myocardial tethering, a septal bounce, and inferior vena cava plethora.[437] Precise measurement of pericardial thickness may be challenging by TTE; however, measurement by TEE correlates strongly with CT measurements.[398] Transmitral flow patterns are similar to those seen with restrictive cardiomyopathy: high velocity E waves with very short duration times are observed with a reduced A-wave velocity. In contrast to restrictive disease, there is usually a prominent e′ velocity (ie, tissue Doppler velocity during early diastole), and the color M-mode propagation velocity during early systole is either normal or increased. In a study of 122 patients, 89% of patients with surgically proven constrictive pericarditis had normal e′ velocities, and 73% of patients with restrictive disease had reduced e′ velocities.[438] Because of the tethering of the lateral mitral annulus to the pericardium, the lateral mitral annular e′ is usually lower than e′ from the medial annulus ("annulus reversus") in patients with constrictive pericarditis. The echocardiographic differentiation between constrictive pericardial physiology and restrictive disease is summarized in Table 15.30.

Pericardial Cysts and Masses

Pericardial cysts may be congenital, inflammatory, or echinococcal.[425] Congenital pericardial cysts can be unilocular or multilocular with diameters from 1 to 5 cm. Inflammatory cysts may be pseudocysts or alternatively encapsulated or loculated pericardial effusions. Causes of these inflammatory cysts include rheumatic pericarditis, bacterial infection, trauma, or cardiac surgery. Finally, echinococcal cysts may be caused by ruptured hydatid cysts from the liver or lung. In contrast, pericardial diverticula are outpouchings or herniations through a pericardial defect. As opposed to pericardial cysts, these diverticula may rapidly change in size within a short period of time. As opposed to cysts, diverticula communicate with the pericardial sac. On echocardiograms they appear as a distinct echogenic space adjacent to the pericardium. They are commonly adjacent to and compressing the right atrium.

TABLE 15.30 Comparison of Constrictive Pericarditis and Cardiac Tamponade

Cardiac Tamponade	*Constrictive Pericarditis*
Fixed cardiac volume limiting cardiac filling (respiratory variation of ventricular filling)	Fixed cardiac volume limiting cardiac filling (respiratory variation of ventricular filling)
Ventricular interdependence (septal shift)	Ventricular interdependence (septal shift)
Elevated and equalized central venous, pulmonary venous, and ventricular diastolic pressures	Elevated and equalized central venous, pulmonary venous, and ventricular diastolic pressures
Prominent systolic filling (attenuated Y descent)	Prominent early diastolic filling (exaggerated Y descent)
Inspiratory Y in intrathoracic pressure not transmitted to heart (dissociation of intracardiac and intrathoracic pressures)	Inspiratory Y in intrathoracic pressure not transmitted to heart (dissociation of intracardiac and intrathoracic pressures)
Pulsus paradoxus common	Pulsus paradoxus uncommon
Kussmaul sign not present	Kussmaul sign

Adapted from Klein AL, Abbara S, Agler DA, et al. American Society of Echocardiography clinical recommendations for multimodality cardiovascular imaging of patients with pericardial disease. *J Am Soc Echocardiogr.* 2013;26:965–1012.e1015.

Pericardial tumors can be benign or malignant. Primary pericardial tumors are significantly less common than metastatic tumors.[425] The most common primary benign tumors of the pericardium are teratoma, lipoma, fibroma, hemangioma, and lymphangioma. These tumors may be small or very large, causing compression, and may be found either in the parietal or the epicardial pericardium. The most common malignant primary tumor of the pericardium is mesothelioma, followed by angiosarcoma, whereas the most common source of the metastatic tumors are lung, breast, malignant melanomas, lymphomas, and leukemia. These malignancies may cause either small or large serosanguineous pericardial effusions with resultant pericardial tamponade (see Chapter 24).

Although pericardial masses may be easily appreciated by echocardiography, other modalities are generally used for further tissue classification and delineation. Generally they appear as echodense masses on the pericardium. They may either be nodules or result in general pericardial thickening. Malignant tumors tend to have a diffuse growth pattern. The masses can be homo- or heterogeneous, cystic, or have a more complex septated pattern.

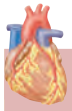
Evaluation of Cardiac Masses

A cardiac mass is defined as an abnormal structure within or immediately adjacent to the heart. Cardiac masses are typically divided into three categories: thrombus, vegetation, and tumor. Identification of an unfamiliar structure during echocardiography should lead to further analysis and differentiation from normal anatomy. In addition, the presence of intracardiac catheters (central venous or PA catheters, dialysis catheters) and cardiac pacing wires need to be considered.

Unfamiliar structures should be evaluated for location, anatomic characteristics (shape, mobility), spatial relationship with other known cardiac structures throughout the entire cardiac cycle, and impact on blood flow dynamics. All masses should be evaluated in two or more imaging planes with optimized frequency and depth to avoid the possibility of misdiagnosis of an artifact.[439] Intracardiac structures that frequently lead to incorrect diagnosis of intracardiac masses can be found in Box 15.11.

Thrombus

When a cardiac mass is identified, it is frequently a thrombus or vegetation.[440] Intracardiac thrombus formation occurs when there is low velocity or stasis of blood. Conditions predisposing patients to thrombus formation in the left atrium include LA enlargement, MS, and atrial fibrillation (Video 15.16). LA enlargement secondary to severe



BOX 15.11 NORMAL ANATOMIC STRUCTURES AND DEVICES THAT ARE OFTEN CONFUSED FOR INTRACARDIAC MASSES

Right Atrium
Pacer wires, catheters, Chiari network, crista terminalis, eustachian valve, right atrial appendage, lipomatous hypertrophy of the intraatrial septum

Left Atrium
Left atrial appendage variants, pectinate muscles, Coumadin ridge (raphe between the left atrial appendage and the left superior pulmonary vein)

Right Ventricle
Pacer wires, pulmonary artery catheters, trabeculae, moderator band

Left Ventricle
False tendons, papillary muscles, calcified mitral valve chordae

Aortic Valve
Nodules of Arantius, Lambl excrescences

MR does not predispose patients to thrombus formation. The turbulent blood flow of the regurgitant jet and subsequent lack of blood stasis make thrombus formation unlikely. LA thrombi are frequently homogenous, well-demarcated, and typically located in the LAA; they must be distinguished from pectinate muscles. Particular attention should be given to patients with spontaneous echo contrast in the left atrium. Pulsed-wave Doppler should be placed 1 cm into the LAA to determine blood velocity. A velocity less than 40 cm/s indicates low flow and increased likelihood of thrombus formation. Three-dimensional TEE and biplane evaluation greatly enhances imaging of the LAA and has been shown to aid in the diagnosis of thrombus.

Thrombus formation in the left ventricle is typically seen in the presence of severe global systolic dysfunction, LV aneurysms, and areas of significant RWMAs, particularly in the apical regions. Although apical thrombi are seen best using TTE, detection using TEE is possible if foreshortening of the left ventricle is avoided. A thrombus in the left ventricle may be sessile, smooth walled, and challenging to differentiate from the myocardium, or may be large, irregular, and mobile (Video 15.17). The use of left-sided contrast agents can aid in detection of a LV thrombus if suspicions are high. Just as with artifacts, evaluation of a thrombus in multiple imaging views and throughout the cardiac cycle is necessary to ensure correct diagnosis.

Thrombus formation in the right atrium or right ventricle is rare and is frequently associated with indwelling catheters or pacing wires. If no associated foreign material is present, the thrombus likely originated in the systemic venous system and is in transit to the PA.

Vegetations

Vegetations are highly mobile, irregularly shaped masses that occur on a valve or subvalvular apparatus. They can be infectious resulting in bacterial or fungal endocarditis, or noninfectious. They are frequently found on the upstream (low-pressure) side of valves in the path of regurgitant jets. The echogenicity resembles soft tissue or myocardium in contrast to the bright connective tissue appearance of the valve or chordae (Video 15.18). If a catheter or pacing wire is present, vegetations may be adherent to the foreign material. In this instance, it would be challenging to distinguish from a thrombus using echocardiography.

Intracardiac Tumors

Although many intracardiac tumors have characteristic appearances, the goal of using echocardiography in the evaluation is not to gain pathologic diagnoses but rather to evaluate the location, anatomic extent, and physiologic consequences of the tumor (see Chapter 24).

Primary Cardiac Tumors

Primary cardiac tumors are rare, occurring about 20 times less frequently than nonprimary cardiac tumors.[440] Pathologically, 75% of these tumors are benign. The majority of benign cardiac tumors are myxomas, which represent more than 85% of the cardiac masses that are surgically excised. Myxomas are typically single, pedunculated, and smooth-walled in appearance, but occasionally they have an irregular, grape cluster appearance (see Fig. 24-3, Video 15.19). They often have inhomogenous echogenicity and can have areas of calcification. More than 75% of myxomas arise from the LA side of the IAS. Other sites of origination include the RA and, infrequently, the right ventricle or left ventricle. Although benign, these tumors can be quite large and result in obstruction to LV filling if they prolapse across the MV in diastole.

Papillary fibroelastomas are the second most common type of benign intracardiac tumor and are typically associated with cardiac valves. Often mistaken for valvular vegetations, papillary fibroelastomas arise from native valve tissue. These tumors are often less than 1 cm in diameter and are highly mobile. Typically they are located on the mitral and AVs; however, they can be seen on the right-sided heart valves or, rarely, arising from nonvalvular sites.[441] It is controversial as to whether or not large papillary fibroelastomas provide a source of systemic embolization and therefore whether excision or anticoagulation is necessary. The most common benign cardiac tumors in the pediatric population are rhabdomyomas and LV fibromas.

Malignant primary cardiac tumors are far less common than benign ones. The most common malignant primary cardiac tumors in the adult population are angiosarcomas, rhabdomyosarcomas, mesotheliomas, and fibrosarcomas.[442] Malignant tumors are often immobile because of their tendency to infiltrate adjacent cardiac anatomy. Similar to metastatic disease, malignant primary cardiac tumors often cause pericardial effusions.

Nonprimary Cardiac Tumors

Nonprimary tumors consist of four categories: metastases from distant primary tumors (liver, colon), metastases by lymphatic spread (lymphoma), direct invasion of adjacent malignancy (lung, breast), or through direct extension from distant malignancy through the inferior vena cava (renal cell carcinoma). Lung cancer, lymphoma, breast cancer, and leukemia represent the top four sources of metastatic cardiac tumors in adults.[441] Nonprimary tumors affect the pericardium more commonly than the myocardium, causing pericardial effusions that may lead to cardiac tamponade. Myocardial involvement is more common with melanoma or lymphoma.[441]

Decision Making and Perioperative Transesophageal Echocardiography

JARED W. FEINMAN, MD | JOSEPH S. SAVINO, MD | STUART J. WEISS, MD, PhD

KEY POINTS

1. The first step in decision making is to frame the problem by defining the parameters, priorities, and pertinent criteria.
2. The second step is the directed acquisition of data, "data collection," which includes all pertinent information, regardless of whether it is confirmatory or contradictory. The supplemental information from the preoperative evaluation should always be taken into consideration.
3. A comprehensive systematic transesophageal echocardiography (TEE) examination permits the acquisition and interpretation of both qualitative and quantitative echocardiographic data for most cardiovascular diseases. The greatest risk and source of error are omission and misinterpretation of data that lead to mismanagement.
4. The decision regarding management of a specific anatomic abnormality in an individual patient should take an evidence-based approach reflecting the severity of the lesion, coexisting factors, the patient's wishes, and the current literature.
5. Intraoperative findings should be objectively and effectively characterized and discussed with the pertinent clinicians, surgeon, or cardiologist and the patient's family.
6. The decision and recommendations should be formally communicated through a reporting document that is accessible to other health care providers.
7. A systematic process for learning from the results of past decisions (quality improvement program) and continued education are critical for the future success of any intraoperative TEE program.

"In the affair of so much importance, wherein you ask my advice, I cannot make for want of sufficient premises advise you what to determine, but if it please I will tell you how."

Benjamin Franklin

All too often in medicine, critical decisions are made without the benefit of a thorough consideration of data, evidence, and framework. The paucity of clinical outcomes research in echocardiography, especially in the perioperative period, dampens the prospects for evidence-based decision making. In the absence of evidence-directed practice, decision making often devolves into a reliance on anecdote, clinical impression, and tradition. With this lack of clear evidence-based guidelines, combined with the ever-increasing flow of information that physicians must process on a daily basis, it becomes imperative to develop a systematic approach to handling data streams, organizing ideas and thoughts, defining and prioritizing problems, and effecting care through a well-thought-out decision. Such a formalized approach (Fig. 16.1) enhances the quality of the intraoperative echocardiogram, its interpretation, and the confidence with which the findings are communicated to other members of the operative and nonoperative teams. Poor decisions are not made with bad intentions. Rather, they are the result of relying on limited medical knowledge, narrow framing, and false or tenuous anchors (eg, an echocardiographer who is overly confident in the abilities of his or her surgeon may not interrogate a repaired valve to the same extent as one without such preconceived notions).

The lack of a structured paradigm for decision making is most worrisome when clinicians with lesser ability or experience are making the decisions. The least accomplished clinicians often have the most inflated estimate of their own abilities, thus lending themselves to the vulnerabilities of both limited skills and a lack of a decision-making process.[1]

Expertise is gained from experience and enhances the repertoire of experiences from which a practitioner can draw, but it does not alter cognition and does not immunize the practitioner from errors in decision making. Intuition and experience are not reliable predictors of success, and even experienced physicians can fall prey to heuristic methods of decision making that create a systematic and predictable bias. It is acceptable to be wrong. It is unacceptable to be consistently wrong in the same direction. A structured process of assessing all the data and weighing various alternatives (cognitive engine) enables the physician to formulate a concise, organized approach to problem solving, communicating the findings, and managing alternatives. For the echocardiographer confronted with multiple channels of information, including data specific to providers, operations, and patients (Boxes 16.1 to 16.3), the best approach is through a systematic transesophageal echocardiography (TEE) examination of the heart and great vessels. Such an approach helps prevent the practitioner from missing important information that may be overlooked as a result of bias or intuition.

Decision making can also be encumbered by cognitive and emotional attachments that limit clinicians' intellectual flexibility. Poor problem solving and an unfavorable outcome can follow a single poor decision of great magnitude. However, the "creep effect" of a series of small poor decisions can insidiously lead to an unfavorable outcome. The adherence to a poor course of action because of an attachment to the original decision is common in medicine. In the perioperative setting, this process is most vivid in the care of critically ill patients with little or no hope for survival. Continued commitment of resources and intervention often contribute to a patient's discomfort and cost without benefit in quality of life or longevity. The previous commitment of resources often encourages further commitment and investment in a losing cause. The echocardiographic decisions during surgical procedures may become part of an intraoperative sequence of

BOX 16.1 PATIENT HISTORY AND PHYSICAL SIGNS

- Symptoms: shortness of breath
- New York Heart Association classification for heart failure
- Level of activity
- Functional disability
- Age
- Signs: vital signs, rales, peripheral edema, peripheral circulation
- Cardiac and noncardiac comorbidities, including esophageal disease
- Patient's preferences (eg, Jehovah's Witness, long-term anticoagulation)

BOX 16.2 PATIENT-RELATED DATA

- Intraoperative transesophageal echocardiography
- Left ventricle: systolic or diastolic function, ejection fraction, chamber size, wall thickness, regional wall motion
- Valvular function: pathologic process, severity, location, vena contracta, annular size, size of donor chamber, pressure gradient, flow-velocity profiles
- Cardiac catheterization
- Chest radiographs, electrocardiogram, blood tests, radionucleotide studies, positron emission tomography scans, stress test, transthoracic echocardiography
- Hemodynamics
- Surgical inspection of the pathologic features

BOX 16.3 OPERATIVE FACTORS

- Complexity of planned surgical procedure (eg, redo sternotomy, previous valve repair, infectious process)
- Alternatives to the planned surgical procedure
- Anticipated risk for a failed intervention
- Alternatives if the original procedure is unsuccessful
- Equipment availability (eg, ventricular assist device backup, special retractors, specific valves, homografts)
- Expertise and experience of the operating team

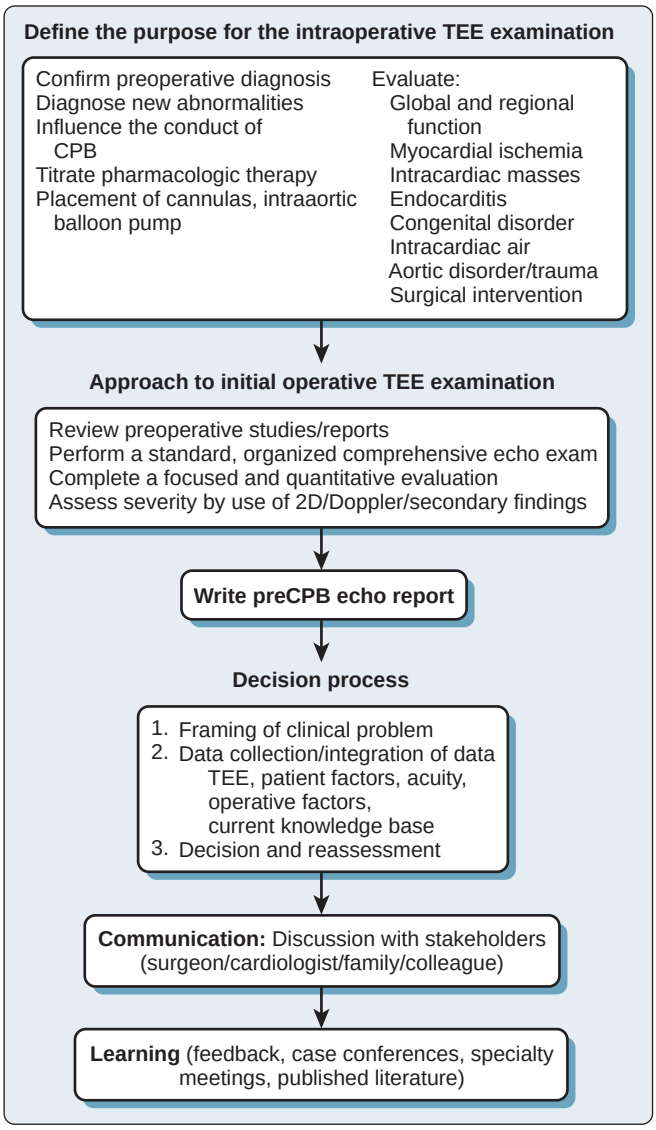

Fig. 16.1 An algorithm for the decision-making process. *CPB*, Cardiopulmonary bypass; *TEE*, transesophageal echocardiography; *2D*, two-dimensional.

diagnostic and therapeutic interventions in which the best course of action is a complete reversal of direction. Repeated attempts at repairing a mitral valve (MV) may follow an initial unsuccessful repair. The decision to replace the valve instead of repairing it often is not considered until late in the course. Repeated intervals of cardiopulmonary bypass (CPB) and aortic cross-clamping are not without their complications and associated morbidities. It often is difficult to retain an open mind and to consider alternative diagnoses or therapeutic alternatives. Effective decision makers are able, if necessary, to abandon the original decision to repair an MV and move toward valve replacement.

A thorough intraoperative TEE examination can correct preoperative inaccuracies in diagnosis or detect occult disease. With increasing emphasis on decreasing preoperative testing, avoiding redundant testing, and decreasing costs, accurate diagnoses of disease may not occur until the time of surgical intervention. The increased reliance on the intraoperative TEE is fiscally wise, but it places greater responsibility and impact on the intraoperative echocardiographer. The detection of occult disease not appreciated during the preoperative evaluation often affects operative management. It is necessary to reframe a problem when the data acquired provide new insights. For example, the detection of mobile atheroma in the ascending aorta may influence positioning of an aortic infusion cannula or cross-clamp, hence changing circulatory management and the operation.[2–4] A change in clinical management with respect to otherwise asymptomatic and silent findings is often controversial. The change in the operation has typically not been discussed with the patient because the findings were unanticipated. The intraoperative diagnosis of moderate aortic regurgitation (AR) that was not detected preoperatively creates a clinical challenge for the surgical team regarding administration of cardioplegia and the decision whether to replace the aortic valve (AV). Hence, the decision to proceed with an unplanned AV replacement (AVR) relies on the ability of the echocardiographer to establish the diagnosis and mechanism of valvular disease, define the pertinent factors that sway the decision (preoperative symptoms of congestive heart failure, ventricular size and function, pulmonary hypertension), and communicate with the surgeon and the other pertinent stakeholders. The decision

to recommend AVR to a patient is not often guided by the degree of AR, but rather by the degree of corresponding ventricular dilatation and dysfunction. The finding of moderate AR with normal ventricular systolic function and chamber size, normal left atrial pressure, and no preoperative history of congestive heart failure may sway the operative team to proceed with the originally planned surgical procedure and to treat the occult finding medically with postoperative afterload reduction and follow-up serial echocardiograms. In contrast, in a patient with otherwise unexplained shortness of breath, pulmonary hypertension, and a dilated left ventricle, the presence of moderate AR typically leads to AVR. The introduction of new findings to the operative team warrants a "time-out" approach to determine the impact of the findings on the intraoperative care.

Decision-Making Process

The process of decision making is, in essence, "deciding how to decide."[5] What is the primary issue that must be addressed? What are the pitfalls in the decision? What are the consequences of the decision? What tools and resources does the decision maker require? What information is needed to make an informed decision? Does evidence support one decision over another? How much time does the decision maker need to make the decision? Rarely does a valid reason exist for not taking enough time to make a well-thought-out decision, even in the high-productivity, high-throughput environment of the operating room. The anchor to a "last case" experience creates bias and is all too prevalent in medicine; the experience from the previous case dictates decision making on the subsequent case. If physicians are to remain the dispensers of medical care and resources, then they must be cognizant of the effects of their decisions on all patients, not just the one lying on the operating room table. It is inappropriate to accrue health care costs without evidence that such financial investment provides any health care benefit. We have applied the methods of Russo and Schoemaker[5] to decision making in medicine: framing, data collection, decision and implementation, and learning from knowledge to wisdom.

Framing

Framing defines the question and the factors that influence or sway the decision maker. Framing sets the vantage point of the decision maker and defines the boundaries, parameters, and priorities. Framing a question in the early stages of problem solving permits focus and bounded rationality. However, the price of focusing on a specific issue may be loss of peripheral vision. Adopting a narrowed vantage point can inadvertently impose significant bias and limitation. The decision should be addressed from a variety of vantage points so that all aspects of the decision can be considered. Failure to work beyond a single conceptual frame can lead to difficulties in communication among the different participants of the care team. In the setting of a complex MV repair, the intraoperative echocardiographer often is focused on performance of the TEE, successful remedy of hemodynamic disturbances, surgical intervention, and documentation. If the echocardiographer is also the anesthesiologist, his or her frame is broadened to include the patient's safety and comfort, vigilance, and maintenance of body homeostasis. The surgeon's frame includes his or her abilities and limitations in achieving a competent surgical repair, alternatives in surgical management, the covenant with the patient and family regarding surgical management (eg, repair vs replacement, bioprosthesis vs mechanical prosthesis), the patient's overall outcome, and the surgeon's own reputation. The patient's vantage point may differ from those of the operative team. The patient wants the mitral regurgitation (MR) to be fixed, for the symptoms to be resolved, to return to a "normal routine," for the remedy to be long lasting, and to be able to ride a Harley Davidson, which he or she would otherwise have to forfeit if lifelong warfarin (Coumadin) is required. Hence as a decision maker, broadening the understanding of the issues and considering multiple frames will account for the interests of multiple parties.

Data Collection

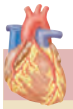
Data collection is aimed at reducing uncertainty. Uncertainty is never eliminated and hence must be managed. The perioperative echocardiographer manages uncertainty not through pinpoint predictions but by uncertainty estimates. It is imperative in the decision-making process to identify the causes systematically that could lead to decision failure and to quantify the likelihood that such causes will occur.

The ability to render a sound conclusion often is predicated on the performance of a complete and quantitative echocardiographic examination. Incomplete and qualitative assessments may be subject to missed or inaccurate diagnoses. The "soft" interpretation of the "mild-to-moderate" category is not always avoidable. The ability to "nail down" a diagnosis and establish a quantifiable measure of dysfunction allows for serial follow-up and comparison before and after treatment. The imperative for quantitative measures is directed at producing reproducible conclusions and trackable results.

The importance and impact of TEE decisions have been generally recognized and accepted. The ability to make an appropriate decision is predicated on a comprehensive examination. Confirmatory information is useful, as is contradictory information. The process of decision making also includes defining what information not to collect. Collecting as many data as possible typically leads to confusion and loss of direction in the reasoning process. A common hazard for the echocardiographer is the performance of an abridged examination because of either increased clinical demands or reliance on a preoperative examination. The conclusions drawn from an intraoperative examination and associated decisions should not be hurried and should be based on all aspects of the examination. Although physical injury from the TEE examination is a serious matter, the greatest risk of TEE is that of errors of omission or misinterpretation, leading to mismanagement and poor outcome.[6–11] Guidelines describing the comprehensive TEE examination have been published jointly by the American Society of Echocardiography and the Society of Cardiovascular Anesthesia, most recently in 2013.[12] Time permitting, the echocardiographer is encouraged to document in writing the prebypass TEE findings at the time they are discovered. It is acceptable to document a finding only to discover later that it has poor agreement with the surgical findings. This practice fosters learning and a systematic process. The process of writing a report ensures a formalized approach to evaluating the TEE examination.

Decision and Implementation

A clinical decision is made based on the integration of knowledge, framing, and information (Box 16.4). Primary knowledge is "knowing



BOX 16.4 DECISION PROCESS

Projecting the Impact of:
- Progression of disease
- Risk for redo operation
- Short- and long-term outcomes
- Associated risks (eg, anticoagulation)
- Size mismatch of the prosthesis
- Effect of prolonged cardiopulmonary bypass on the immediate postoperative outcome

Does the Decision Account for:
- Inconsistencies (among two-dimensional images, Doppler images, patient's symptoms, preoperative evaluation)
- Plausibility of an alternate explanation
- Alternate therapy
- Current literature
- Preoperative evaluations
- Patient-related factors (eg, age, cardiac status, ability to tolerate anticoagulation)

what you know" and "knowing what you do not know," with the latter prompting a practitioner to seek assistance. Second-order knowledge is "not knowing what you do not know"; hence diagnoses are missed rather than misinterpreted. The broader the repertoire of primary knowledge, the more informed is the decision maker and the more reliable is the decision. The echocardiographer is an intraoperative consultant who generates vital information that has a direct impact on intraoperative care and decision making. As consultants, echocardiographers offer suggestions and recommendations, but rarely does the echocardiographer dictate the management to the operative team. The suggestion or recommendation is shared with the stakeholders (surgeons, perfusionists, nurses, referring cardiologists, postoperative intensivists, family, and patient) and is communicated verbally and by written report. Decisions often are accompanied by discussion and sometimes persuasion. Making a sound decision concerning the surgical approach to an anatomic problem can benefit the patient only if the recommendation is effectively communicated to the operating surgeon. However, clinical judgment must take into account the skill set of the operative team and the pitfalls associated with each intervention. Persuading a surgeon to proceed with a complex reconstruction may appear to be the appropriate course of action according to an echocardiographer, but it may be the wrong thing to do if the surgeon is unfamiliar with the recommended repair (ie, poor framing).

Learning From Knowledge to Wisdom

A systematic process for learning from the results of past decisions is designed to increase the decision maker's primary knowledge base and defines an effective clinical quality improvement program. The ability to achieve success or failure may depend on the ability of the decision maker to learn from past decisions and the decisions of others.[5] A fund of knowledge gained through training, continuous medical education, readings, and the performance of echocardiograms on a regular basis maintain the skills of the echocardiographer. Although it is often difficult to obtain feedback on the impact of decisions on long-term outcome, the increment in effort to seek such insight always renders the echocardiographer better prepared for the next clinical case that shares common cardiovascular themes (wisdom). Feedback can be sought from a variety of sources: the surgeon, the cardiologist, and outpatient echocardiography data files, among others. Participation in quality improvement forums with cardiovascular anesthesiologists, cardiologists, and cardiac surgeons who tend to follow the patients longitudinally is a useful learning tool.

A significant limitation of assessing performance during uncertainty is that it is often judged not by the decision-making process, but by single case results. If the decision is followed by a good outcome, the decision maker often is applauded with little regard to the ability to reach an intelligent conclusion. An unfavorable outcome does not necessarily imply a poor process or a poor decision. High-risk surgical intervention leads to poor outcomes in many cases despite robust decisions. As a result, in medicine, practitioners are often reluctant to make any decision at all because they know that a poor outcome is likely and that it will be linked to their decision making. The reality of performance assessment is that even if the decision to proceed with therapy is substantiated, a poor outcome often will reflect negatively on the abilities of the echocardiographer, the anesthesiologist, the surgeon, and the operative team. Conversely, a favorable outcome does not imply a good process or a good decision.[5] The surgeon's decision to perform a posterior sliding mitral valvuloplasty and quadrilateral resection of the posterior leaflet based on a dilated mitral annulus with normal leaflet motion as defined by TEE may result in a technically competent MV repair and good long-term results. The decision to perform a posterior sliding valvuloplasty may or may not have been a wise decision. Equally good results may have occurred with the insertion of an annular ring without leaflet resection. The measure of an outcome by recording a metric is a valid assessment of quality only if the metric is a function of the actions of the provider.[13] The outcome cannot be random; otherwise, no basis exists for estimating quality.

Case Study 1: The Regurgitant Carpenter

A 48-year-old asymptomatic woman presented for elective MV repair secondary to MR. She was otherwise healthy, except for mild pulmonary hypertension and rapidly increasing left ventricular (LV) dimensions. The woman was a union carpenter and absolutely refused to be subjected to lifelong anticoagulation. Physical examination was notable for a loud holosystolic murmur from the apex to the axilla. The lungs were clear. The baseline electrocardiogram (ECG) was normal, as were all laboratory blood tests. The preoperative chest wall echocardiogram demonstrated severe MR, no segmental wall motion abnormalities (SWMAs), and a flail MV. Intraoperatively, after induction of general anesthesia and tracheal intubation, two-dimensional (2D) and three-dimensional (3D) TEE was performed and showed a severely dilated left atrium, a dilated left ventricle, a flail and thickened middle scallop of the posterior leaflet with multiple ruptured primary and secondary chordae to all scallops of the posterior leaflet, prolapse of the anterior leaflet, and a small perforation. The short-axis and bicommissural views, along with 3D color acquisition of the MV, suggested three regurgitant orifices. The surgeon was experienced in complex mitral repairs and chordal transfer. Consultation between the surgeon and the echocardiographer resulted in the surgeon proceeding with an MV repair, resection of excessive leaflet tissue of the posterior leaflet, chordal transfer from the anterior leaflet, and patch closure of the perforation, in addition to a mitral annular ring. Separation from CPB was facilitated with epinephrine, but the postrepair TEE demonstrated residual moderate central MR and residual anterior leaflet prolapse. No systolic anterior motion (SAM) of the MV was evident. No gradient existed between the left ventricle and the aorta. CPB was reinstituted. The surgeon elected to replace the MV with a pericardial bioprosthesis, despite the patient's young age. The patient required the transfusion of blood, plasma, and platelets, as well as return to the operating room on the evening of the operation because of mediastinal bleeding. The patient emerged from anesthesia and operation on postoperative day 1 edematous and confused. Heart function showed a cardiac index of 2.4 L/m^2 per minute, mild pulmonary hypertension, and bounding peripheral pulses. Neurologic function recovered fully before discharge on postoperative day 7. Was the initial decision to repair the MV a sound decision? Do the poor initial results of the operation suggest that the decision was poor? Would it have been wise to attempt a second repair after the initial attempt failed? Was the better decision to proceed directly to an MV replacement, thereby decreasing the CPB and aortic cross-clamp times?

Myxomatous Degeneration of the Mitral Valve and Mitral Regurgitation

Framing

Myxomatous degeneration of the MV is a common cause of MR. Patients often are young and otherwise quite healthy. The diagnosis is commonly established preoperatively, and patients are scheduled for elective surgical procedures unless acute leaflet or chordal rupture leads to acute pulmonary edema and emergency operation. The decisions to be addressed in this setting include the following: Can the surgeon perform the MV repair to address the MR, or is valve replacement necessary? If MV replacement is necessary, would the patient prefer a mechanical or a bioprosthetic valve? What does the surgeon need to know to assess the possibility of repair and how to accomplish it? What are the possible complications of MV repair? Is the MV repair acceptable?

Data Collection

The first decision by the echocardiographer is whether TEE is indicated. Application of intraoperative TEE in the care of the patient with mitral disease is widely accepted. Even in this area, however, data supporting an improved outcome for intraoperative patients cared

BOX 16.5 INDICATIONS FOR THE USE OF TRANSESOPHAGEAL ECHOCARDIOGRAPHY

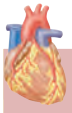
Category I
- Heart valve repair
- Congenital heart condition procedures
- Hypertrophic obstructive cardiomyopathy
- Endocarditis
- Acute aortic dissection
- Acute, unstable aortic aneurysm
- Aortic valve function in the setting of aortic dissection
- Traumatic thoracic aortic disruption
- Pericardial tamponade

Category II
- Myocardial ischemia and coronary artery disease
- Increased risk for hemodynamic disturbances
- Heart valve replacement
- Aneurysms of the heart
- Intracardiac masses
- Intracardiac foreign bodies
- Air emboli
- Intracardiac thrombi
- Massive pulmonary emboli
- Traumatic cardiac injury
- Chronic aortic dissection
- Chronic aortic aneurysm
- Detection of aortic atheromatous disease as a source of emboli
- Evaluating the effectiveness of pericardiectomies
- Heart-lung transplantation
- Mechanical circulatory support

Category III
- Other types of cardiomyopathy
- Emboli during orthopedic procedures
- Uncomplicated pericarditis
- Pleuropulmonary disease
- Placement of an intraaortic balloon pump or a pulmonary artery catheter
- Monitoring the administration of cardioplegia

Modified from Practice guidelines for perioperative transesophageal echocardiography: a report by the American Society of Anesthesiologists and the Society of Cardiovascular Anesthesiologists Task Force on Transesophageal Echocardiography. *Anesthesiology*. 1996;84:986.

for with TEE compared with no TEE are few. The decision to perform TEE during cardiac surgical procedures is substantiated by practice expectations and consensus opinion. In an attempt to develop an evidence-based approach to this expanding technology, the American Society of Anesthesiologists and the Society of Cardiovascular Anesthesiologists cosponsored a task force to develop guidelines for defining the indications for perioperative TEE. Despite the scarcity of outcome data to support the application of TEE in the perioperative period, TEE had rapidly been adopted by cardiac surgeons and cardiac anesthesiologists as a routine monitoring and diagnostic modality during cardiac surgical procedures. In 1996, the task force published their guidelines, designed to establish the scientific merit of TEE and the justification of its use in defined cohorts of patients.[14] The indications were grouped into three categories based on the strength of the supporting evidence or expert opinion that TEE improves outcome (Box 16.5). Category I indications suggested strong evidence or expert opinion that TEE was useful in improving clinical outcome. Category II indications suggested weak evidence or expert opinion that TEE improves outcome in these settings. Category III indications suggested little or no scientific merit or expert support for the application of TEE in these settings (see Chapters 14, 15, and 17). These guidelines were further updated in 2010 to include virtually all adult cardiac surgical procedures (Box 16.6).[15]



BOX 16.6 2010 UPDATED RECOMMENDATIONS FOR TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Cardiac and Thoracic Aortic Surgery
- *All* adult open-heart (eg, valves) and thoracic aortic surgical procedures
- Consider in coronary artery bypass grafting procedures
- Transcatheter intracardiac procedures

Critical Care
- When diagnostic information that is expected to alter management cannot be obtained by transthoracic echocardiography or other modalities

Modified from Practice guidelines for perioperative transesophageal echocardiography: an updated report by the American Society of Anesthesiologists and the Society of Cardiovascular Anesthesiologists Task Force on Transesophageal Echocardiography. *Anesthesiology*. 2010;112:1084.

TEE is not without its serious complications. The risks of intraoperative TEE include physical injury to the mouth, dentition, and esophagus, in addition to the misinterpretation of a finding leading to mismanagement. When deciding whether to perform intraoperative TEE, the physician should consider the cumulative effects of the indications and risks. TEE should not be performed if the appropriate equipment, safety precautions, and skilled examiners are not available. In this instance, the surgeon cannot rely on visual inspection of the native MV in the flaccid, arrested heart to discern the mechanism of MR. As such, intraoperative TEE is often critical in assisting the surgeon to plan the appropriate surgical correction, as well as evaluate the repair during separation from CPB.

The intraoperative TEE examination targets the MR, left atrium, left ventricle, and right ventricle. The 2D and color-flow Doppler examinations have long been the standard assessment tools, but more recently 3D echocardiography has become a recommended modality for examining MV disorders.[16] The TEE examination of MR should first quantify the degree of regurgitation, which may differ significantly from that seen in the preoperative echocardiogram as a result of changes in hemodynamics and loading conditions. This examination is traditionally done using a 2D color-Doppler method,[17] although 3D echocardiographic techniques have shown promise in several studies.[18–21]

Following the establishment of regurgitation severity, the anatomy of the regurgitant MV must be interrogated and the cause of the regurgitation identified. Typical findings of myxomatous valves include excessive leaflet motion, redundant leaflet tissue, and a dilated mitral annulus. Leaflets commonly prolapse into a dilated left atrium, the degree of which is based on the chronicity of the illness. Chordal rupture is common and leads to flail leaflets and severe MR. The imperative is to be exact in the descriptive anatomy of MV disorders, including the location of any flail or prolapsing leaflet segments, as well as any coexisting leaflet perforations or clefts. Mounting evidence indicates that 3D echocardiography may be more accurate than 2D echocardiography, especially in the hands of less experienced users, in identifying these disorders.[22–24] The width of the anterior and posterior leaflets, the bisecting widths of the mitral annulus (minor and major axes), the severity of annular calcification (less common in isolated ischemic or myxomatous disease), and the size of the left atrium also contribute significantly to the planned repair and should be accurately communicated to the surgeon.

SAM risk should also be assessed before any MV repair. Maslow and colleagues[25] examined the predictors of LV outflow tract (LVOT) obstruction after MV repair. In this study of patients who were undergoing repair for myxomatous valve disease, 11 of 33 patients experienced development of SAM and outflow tract obstruction. The major predictive factors were a smaller anteroposterior length ratio (annulus

to coaptation; 0.99 vs 1.95) and a short distance from the septum to the MV coaptation point (2.53 vs 3.00 cm). The surgeon may elect to perform a posterior sliding valvuloplasty to move the point of coaptation laterally, thereby decreasing the risk for outflow obstruction and mitral incompetence associated with SAM (see Chapter 21).

The repaired MV is scrutinized closely, with the ventricular vent removed at the discontinuation of CPB under typical loading conditions. The systolic and diastolic functions of the valve are examined for residual regurgitation, stenosis, and the presence of outflow tract obstruction. The examination after bypass is critical for determining the acceptability of the repair or for guiding subsequent revision should the initial repair be unacceptable. Systolic valve dysfunction after repair typically produces residual MR. Residual MR after mitral repair is not uncommon and may not necessitate revision if the grade is trace or mild. Diastolic mitral function is ascertained by Doppler flow measurements across the mitral orifice to provide assurance that the repaired valve has not been rendered stenotic. Peak transvalvular blood-flow velocities and pressure half-times are measured to calculate valve gradients and valve areas.

Discussion

The growing imperative is to repair instead of replace myxomatous MVs. The intraoperative echocardiographer soon becomes familiar with the abilities and limitations of his or her surgical counterparts. Outcomes of valve repair may depend on the ability of the individual surgeon, more so than in valve replacement operations. Hence it may be prudent to track short-term (intraoperative) results of these operations because outcomes may be defined less by national databases and more by individual providers. In general, the likelihood of a successful repair is based on the severity and extent of involvement of the mitral leaflets. Isolated prolapse of the middle scallop of the posterior mitral leaflet in an eccentric MR that overrides an otherwise normal anterior leaflet is associated with a high success rate. However, cases of extensive leaflet degeneration with bileaflet prolapse, multiple chordal ruptures from both leaflets, leaflet destruction from preceding endocarditis, the presence of two or more regurgitant orifices, and extensive calcification are associated with a significantly lower success rate for repair.[26] Many patients leave the operating room with a prosthetic MV replacement with preservation of the subchordal apparatus, with excellent long-term results. Retention of the subvalvular apparatus preserves longitudinal shortening of the left ventricle and decreases the incidence of heart failure in the long term.[27,28] In a comparative study, the ejection fraction (EF) of patients without chordal transfer decreased 24% postoperatively compared with patients having chordal transfer who maintained preoperative function.[28]

Some degree of residual MR after repair is common. Most surgeons do not accept residual MR of 2+ or greater and readdress the valve surgically. Assessment of valve function after bypass under unloaded conditions (decreased afterload with relative hypovolemia) may not accurately reflect MR under normal hemodynamic parameters. Similarly, a left ventricle that is struggling with hypokinesis and dilation immediately after bypass often responds well to the introduction or escalation of inotropes, with concomitant improvement in the degree of MR.

If the valve is left with significant regurgitation after the optimization of LV function and loading conditions, then the repair has failed and the mechanism of failure must be determined. Residual mild regurgitation associated with persistent leaflet prolapse may warrant further leaflet resection. Mild residual regurgitation in the setting of a "normal" MV may sway the surgeon to accept it. The presence of a central jet of MR may require resizing (ie, smaller) of the annuloplasty ring or consideration of an edge-to-edge repair (ie, Alfieri stitch). The decision to repeat a repair or valve replacement often is difficult and requires weighing the balance between the risks for reoperation and the risk for residual MR. The final decision of what constitutes acceptable residual valvular regurgitation is patient specific (eg, age, anticipated level of activity, ability to tolerate a return to CPB).

In addition to residual regurgitation, the presence or absence of LVOT obstruction caused by SAM must be assessed after MV repair. This phenomenon is the result of displacement of leaflet coaptation toward the septum that causes the anterior leaflet paradoxically to move into the LVOT, rather than toward the left atrium late in systole (Fig. 16.2).[29] Displacing the anterior leaflet into the LVOT during ventricular ejection (Venturi effect) produces outflow tract obstruction, early closure of the AV, and worsened MR. The incidence of postoperative SAM and the need to revise the surgical repair have decreased as understanding of the predisposing factors and management strategies have improved. SAM may be intermittent and dependent on loading conditions. If possible, patients should be examined after adequate volume resuscitation and with minimal inotropic support. Most cases of SAM resolve with conservative measures including β-blockade, vasoconstriction, and fluid administration to augment preload. In a single-center retrospective study of 2076 patients who underwent MV repair, the incidence rate of intraoperative SAM was 8.4% (174 cases).[30] Revision of repair or valve replacement related to SAM during initial operation was undertaken in only 2 of these patients. However, in the case of persistent severe SAM with a high left ventricle–to-aorta gradient, returning to CPB and revising the mitral repair (eg, posterior sliding mitral valvuloplasty to shift the locus of coaptation laterally), performing an edge-to-edge repair, or possibly replacing the MV should be considered. Patients who transiently demonstrate SAM or turbulence in the outflow tract in the operating room may be at increased risk during the immediate postoperative period (Fig. 16.3). An important role of the clinical echocardiographer is to recognize potentially important findings that may have an impact on subsequent patient care and long-term follow-up (see Chapters 14, 15, 21, and 24).

Management of Ischemic Mitral Regurgitation During Coronary Artery Bypass Grafting

Framing

Ischemic heart disease is the most common cause of mitral insufficiency in the United States. Mechanisms of valve incompetence are varied and include annular dilatation, papillary muscle dysfunction from active ischemia, papillary muscle rupture, or LV remodeling and papillary muscle displacement, thus leading to a tethering effect of the subvalvular apparatus. MR leads to pulmonary hypertension, pulmonary vascular congestion, and pulmonary edema with functional disability. Ventricular function deteriorates as the left ventricle becomes volume overloaded with corresponding chamber dilatation. Left untreated, severe MR from ischemic heart disease has a poor prognosis, hence the imperative for diagnosis and treatment.[31–33] Less certain is the impact of lesser degrees of mitral insufficiency on functional status and long-term morbidity and mortality. Patients presenting for coronary artery bypass grafting (CABG) often have concomitant MR of a mild or moderate degree.[34] The intraoperative team is confronted with the decision whether to address the MV surgically during the coronary artery operation.

Does MR warrant mitral surgical treatment? What is the mechanism of the regurgitation? What are the grade and chronicity of the MR? Is the MR likely to improve by coronary revascularization alone?

Data Collection

Pertinent data, including preoperative functional status and evaluation, must be considered to interpret and place the intraoperative data in context appropriately. The preoperative echocardiogram and ventriculogram must be reviewed. The intraoperative hemodynamic data are coupled with TEE information to complete the data set needed to move forward with the decision-making process. The severity of MR on TEE is assessed by conventional methods (eg, vena contracta width or area, regurgitant jet area, regurgitant orifice area, and pulmonary vein inflow velocities), although 3D echocardiography is becoming

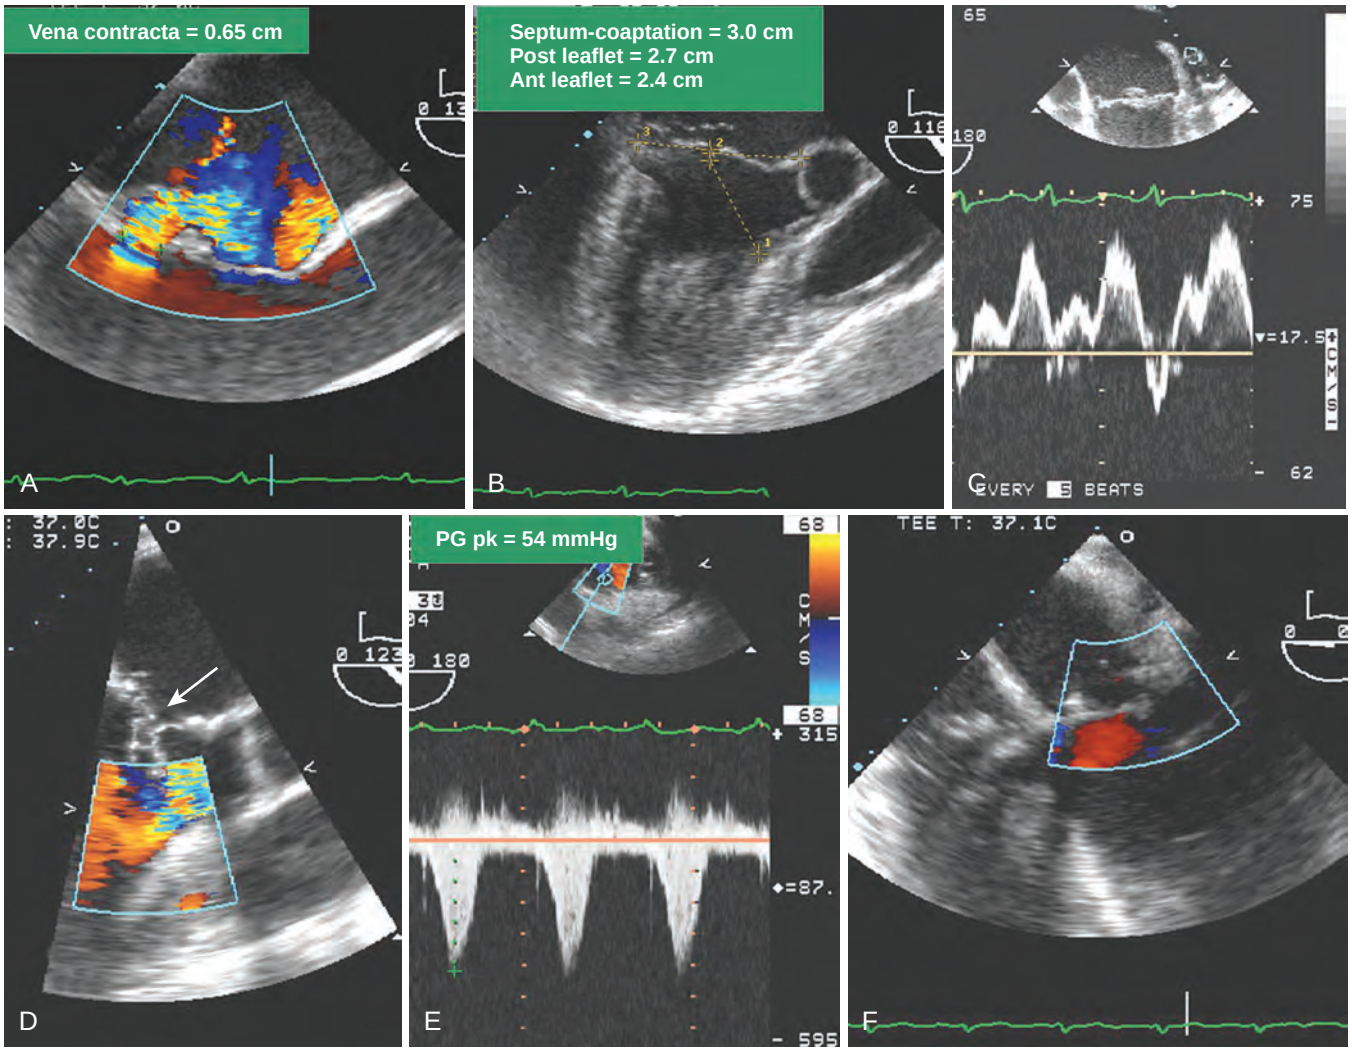


Fig. 16.2 Complex mitral valve (MV) replacement or repair revision. A 58-year-old woman with severe mitral regurgitation (MR) and a history of congestive heart failure, pulmonary edema, and hypertension was scheduled for surgical repair of mitral insufficiency. (A) The prebypass transesophageal echocardiogram characterized the MV as having severe MR with mildly thickened, myxomatous leaflets and several ruptured chordae tendineae. The markedly dilated annulus was consistent with the chronic disease process. Prolapse of the posterior leaflet caused the MR jet to override the anterior leaflet. (B) Although the distance from the septum to the coaptation point of the MV was greater than the value cited by Maslow as predictive of postbypass systolic anterior motion, the ratio of the length of the anterior *(Ant)* and posterior *(Post)* leaflets (0.89) suggested a risk for left ventricular (LV) outflow obstruction.[39] The midesophageal long-axis view demonstrates several ruptured chordae that resulted in MR having a vena contracta of 0.65 cm. (C) Blunting of the systolic component of pulmonary vein blood flow velocity corroborated the diagnosis of significant MR. The surgeon performed a quadrangular resection of the posterior leaflet and secured the annulus with a no. 30 Physio ring. (D) Postbypass imaging of the midesophageal long-axis view demonstrated a coaptation defect, designated by the *arrow,* and nonlaminar flow in the LV outflow tract. Shift of the coaptation point medially created laxity of the redundant chordae that were drawn into the outflow tract by systolic LV ejection. (E) The outflow tract obstruction was characterized by peak pressure gradient *(PG pk)* of 54 mm Hg as determined by continuous-wave Doppler through the outflow tract by using the transgastric long-axis view. Neither the MR nor the outflow tract obstruction was effectively addressed by volume loading and decreasing the inotropic support. Circulatory bypass was reinstituted, and the surgeon revised the previous repair by further resecting the posterior leaflet and enlarging the annular ring to a no. 34. (F) The patient was successfully separated from bypass by using minimal support and had resolution of LV outflow tract obstruction, return of normal hemodynamics, and reduction of MR to trace severity (F).

more frequently used for this purpose.[18–21] The degree and angle of leaflet tethering should also be determined. Long-standing ischemic MR often causes changes in other cardiac structures and may be associated with a dilated left atrium, pulmonary hypertension, and right ventricular (RV) dysfunction. Wall motion assessment and the ECG are used for detecting reversible myocardial dysfunction that may benefit from revascularization. The hemodynamic and TEE data are coupled with provocative testing of the MV in an attempt to emulate the working conditions of the MV in an awake, unanesthetized state. It is not uncommon that preoperative mild-to-moderate MR with a structurally normal valve totally resolves under the unloading conditions of general anesthesia.[35–37]

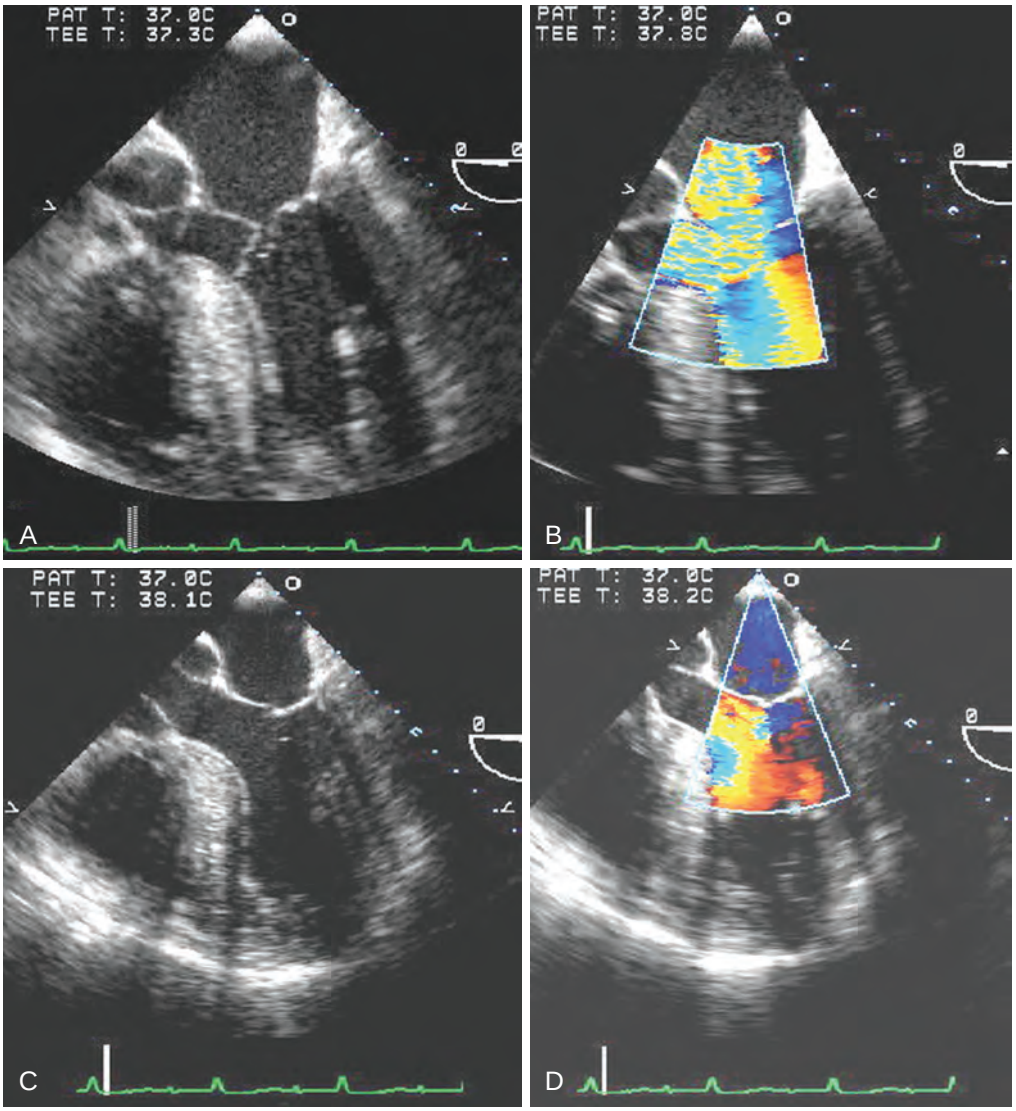

Fig. 16.3 Acute intraoperative hemodynamic deterioration. A 65-year-old man with a medical history of hypertension, sleep apnea, and smoking was scheduled for resection of colon cancer. During the bowel resection, the patient had a profound episode of hypotension and new-onset hypoxia. Although the patient's hemodynamic condition initially improved after administration of phenylephrine and ephedrine, the patient became more hypotensive and hypoxic with evidence of pulmonary edema. Transesophageal echocardiography was requested and was performed on an emergency basis to diagnose the cause of cardiovascular collapse and to guide management. (A) The midesophageal four-chamber view showed a moderately hypertrophied left ventricle. Left ventricular (LV) systole was associated with displacement of the mitral leaflet and chordae tendineae down into the outflow tract. The resulting defect in leaflet coaptation of the mitral valve (MV) and the abnormal chordal position noted in (A) were associated with overwhelming mitral regurgitation (MR) and LV outflow tract obstruction. (B) Administration of inotropes (epinephrine and ephedrine) was discontinued; the management strategy was changed to volume resuscitation and pressor administration. (C) and (D) The hemodynamics normalized, and the examination was repeated 10 minutes later. Displacement of the mitral leaflet and chordae had resolved, together with the findings of MR and outflow tract obstruction. The patient was believed to have experienced a profound acute decline in systemic vascular resistance in response to the release of vasoactive substances during bowel manipulation. The initial exacerbation of the hemodynamics was created by the relative hypovolemia and the use of inotrope, thus leading to dynamic LV outflow tract obstruction. The concomitant episodes of hypoxia and pulmonary edema, which were attributed to the severe MR and increased left atrial pressures, resolved with the decrease in MR. The application of transesophageal echocardiography was critical in making the correct diagnosis, altering management strategies, and initiating the appropriate therapy.

Discussion

Most cases of ischemic MR are categorized as "functional" rather than structural. In a study of 482 patients with ischemic MR, 76% had functional ischemic MR, compared with 24% of patients with significant papillary muscle dysfunction.[38] The mechanism of ischemic MR is attributed to annular dilatation secondary to LV enlargement and regional LV remodeling with papillary muscle displacement, thereby causing apical tethering and restricted systolic leaflet motion.[39] The importance of local LV remodeling with papillary muscle displacement as a mechanism for ischemic MR was reproduced in an animal model.[40]

Severe MR in a patient presenting for CABG is almost always addressed through valve repair or replacement, and cases of trace or mild MR are usually left alone. However, the question of what to do with moderate ischemic MR in patients undergoing CABG is more difficult. Evidence indicates that patients with mild-to-moderate ischemic MR have an increased risk of cardiovascular death if the condition is left untreated,[41] but it remains unclear whether revascularization alone will provide enough improvement in the degree regurgitation to alter mortality rates. Multiple studies looked at this issue without any clear resolution. Following CABG alone, the degree of MR often improves in the immediate postoperative period, but many patients have residual moderate or greater MR after several weeks.[42,43] A study by Penicka and associates[44] identified characteristics (more than five segments of viable myocardium, absence of papillary muscle dysfunction) that help predict improvement in the degree of ischemic MR with revascularization alone (Fig. 16.4).

If MV repair is elected, the most common technique is the use of a restrictive (ie, downsized) annuloplasty ring. Unfortunately, despite this repair, some patients have recurrence of moderate or greater MR postoperatively, especially patients with an LV end-diastolic dimension greater than 65 mm, a coaptation depth greater than 10 mm, or a posterior leaflet tethering angle greater than 45 degrees.[45–47] The first major randomized controlled trial examining this issue was performed by the National Heart, Lung, and Blood Institute Cardiothoracic Surgical Trials Network. This study involved 301 patients from 26 centers across the United States and Canada who had moderate ischemic MR and randomized them to CABG alone or CABG with mitral annuloplasty. The study found no differences in mortality rates or LV systolic volumes after 1 year (subsequent 3- and 5-year follow-up results will be of great interest). Those patients who were randomized to the annuloplasty group had longer CPB times, longer hospital stays, and worse neurologic outcomes, but they did have a reduction in residual moderate or severe MR (11% vs 31% for CABG alone).[48] A second randomized trial, Moderate Mitral Regurgitation in Patients Undergoing CABG (MoMIC) is also under way and should shed additional needed light on this topic.[49,50] Without definitive evidence in either direction, the most recent American College of Cardiology/American Heart Association (ACC/AHA) guidelines from 2014 state that MV repair should be considered on a case by case basis in patients with moderate secondary MR who are undergoing other cardiac surgical procedures (class IIb recommendation, evidence level C). Adjunctive techniques to restrictive annuloplasty, including papillary muscle relocation, secondary chordae resection, and posterior leaflet extension, as well as percutaneous techniques such as the MitraClip device (Abbott Vascular, Santa Clara, CA), require further study to determine what role, if any, they may play in reducing the rates of residual ischemic MR after valve repair.[51]

Functional Mitral Regurgitation in the Setting of Aortic Stenosis

Framing

Valvular diseases do not often occur in isolation. Other anatomic structures may be influenced, either by the same pathophysiologic process or as a secondary consequence of the primary valvular lesion. Mitral insufficiency is a common finding, occurring in approximately two-thirds of the patients having significant AS.[52] Patients presenting for AVR commonly have MR, and the question is whether to repair or replace the MV in addition to the AV (Fig. 16.5). Such an undertaking is not without risk. Patients undergoing double-valve replacement have increased mortality rates compared with patients undergoing isolated AVR.[53,54]

Should moderate MR be surgically addressed in patients undergoing AVR for aortic stenosis (AS)? Does the severity of MR regress after AVR? Can it be predicted which cohort of patients with AS would benefit from concomitant MV repair? In which patient cohort would the MR be expected to regress with the unloading effects of replacing a stenotic AV?

Data Collection

The most important data for these decisions are the grade of MV, AV area, anatomy of the MV, and cause of MR (ie, rheumatic disease, ischemic, myxomatous degeneration). Patients are likely to have the signs and symptoms of AS, MR, and pulmonary hypertension. The grade of MR is often not evident until TEE is performed and may be underestimated by a preoperative transthoracic examination. An enlarged left atrium suggests that the MR is chronic, rather than acute.

Discussion

MR is a maladaptive consequence of increasing AS. More significant MR is associated with greater trans-AV pressure gradients, as well as more progressive dilatation and worsening systolic function.[55,56] If the anatomic features of the MV are markedly abnormal and the regurgitation is severe, the decision is relatively obvious: MV repair or replacement at the time of AVR. If the MV is anatomically normal (no leaflet prolapse, no perforation, no rheumatic changes) and the regurgitation is trace or mild, the decision is also relatively obvious: correct the AS and do not surgically address the MV.

The more controversial decision is whether to surgically address the MV that has mild-to-moderate regurgitation when a patient presents for AVR for AS. The evidence currently available on this issue is conflicting. Some studies have shown unchanged or worsened mortality rates in patients who received a concomitant MV repair with their AVR,[57,58] a finding suggests that AVR alone may be the prudent decision. Other investigators, however, have shown an increase in mortality rates for patients left with residual moderate or greater MR following AVR alone and no real effect on mortality rates of concomitant valve repair.[59,60] In general, functional MR of moderate severity usually regresses at least one grade after AVR for severe AS (see Fig. 16.5). Mild-to-moderate MR that improves after AVR for AS seems to be a lasting phenomenon.[61] Harris and colleagues[62] ascribed the decrease in the severity of MR after AVR to several anatomic changes: decreases in mitral annular area, left atrial size, and LV length. Together with the decrease in driving pressure that occurs with resolution of AS, all three of these anatomic changes alter the architecture of the MV and ventricle and contribute to decreasing functional MR.

Coexisting moderate or greater MR is also extremely common in patients presenting for transcatheter AVR (TAVR), with an incidence approaching 20%. As with open AVR, evidence of the effect of untreated significant MR on outcomes following TAVR is conflicting. Data from the Italian and German TAVR registries indicate that moderate or greater MR is an independent predictor of late death following TAVR. In contrast, the Placement of Aortic Transcatheter Valves (PARTNER) trial showed no difference in mortality rates between these patients and those with no or mild MR. Approximately 50% of patients will have an improvement in the degree of MR following TAVR, whereas the remainder will have unchanged or even worsened MR. Some evidence also indicates that MR improvement is greater with the balloon-expandable Edwards valve (Edwards Lifesciences, Irvine, CA) than with the self-expanding CoreValve (Medtronic,

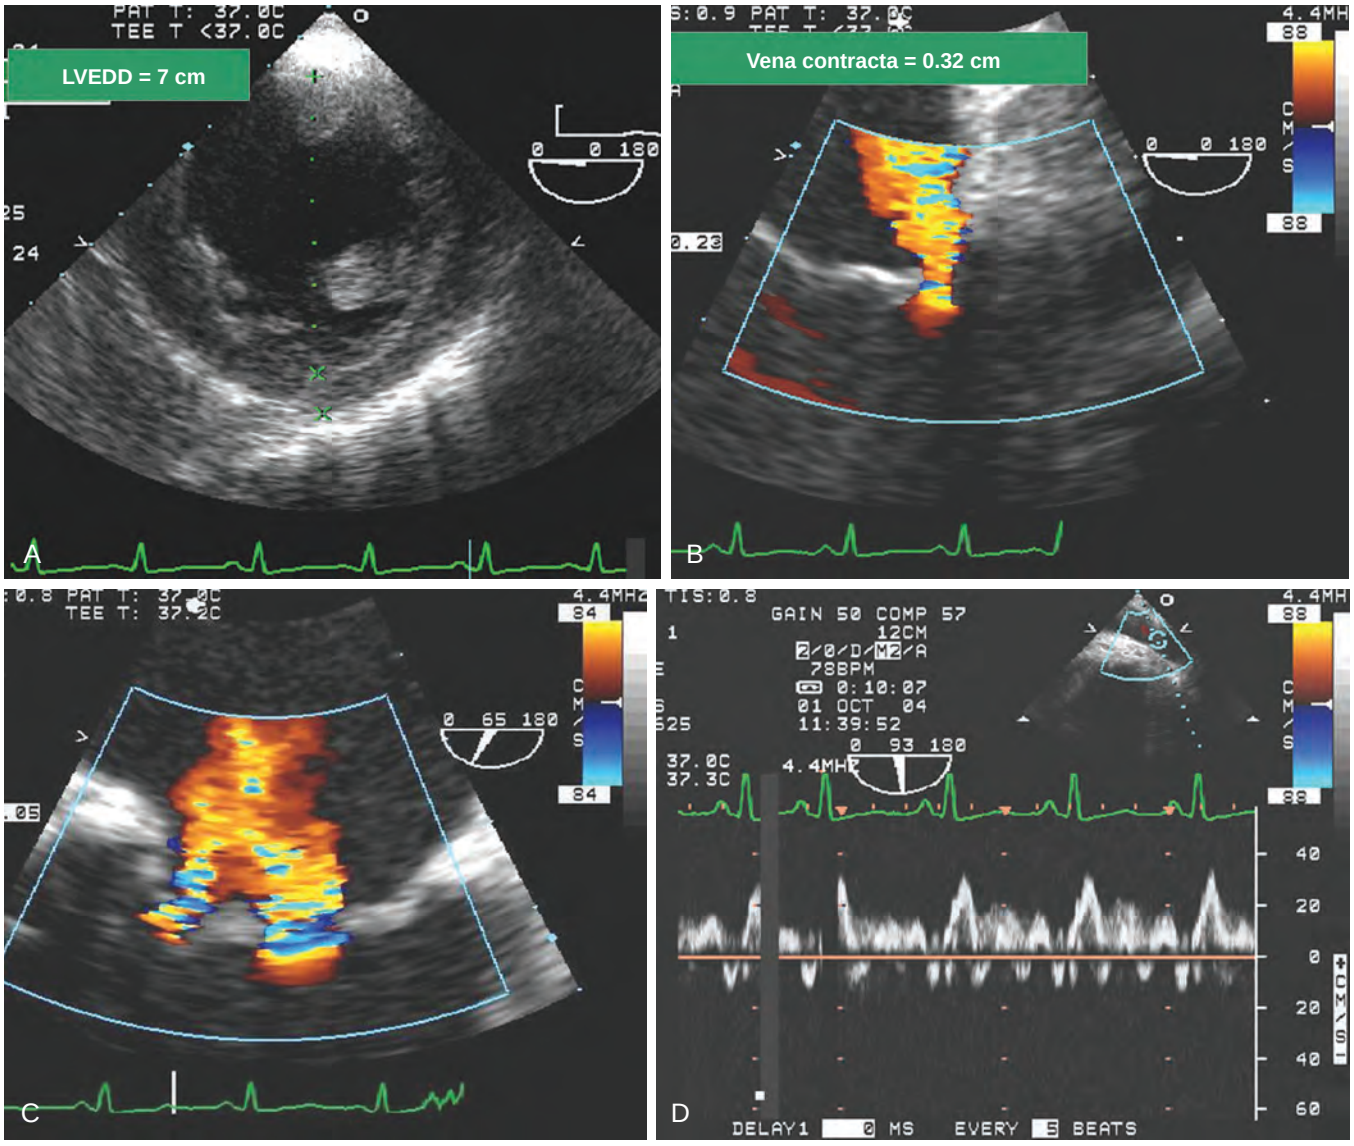

Fig. 16.4 Evaluation of mitral regurgitation (MR) in a patient undergoing coronary artery bypass grafting. A 63-year-old man was scheduled to undergo off-pump coronary artery revascularization. The patient had a history of progressive congestive heart failure without evidence of acute pulmonary edema. The physical examination was significant for a diffuse, laterally displaced point of maximum impulse and a systolic murmur at the apex that radiated to the axilla. (A) The patient received an intraoperative transesophageal echocardiography examination to evaluate the severity of MR. The left ventricle was significantly dilated with a left ventricular end-diastolic dimension *(LVEDD)* of 7 cm and had depressed systolic function with an estimated ejection fraction of 40%. (B) The MR was characterized by color-flow Doppler imaging to be a central jet of mild-to-moderate severity. The grading of MR was based on the area of the regurgitant jet and the vena contracta viewed in a long axis view. The pathogenesis of MR was believed to be functional and resulted from restricted leaflet mobility caused by the dilated left ventricle. (C) The coaptation of the anterior and posterior leaflets was below the valve plane. (D) The absence of reversal of pulmonary vein blood flow measured in the left lower pulmonary vein supported the assessment of moderate MR. Because the annulus was not significantly dilated (the minor axis measured 2.97 cm) and the MR was graded as only mild to moderate, the surgeon proceeded with the initial plan of off-pump coronary artery bypass grafting. The MR decreased immediately after revascularization, and the patient's symptoms were expected to improve further with afterload reduction.

Minneapolis, MN), although this difference must be studied further for confirmation[63] (see Chapter 27).

Factors that may predict an improvement in the severity of MR following both open AVR and TAVR for AS include a functional (as opposed to structural) origin of the regurgitation, poorer LV ejection fraction, greater LV dimensions, and higher aortic transvalvular gradients.[64–66] Negative predictors for the regression of MR after AVR alone include structural MV disease, significant mitral annular calcification, an enlarged left atrium (>5 mm), pulmonary hypertension, and atrial fibrillation.[67,68]

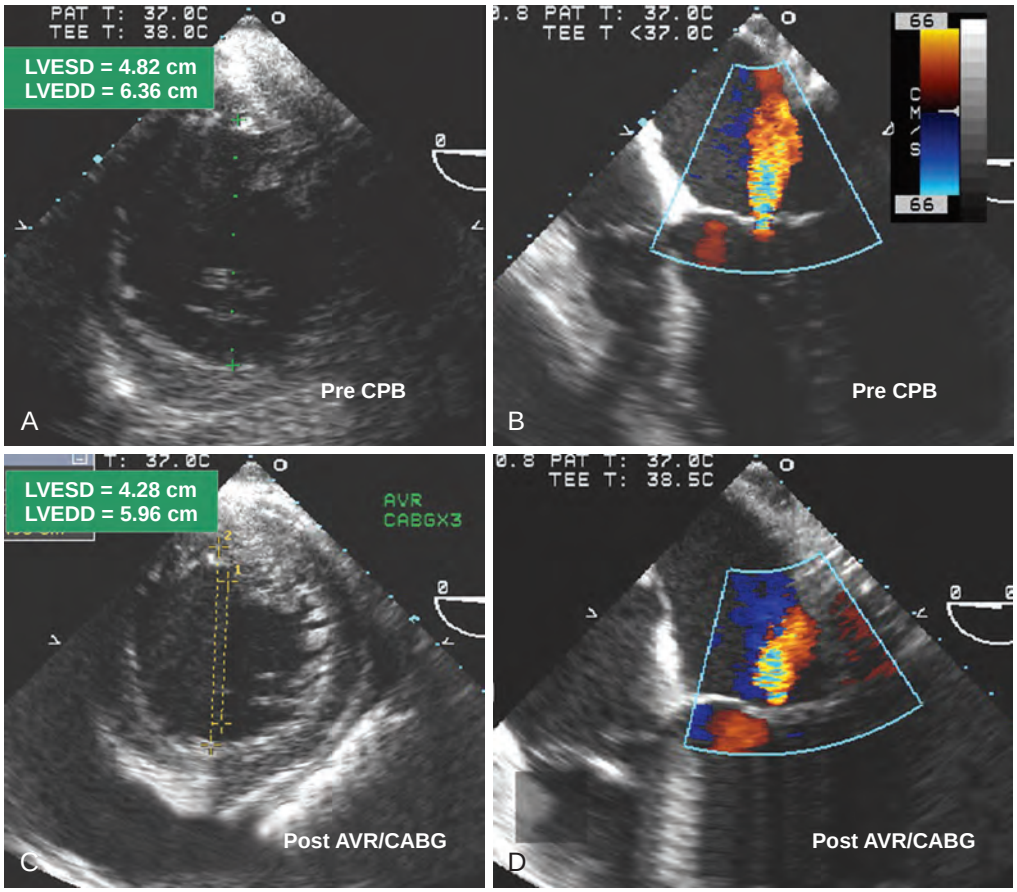

Fig. 16.5 Management of concurrent mitral regurgitation (MR) in a patient undergoing aortic valve replacement (AVR) for aortic stenosis (AS). This 70-year-old patient underwent an AVR for critical AS. The patient had history of hypertension, moderate MR, congestive heart failure, and episodes of shortness of breath. (A) Left ventricular (LV) function was moderately depressed, and the chamber size was dilated (LV end-diastolic dimension *[LVEDD]* = 6.36 cm). (B) The patient had a central jet of MR that was graded as mild; the annulus was mildly dilated, and the pathologic features of the leaflets and apparatus were only mildly thickened. The pulmonary vein blood flow showed minimal blunting of the systolic component, consistent with increased left atrial pressures but not clinically significant MR. The discrepancy in the severity of MR between the preoperative study and intraoperative transesophageal echocardiography (TEE) reflects the effect of general anesthesia on loading conditions. After reviewing the prebypass TEE examination and the patient's history, it was decided to perform only an AVR. A bioprosthetic valve was chosen by the surgeon because of the patient's age, thus eliminating the requirement for anticoagulation. Because the MR was believed to be more functional, the replacement of the severely stenotic AV, the major pathologic lesion, was anticipated to decrease MR over time. The choice of implanting a no. 23 pericardial prosthetic valve was based on the annular size that was measured before initiation of bypass. (C) and (D) The postbypass TEE examination documented that the gradient across the AV decreased from 74 to 18 mm Hg, and (C) cardiac function and (D) MR improved after AVR.

Management of Previously Undiagnosed Aortic Valve Disease

Framing

A relatively common clinical situation for the echocardiographer is to assess the significance of previously unrecognized AV disease. This discussion has pertinence for the echocardiographer faced with the new diagnosis of bicuspid AV, AS, or AR.

What are the symptoms that brought the patient to medical attention? What is the patient's baseline function? What is the anatomy of the AV? What is the severity of AR or AS? How do the intraoperative findings of AV disease differ from the preoperative assessment? Would surgical repair or replacement of the AV benefit the patient's short-term or long-term outcome? What is the planned procedure, and how would the risks be changed if the procedure is altered to address the new finding? Does another health care provider need to be involved in the decision whether to address the valve surgically? Is the disorder of the AV significant enough to require surgical intervention at this time?

Data Collection and Characterization of the Aortic Valve

Multiplane TEE permits an accurate assessment of AV area, valvular disease, severity of regurgitation and stenosis, and detection of secondary cardiac changes. In the case of AS, the severity of valvular dysfunction is determined by measuring the transvalvular pressure gradient, calculating the AV area using the continuity equation, and performing planimetry of the AV systolic orifice. Planimetry of the AV orifice with TEE is more closely correlated with the catheter-derived valve area (using the Gorlin formula) than the value derived from transthoracic

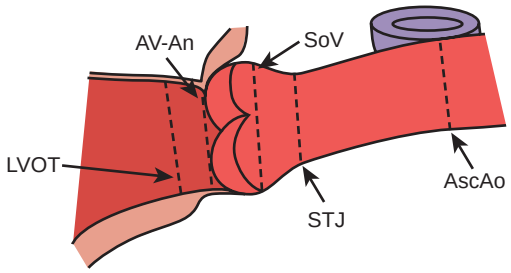

Fig. 16.6 Anatomy of the aortic root. The aortic valve in long axis shows the components of the aortic root, which include the sinotubular junction *(STJ)*, the sinus of Valsalva *(SoV)*, and the annulus of the aortic valve *(AV-An)*. *AscAo*, Ascending aorta; *LVOT*, left ventricular outflow tract.

echocardiography (TTE) ($r = 0.91$ vs 0.84), and 3D TEE assessments of AV area may be more accurate than those obtained by 2D methods.[69,70] The presence of subvalvular disease, such as a discrete fibrous subaortic membrane, should also be excluded, and the aortic root and ascending aorta should be inspected for any pathologic features (Fig. 16.6). Secondary findings associated with AS depend on where the patient's condition is along the natural course of the disease. AS is commonly associated with LV hypertrophy and abnormal filling of the left ventricle. The diastolic function is often impaired in response to a thickened, noncompliant left ventricle. Hence MV and pulmonary vein blood flow velocities would demonstrate a blunted passive filling phase of the ventricle. Systolic function often is normal or hyperdynamic. The LV chamber size is normal or small. However, long-standing AS results in progressive ventricular systolic dysfunction and heart failure. The left ventricle becomes dilated with compromised contractile function. As the ventricle fails, cardiac output (CO) decreases with a resultant decrease in transvalvular pressure gradient. Hence the pressure gradient across the AV may be misleading as a measure for severity of AS.

The severity of AR as seen on TEE generally is graded with color-flow Doppler imaging, with measurement of the width of the regurgitant jet relative to the width of the LVOT. TEE is sensitive to even the most trivial amount of AR. Jet areas measured by TEE tend to be larger, and their severity is graded as greater compared with AR assessed by TTE.[71] The structure of the AV leaflets themselves should also be examined for the presence of any vegetations, perforation, thickening or calcification, or prolapse. The aortic root and ascending aorta should be examined and assessed for any dilation or other structural abnormality that may be contributing to the AR.

The presence of a bicuspid AV presents its own set of associated disorders because it is at increased risk for degeneration and calcification that lead to AR and calcific AS. Bicuspid AVs predispose patients to ascending aortic and arch aneurysm formation,[72,73] and these valves are associated with increased incidences of aortic coarctation and atrial septal defect (ASD). As such, the diagnosis of bicuspid AV should prompt the echocardiographer to search for other commonly associated findings. The presence of isolated asymptomatic bicuspid AV without AS or AR does not mandate surgical correction. Bicuspid AVs can function without major hemodynamic abnormality well into the seventh decade of life.[74] In contrast, many patients experience either progressive dilatation of the aortic root, which produces AR, or premature calcification of the valve, which produces AS.[75–78] For patients in their fourth decade of life, the predominant lesion at operation is AR, which is increasingly treated with surgical repair of the bicuspid AV in young patients.[79–82] With increasing age, the predominant lesion associated with bicuspid AVs becomes AS.[83] The decision-making process with regard to surgical correction of a bicuspid AV must account for the size of the aortic root and the likelihood the patient will return for an aortic root operation in the not-too-distant future. The rate of ascending aortic dilatation in patients with a bicuspid AV may be as high as 0.9 mm/year.[84]

Discussion: Unexpected Mild-to-Moderate Aortic Stenosis

The intraoperative management of mild-to-moderate AS at the time of cardiac operation remains controversial. A patient arrives in the operating room scheduled for CABG but is discovered also to have mild or moderate AS that was unappreciated preoperatively. The operative team must decide whether to address the AV surgically. The ACC/AHA Task Force recommends valve replacement at the time of coronary artery operation if the asymptomatic patient has severe AS but also acknowledges that data to support intervention in the case of mild or moderate AS are limited. In this exact situation, the rate of progression of AS is of value but is rarely obtainable. A rapidly calcifying valve in a young patient that is becoming rapidly stenotic would sway the operative team to perform AVR. A combined double cardiac procedure (CABG/AVR) increases the initial perioperative risk, as well as those risks associated with long-term prosthetic valve implantation. A delay in AVR and a commitment to a second cardiac operation in the future subject the patient to the risk for a redo sternotomy in the setting of patent coronary grafts and its associated morbidities. If the AV is not operated on during the initial presentation for CABG, the development of symptomatic AS may be quite delayed or may not happen.

A review in the national database of The Society of Thoracic Surgeons of 1,344,100 patients who had CABG, CABG/AVR, or AVR alone culminated in a decision paradigm recommendation.[85] The study assumed rates of AV disease progression (pressure gradient of 5 mm Hg/year), valve-related morbidity, and age-adjusted mortality rates that were obtained from published reports. These investigators proposed three factors in the consideration of CABG or AVR/CABG: age (life expectancy), peak pressure gradient, and rate of progression of the AS (if known). Because the rate of AS progression is difficult to discern, the analysis assumed an average rate of disease progression and recommended that patients should undergo AVR/CABG when the peak pressure gradient exceeds 30 mm Hg. The threshold (AS pressure gradient) to perform both procedures is increased for patients older than 70 years of age because the reduced life expectancy diminishes the likelihood that these patients will become symptomatic from the AV disease. Whether to perform concomitant AVR at the time of revascularization was also addressed by Rahimtoola,[86] who advocated a less aggressive approach. All this is beginning to change, however, with the widespread adoption of TAVR. TAVR not only offers a valve replacement option to older or otherwise high-risk patients who previously would have been denied open surgical AVR but also is increasingly being held out as a future treatment option to patients undergoing a needed cardiac procedure who have coexisting mild-to-moderate AS. Rather than add AVR onto a CABG or other procedure, which increases mortality rates, a patient can be referred for TAVR 5 to 10 years down the line when his or her AS becomes symptomatic, without the added morbidity of a redo sternotomy. Thus far the outcomes of TAVR have been quite good, although the long-term outcomes remain uncertain.

The transvalvular pressure gradient, heretofore used as a grading tool for AS severity, may be a misleading measure of the degree of stenosis of the AV because its value depends on CO. A low CO and flow rate produce a low transvalvular pressure gradient, even in the setting of a severely stenotic AV. Patients with LV dysfunction and decreased CO in the setting of AS often present with only modest transvalvular pressure gradients (<30 mm Hg). Distinguishing patients with a low CO and severe AS from patients with mild-to-moderate AS can be challenging (Fig. 16.7). The standard for assessing the severity of AS is AV area, typically calculated using either a continuity method or by planimetry. Patients with low-gradient AS with severe LV dysfunction who underwent AVR had improved survival and functional status compared with patients who did not have a valve replacement.[87–89]

Dobutamine challenge in a patient with low-pressure gradient AS can be useful in establishing the true AV area. The ability to distinguish

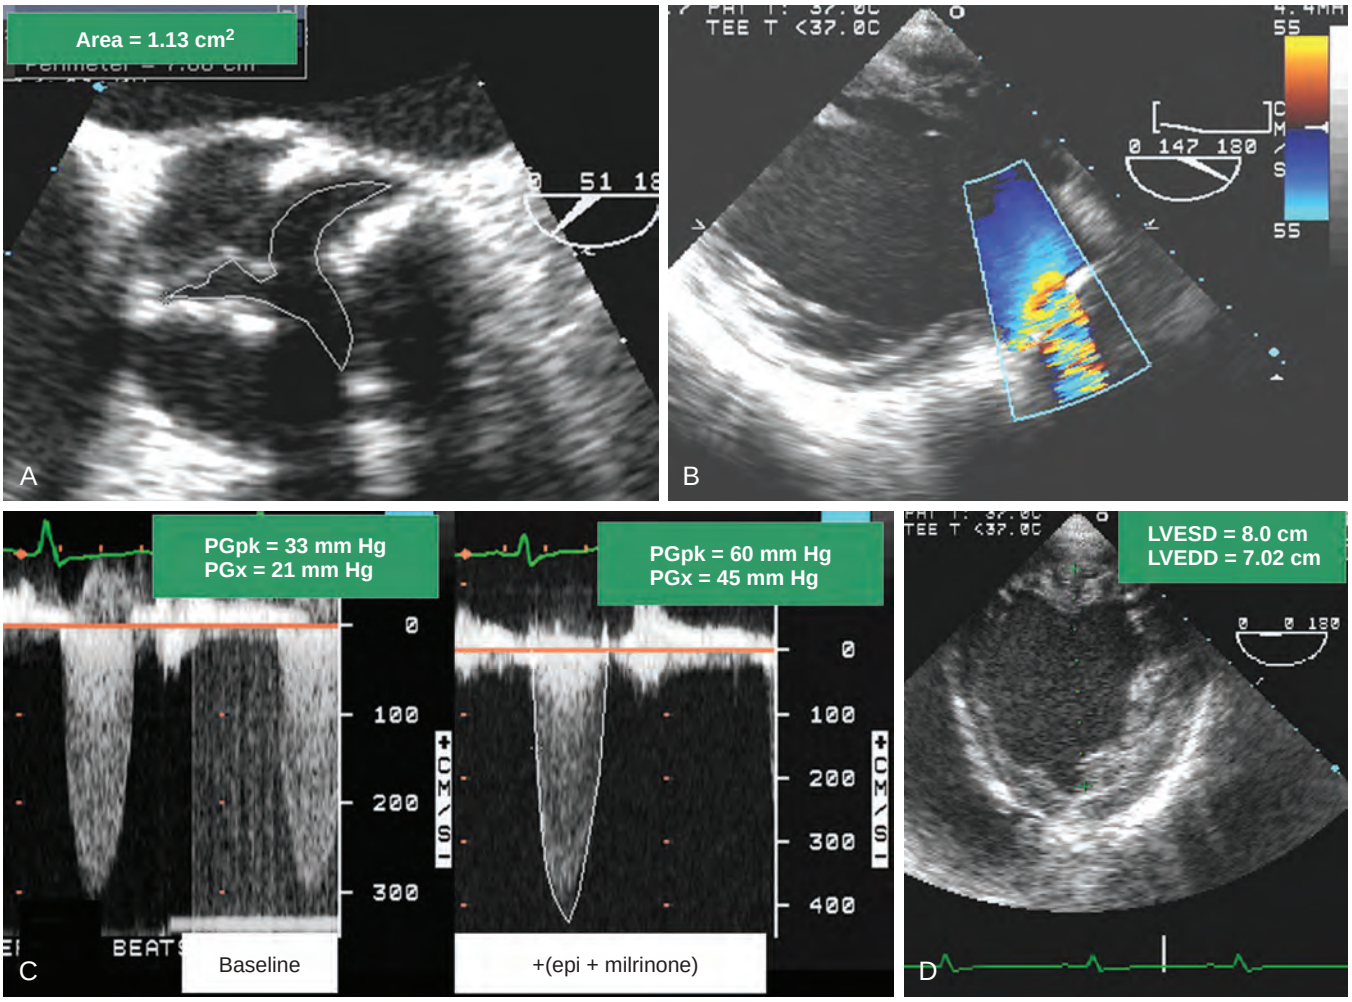

Fig. 16.7 Low-pressure gradient severe aortic stenosis (AS). A 76-year-old cachectic man was scheduled to undergo a corrective surgical procedure for severe mitral regurgitation (MR) and possibly clinically significant AS. (A) The midesophageal short-axis view of the aortic valve (AV) showed a highly calcified trileaflet valve with restricted mobility. The measurement of AV area, 1.13 cm^2, which was obtained by planimetry, was believed to underestimate the severity of AS because of the shadowing artifacts related to the severity of calcification. (B) The transgastric long axis of the left ventricle was obtained, and the velocity profiles of blood flow within the left ventricular (LV) outflow tract and the AV were measured. (C) Although the patient had a diagnosis of severe AS, the maximal pressure gradient *(PGpk)* and mean pressure gradient *(PGx)* were 33 and 21 mm Hg, respectively. The area of the AV was calculated to be 0.83 cm^2 using the continuity equation. (D) LV function was characterized by severe dilated cardiomyopathy with an ejection fraction of 8%, an LV end-systolic dimension *(LVESD)* of 7 cm, and an LV end-diastolic dimension *(LVEDD)* of 8 cm. The diagnosis of low-pressure gradient AS was considered, and infusions of epinephrine and milrinone were started. Cardiac performance improved from 2.4 to 4.5 L/minute, and the pressured gradients (C) increased to 60 mm Hg peak and 41 mm Hg mean. Although the calculated valve area that was recorded under conditions of inotrope support slightly increased to 0.9 cm^2, transesophageal echocardiography clarified that the marked increase in the pressure gradient was consistent with a diagnosis of low-gradient AS and confirmed the presence of cardiac reserve.

between true AS and a state of "pseudostenosis" relies on characteristic changes in hemodynamic and structural measurements in response to the augmented CO. The test is not usually performed in the operative setting but rather is used in the preoperative evaluation. The increase in calculated AV area is related to the increase in the CO and is attributed to partial reversal of primary cardiac dysfunction.[90–93] If dobutamine improves CO and increases the AV area, it is likely that the baseline calculations overestimated the severity of the AS. The dobutamine challenge is conducted as follows: patients with low-gradient AS receive intravenous dobutamine at 5 μg/kg per minute with stepwise increases in dose.[91] Patients may exhibit a significant increase in AV area (0.8 to 1.1 cm^2) and a decline in valve resistance after dobutamine challenge. Patients with fixed, high-grade AS would demonstrate no change in valve area and an increase in valve resistance.

Although most patients who exhibit low-gradient AS have reduced EFs, a subset of patients with low-gradient AS (as defined by a mean gradient <40 mm Hg and an AV area <1 cm^2) has preserved EFs. These patients often have small ventricular cavities, severe concentric LV hypertrophy, increased afterload, restrictive physiology, and/or increased subendocardial myocardial fibrosis.[94] The need for valve replacement in this subgroup of patients is still unclear, but early data suggest that outcomes of medical management alone are better than those in high-gradient AS or low-gradient, low-EF AS, and outcomes may be similar to those in patients with mild-to-moderate AS.[95]

Discussion: Unexpected Aortic Regurgitation
